The **great horizontal fissure**, in spite of its depth in the adult brain—a depth which is due to the excessive growth in the later months of development of the two lobules that bound it—appears very late in the development of the cerebellum. It is first seen as a very broad shallow groove or furrow on the outer margin of the hemisphere. From this it runs forwards to the middle peduncle and backwards towards the vermis, where it usually joins the postlunate fissure. At this stage there is no folium cacuminis, so that the combined portion of the postlunate and great horizontal fissures intervenes between the clivus monticuli and the tuber valvulæ. Even at the time of birth the folium cacuminis is not seen on the surface. It rises up from the bottom of the combined portions of the great horizontal and postlunate fissures so as to form a barrier between them.

Very early a transverse groove appears on the smooth anterior or ventricular surface of the cerebellum (Fig. 425, B, T). This is placed much nearer the lower than the upper border of the organ, and it represents at this stage the angular peak of the tent-like roof of the fourth ventricle in the adult brain. As growth goes on, the portions of the cerebellum in front and behind this groove approach each other, so as to deepen the groove and bring about the backward prolongation of the ventricular cavity towards the cerebellum.

The leading distinctive characters of the human cerebellum are: (1) the small size of the flocculus; (2) the large size of the tonsil; (3) the excessive development of the lateral hemisphere, and particularly of the postero-superior and postero-inferior lobules which bound the great horizontal fissure.

## THE MESENCEPHALON.

The mesencephalon or mid-brain is the short, narrow part of the brain-stem which occupies the aperture of the tentorium cerebelli (incisura tentorii), and connects the cerebrum which lies above with the parts which occupy the posterior cranial fossa. It is about three-quarters of an inch in length, and it consists of a dorsal part, composed of the **corpora quadrigemina**, and a much larger ventral part, which is formed by the two **crura cerebri**.

In the undissected brain the corpora quadrigemina are completely hidden from view by the splenium of the corpus callosum, which projects backwards over them, and also by the superimposed cerebral hemispheres. The hinder end of each optic thalamus likewise, to some extent, overhangs the upper part of the mesencephalon on its dorsal and lateral aspect (Fig. 388, p. 482). On this portion of the optic thalamus are seen two projections, which are specially related to the mesencephalon. These are the cushion-like **pulvinar**, which forms the inner and hinder part of the thalamus, and the **corpus geniculatum externum**, an ill-defined oval swelling on the outer and under aspect of the posterior end of the thalamus.

The crura cerebri can to some extent be seen on the base of the brain, where they bound the posterior part of the interpeduncular space. Encircling the upper end of each crus cerebri, where it plunges into the cerebrum, is the optic tract (Fig. 380, p. 474).

The mesencephalon is tunnelled from below upwards by a narrow passage, called the **aqueduct of Sylvius**, which connects the fourth ventricle with the third ventricle (Fig. 429, p. 533). This channel lies much nearer the dorsal than the ventral aspect of the mesencephalon.

**Corpora Quadrigemina.**—This name is applied to four rounded eminences on the posterior aspect of the mesencephalon (Fig. 388, p. 482). The **superior pair** are larger and broader than the **inferior pair**, but they are not so well defined nor are they so prominent. A longitudinal and a transverse groove separate the quadrigeminal bodies from each other. The longitudinal groove occupies the mesial plane and extends upwards to the posterior commissure of the brain. The upper end of this groove widens out into a shallow depression, in which the **pineal body**, a small conical structure which belongs to the diencephalon, rests. From the lower end of the same groove a short but well-defined and projecting band, the **frenulum veli**, passes to the valve of Vieussens, which lies immediately below the inferior pair of quadrigeminal bodies. The transverse groove curves round below each of the superior pair of quadrigeminal bodies and separates them from the inferior pair. It is also continued in an upward and forward direction on the lateral aspect of the mesencephalon.

The quadrigeminal bodies are not marked off laterally from the sides of the mesencephalon, but each has in connexion with it, on this aspect, a prominent strand of white matter, which is prolonged upwards and forwards under the projecting pulvinar and corpus geniculatum externum. These strands are called the **brachia of the corpora quadrigemina**, and they are separated from each other by a continuation on the side of the mesencephalon of the transverse groove, which intervenes between the two pairs of bodies.

The **corpus geniculatum internum** (corpus geniculatum mediale) is closely associated with the brachia. It is a small, sharply-defined oval eminence, which lies on the side of the upper part of the mesencephalon under shelter of the pulvinar of the optic thalamus.

The **inferior brachium** (brachium quadrigeminum inferius), proceeding upwards from the lower quadrigeminal body, advances towards the corpus geniculatum internum and disappears from view under cover of this prominence. Upon the opposite side of the same geniculate body the mesial root of origin of the optic tract takes shape on the surface, and the appearance is such that the conclusion might very naturally be arrived at that the inferior brachium and this root of the optic tract are continuous with each other under the geniculate elevation. This is not the case, however; the fibres of the inferior brachium, to a large extent, proceed into the subjacent tegmentum under cover of the internal geniculate body and help to constitute an ascending tract from the inferior quadrigeminal body, which proceeds upwards to the optic thalamus. Of the fibres of the mesial root of the optic tract some end in the gray matter of the internal geniculate body, whilst others arise within it. They constitute what is called **Gudden's commissure.**

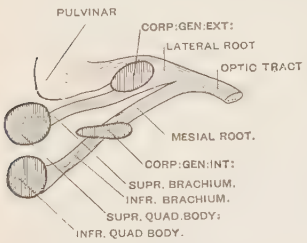

FIG. 428.—DIAGRAM OF THE ROOTS OF THE OPTIC NERVE.

The **superior brachium** (brachium quadrigeminum superius) is carried upwards and forwards between the overhanging pulvinar and the corpus geniculatum internum. A surface examination of the mesencephalon is sufficient to show that, while a large part of this strand enters the corpus geniculatum externum, a considerable portion runs into the lateral root of the optic tract.

The **optic tract** is thus attached to the brain-stem by two roots, viz. a mesial and a lateral, which are separated from each other by a distinct groove. The **mesial root** disappears under the internal geniculate body. The **lateral root** spreads out and some of its fibres enter the superior quadrigeminal body through its brachium, whilst others find their way into the corpus geniculatum externum and the pulvinar of the optic thalamus (Fig. 428).

**Crura Cerebri** (pedunculi cerebri).—The crura cerebri constitute the chief bulk of the mesencephalon (Fig. 429, p. 533). Upon the basal aspect of the brain they appear as two large rope-like strands, which emerge close together from the upper aspect of the pons Varolii and diverge as they proceed upwards to enter the cerebrum. At the place where each crus disappears into the corresponding side of the cerebrum, it is encircled by the optic tract.

Each crus cerebri is composed of two parts, viz. a **dorsal tegmental part** (tegmentum), which is prolonged upwards into the region below the optic thalamus (subthalamic tegmental region), and a **ventral pedal portion** or **crusta** (basis pedunculi), which, when traced upwards into the cerebrum, is seen to take up a position on the outer side of the optic thalamus and to be continuous with the internal capsule of the brain. When the base of the brain is examined it is the crusta which is seen, and it is observed to be white in colour and streaked in the longitudinal direction. In the tegmentum the longitudinally-arranged fibres are, for the most part, *corticipetal*, or, in other words, fibres which are ascending towards the cortex of the cerebrum; the crusta, on the other hand, is entirely composed of longitudinal strands of fibres which are *corticifugal*, or fibres which descend from the cortex cerebri.

On the surface of the mesencephalon the separation between the tegmental and

pedal portions of the crus cerebri is clearly indicated by an inner and an outer groove. The inner or mesial furrow is the more distinct of the two. It looks into the interpeduncular space, and from it emerge the fascicles of the third or oculo-motor nerve. It is, therefore, termed the **sulcus oculo-motorii** (sulcus nervi oculo-motorii). The outer groove, which is placed on the lateral aspect of the mesencephalon, receives the name of the **sulcus lateralis mesencephali.** When traced downwards, it is observed to become continuous with the furrow which intervenes between the middle and superior peduncles of the cerebellum.

A close inspection of the outer surface of the tegmental part of the crus cerebri, below the level of the quadrigeminal brachia, will reveal some faintly-marked bundles of fibres curving obliquely upwards and backwards to reach the inferior quadrigeminal body (Fig. 390, p. 484). These are fibres of the **lateral fillet**, coming to the surface at the sulcus lateralis and sweeping over the subjacent superior cerebellar peduncle to gain the inferior quadrigeminal body.

## INTERNAL STRUCTURE OF THE MESENCEPHALON.

When transverse sections are made through the mesencephalon the aqueduct of Sylvius is seen to be surrounded by a thick layer of gray matter, which receives the name of the **Sylvian gray matter** or the **central gray matter of the aqueduct** (stratum griseum centrale). On the dorsal aspect of the Sylvian gray matter the corpora quadrigemina form a layer which separates it from the surface, and to which the term **lamina quadrigemina** is applied. On the ventral and lateral aspects of the Sylvian gray matter are the tegmental portions of the crura cerebri; whilst, intervening between each of the latter and the corresponding crusta, there is a conspicuous mass of dark pigmented matter termed the **substantia nigra.**

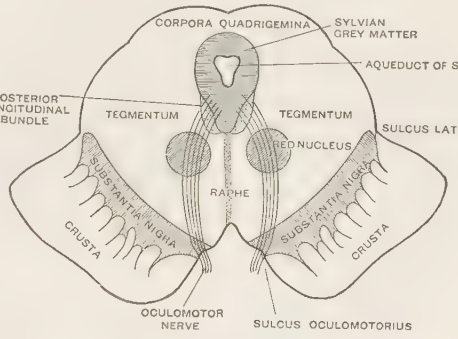

FIG. 429.—DIAGRAMMATIC VIEW OF THE CUT SURFACE OF A TRANSVERSE SECTION THROUGH THE UPPER PART OF THE MESENCEPHALON.

**Sylvian Aqueduct and Sylvian Gray Matter** (aquæductus cerebri —stratum griseum centrale).—The aqueduct of Sylvius is the canal which leads from the fourth ventricle below, upwards through the mesencephalon, to the third ventricle above. It is not quite three-quarters of an inch in length, and it lies much nearer the dorsal than the ventral surface of the mesencephalon. When examined in transverse section, it presents a triangular outline as it passes into the fourth ventricle and a T-shaped outline close to the third ventricle. In the intermediate part of its course it assumes different outlines, and not always the same form at the same level in different individuals.

The aqueduct of Sylvius is lined by ciliated epithelium, and outside this is the thick layer of Sylvian gray matter, which is directly continuous below with the gray matter spread out on the floor of the fourth ventricle, and above with gray matter on the floor and sides of the third ventricle. Scattered more or less irregularly throughout the Sylvian gray matter are numerous nerve-cells of varying forms and sizes, whilst in addition to these there are three definite collections or clusters of cells, which constitute the nuclei of origin of the trochlear nerve, the oculo-motor nerve, and the mesencephalic root of the trigeminal nerve. The position and relations of these will be given at a later stage.

**Substantia Nigra.**—When seen in transverse section, the substantia nigra presents a semilunar outline. It consists of a mass of gray matter, in the midst of which are large numbers of deeply pigmented nerve-cells. It is only when this substance is examined in bulk that it appears dark; in thin sections it does not differ much in colour from ordinary gray matter, although, under the microscope, the brown-coloured cells stand out very conspicuously, even under low powers.

The substantia nigra is disposed in the form of a thick layer, interposed between the tegmental and pedal portions of the crus cerebri. It begins below at the upper border of the pons Varolii and extends upwards into the subthalamic region. The margins of this layer of dark-coloured substance come to the surface at the oculo-motor and the lateral sulci of the mesencephalon, and its inner part is traversed by the emerging fascicles of the oculo-motor nerve. It is not equally thick throughout. Towards the lateral sulcus it becomes thin, whilst it thickens considerably near the inner aspect of the crus cerebri. The surface of the substantia nigra, which is turned towards the tegmentum, is concave and uniform; the opposite surface is convex and rendered irregular by the presence of numerous slender prolongations of the substance into the crusta.

The morphological and physiological significance of the substantia nigra is not fully understood, and the connexions established by its cells are imperfectly known.

**Inferior Quadrigeminal Bodies** (colliculi inferiores).—Each of the inferior quadrigeminal bodies is largely composed of a mass of gray matter which, in transverse section, presents an oval outline (Fig. 432, p. 537). This central nucleus is, to a large extent, encapsulated by white matter. Numerous cells of different sizes are scattered throughout it, and the whole mass is pervaded by an intricate interlacement of fine fibres, which, to a large extent, are derived from the lateral fillet and the inferior brachium.

In transverse sections, through this region, the lateral fillet is seen to abut against the outer margin of the central nucleus. Many of the fibres of this tract enter it at once and become dispersed amongst its cells; others sweep over its dorsal surface, so as to give it a superficial covering; whilst a third group is carried in the form of a thin layer inwards on its ventral aspect, so as to mark it off from the subjacent Sylvian gray matter of the aqueduct (Fig. 432, p. 537). In this manner, therefore, the inferior quadrigeminal nucleus becomes partially circumscribed by the fibres of the lateral fillet. Several of the lateral fillet fibres, which proceed over the superficial or dorsal aspect of the nucleus, reach the mesial plane and form a loose decussation with the corresponding fibres of the opposite side.

The intimate connexion which is thus exhibited between the fibres of the lateral fillet and the nucleus of the inferior quadrigeminal body is very significant. It has already been shown that the lateral fillet, to a large extent, comes from the nuclei of termination of the cochlear nerve of the opposite side, although most of its fibres have to pass through several nuclear internodes before they reach the inferior quadrigeminal body. We must associate, therefore, the inferior quadrigeminal body, and also the corpus geniculatum internum, which likewise receives lateral fillet fibres, with the organ of hearing.

This view of the inferior quadrigeminal bodies is supported both by experimental and by morphological evidence. Speaking broadly, it may be stated that the inferior quadrigeminal bodies are only present as distinct eminences in mammals, and then they are invariably correlated with a spirally-wound and well-developed cochlea. That they have nothing to do with sight, is shown by the fact that, when the eyeballs are extirpated in a young animal, the inferior quadrigeminal bodies remain unaffected, whilst the superior quadrigeminal bodies after a time atrophy (Gudden). When, on the other hand, the cochlear terminal nuclei are destroyed, fibres which have undergone atrophy may be followed to the inferior quadrigeminal bodies of both sides, but particularly to that of the opposite side (Baginski, Bumm, and Ferrier and Turner). A very considerable tract of ascending fibres takes origin within the inferior quadrigeminal body and passes upwards, in the inferior brachium, into the tegmentum subjacent to the internal geniculate body. Within the tegmentum they proceed up to the optic thalamus (Ferrier and Turner).

**Superior Quadrigeminal Bodies** (colliculi superiores).—The superior quadrigeminal body presents a more complicated structure (Fig. 431). Superficially, it is coated with a very thin layer of white matter, which is termed the **stratum zonale**. Underneath this there is a gray nucleus, called the **stratum cinereum**, which in transverse section exhibits a crescentic outline and rests in a cap-like manner upon the subjacent part of the eminence. The succeeding two strata, which respectively receive the names of **stratum opticum** and the **stratum lemnisci**, present this feature in common, that they are composed of gray matter, traversed by numerous fibres. The source from which the fibres are derived differs, however, in each case.

Nerve-fibres reach the superior quadrigeminal body through—(1) the lateral and mesial fillets, and (2) through the superior brachium. The **fillet fibres** enter

the stratum lemnisci, and, in all probability, end there. The **superior brachium** contains fibres of two different kinds, viz. fibres from the optic tract and fibres from the cortex of the occipital lobe of the cerebrum. By the former it is connected with the retina, and by the latter with the visual centre in the occipital region of the cerebral cortex. The *retinal fibres*, for the most part, spread out on the surface of the quadrigeminal body and form the stratum zonale. Most of them dip down into the substance of the body and end in connexion with the cells of the deeper layers; several, however, are carried across the mesial plane, to end in the superior quadrigeminal body of the opposite side. The *occipital fibres*, and probably also some of the retinal fibres, enter the stratum opticum. The fibres from the occipital cortex form part of the optic radiation, and the course which they pursue will be dealt with later on.

**Tegmental Portions of the Crura Cerebri** (tegmenta).—The tegmentum of the crus cerebri may be regarded as the continuation upwards of the formatio reticularis of the medulla and the dorsal or tegmental portion of the pons into the mesencephalon. It therefore consists of fine bundles of longitudinal fibres intersected by arching fibres, which take a transverse and curved course. The interstices between these nerve-bundles is occupied by gray matter containing irregularly scattered nerve-cells. On its dorsal aspect the tegmentum is continuous, at the side of the Sylvian gray matter, with the bases of the corpora quadrigemina, whilst ventrally it is separated from the crusta by the substantia nigra. The two tegmenta of opposite sides are, to some extent, marked off from each other in the mesial plane by a prolongation upwards of the median raphe of the pons and medulla, although, in the lower part of the mesencephalon, this is much obscured by the decussation of the superior peduncles of the cerebellum. The two longitudinal strands, termed the **posterior longitudinal bundle** and the **fillet**, are prolonged upwards throughout the entire length of the mesencephalon: and they present the same relations to the tegmentum as in the lower parts of the brain. The former is placed in relation to its dorsal aspect, whilst the fillet is carried up in its ventral part.

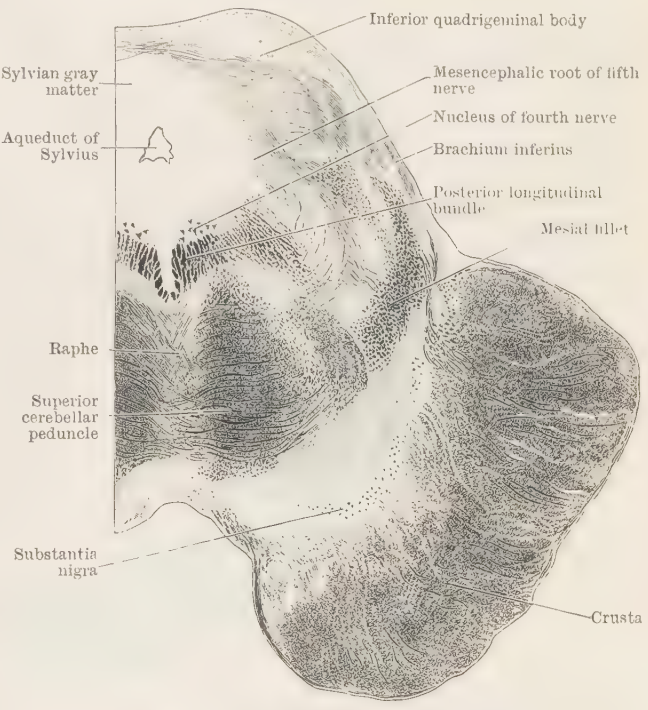

FIG. 430.—TRANSVERSE SECTION THROUGH THE HUMAN MESENCEPHALON AT THE LEVEL OF THE INFERIOR QUADRIGEMINAL BODY.

The tegmentum of the crus cerebri may be considered as presenting two parts: viz. (1) a lower part, which is placed subjacent to the inferior quadrigeminal bodies and which is largely occupied by the decussation of the superior cerebellar peduncles (Fig. 430); and (2) a superior part, subjacent to the superior quadrigeminal bodies, which is traversed by the emerging bundles of the third nerve and which contains a large and striking nuclear mass, termed the nucleus ruber or the red tegmental nucleus (Fig. 431). In the lower part of the mesencephalon is the nucleus of the fourth nerve; in the upper part, the nucleus of the third nerve.

**Superior Cerebellar Peduncles** (brachia conjunctiva).—As the superior cere-

bellar peduncles leave the pons and sink into the tegmenta of the mesencephalon, they undergo a complete decussation subjacent to the inferior quadrigeminal bodies and the Sylvian gray matter (Figs. 407, p. 505; 432, p. 537; and 430, p. 535). In this manner each peduncle is transferred from one side, across the mesial plane, to the opposite side. The decussation is completed at the level of the upper borders of the inferior quadrigeminal bodies, and then each peduncle proceeds upwards into the superior part of the tegmentum, where it encounters the red nucleus. Into this a large proportion of its fibres plunge and come to an end in connexion with the nuclear cells. Many of the peduncular fibres, however, are carried around the nucleus so as to form for it a capsule which is thicker on the inner than on the outer side (Fig. 431). These are prolonged into the subthalamic region, and ultimately penetrate the ventral aspect of the optic thala-

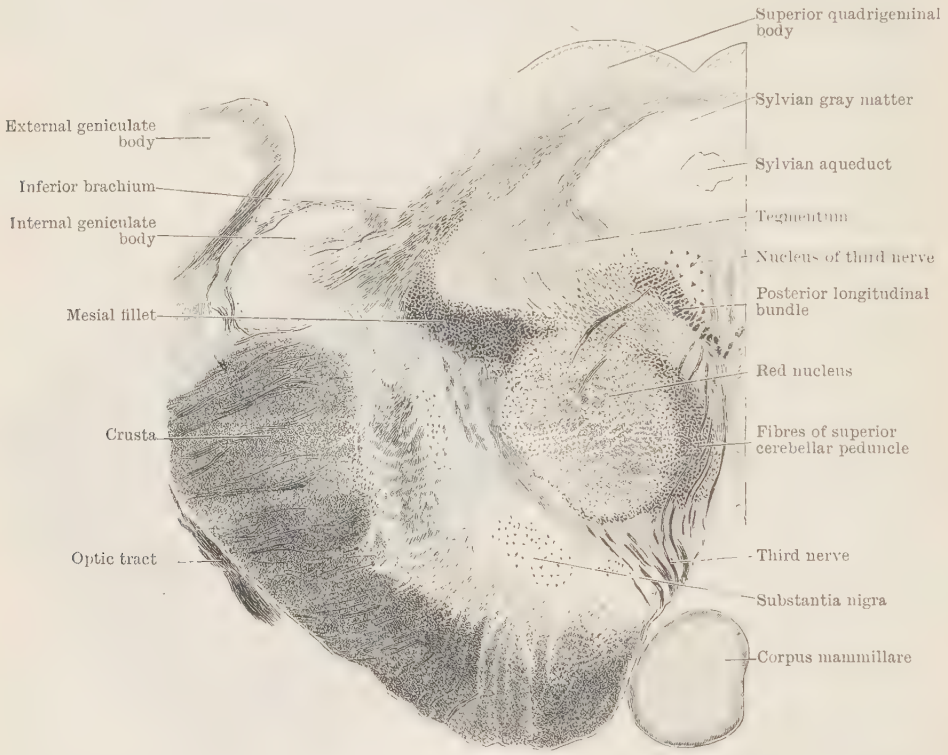

Fig. 431.—Transverse Section through the Human Mesencephalon at the Level of the Superior Quadrigeminal Body.

mus, where they end in connexion with the thalamic cells. The superior cerebellar peduncle is, therefore, a great efferent tract which issues from the lateral hemisphere of the cerebellum, crosses the mesial plane in the lower part of the mesencephalon, and ends in the red nucleus and the ventral part of the optic thalamus.

**Red Nucleus** (nucleus ruber).—This is a rounded nuclear mass, of a reddish tint in the fresh brain, which lies in the upper part of the tegmentum, and in the path of the superior cerebellar peduncle. In transverse section it presents a circular outline. It begins at the level of the lower border of the superior quadrigeminal body and it extends upwards into the subthalamic tegmental region. At first it is small and is placed at a little distance from the mesial plane; but as it proceeds towards the subthalamic region, it increases in bulk and approaches more nearly to the mesial raphe, and its neighbour of the opposite side. The curved emerging bundles of the third nerve pass through it on their way to the surface. The relation which the fibres of the opposite superior cerebellar peduncle present to it has been described. These fibres traverse its lower part in such numbers that in Weigert-Pal specimens it presents a very dark colour; but higher up, as the fibres

are gradually absorbed by the nuclear mass, they become less numerous in its midst, and the nucleus assumes a paler tint.

Numerous fibres which descend from the cerebral cortex and others from the corpus striatum enter the red nucleus. It likewise sends out fibres which proceed in two directions: (1) upwards into the thalamus; (2) downwards to the spinal cord. The former may be regarded as carrying on the continuity of the superior cerebellar path after its internodal interruption in the red nucleus. The fibres to the spinal cord, called the *rubro-spinal tract* and first described by Monakow, cross to the opposite side and then descend in the tegmentum to reach the lateral column of the cord.

**Posterior Longitudinal Fasciculus.**—This is a very conspicuous tract of longitudinal fibres which extends throughout the whole length of the medulla, pons, and mesencephalon, in the formatio reticularis or tegmental part of each. Below, at the level of the decussation of the pyramids, it becomes continuous with the anterior basis-bundle of the spinal cord (p. 491), whilst, by its opposite or upper end, it establishes intricate connexions in the region immediately above the mesencephalon. Throughout its whole length it lies close to the mesial plane and its fellow of the opposite side. In the mesencephalon it is applied to the ventral aspect of the Sylvian gray matter, whilst in the pons and medulla it is situated immediately subjacent to the gray matter of the floor of the fourth ventricle. One of its most salient features is the intimate association which it presents with the three motor nuclei from which the nerves for the supply of the muscles of the eyeball take origin, viz. the oculo-motor or third nucleus, the trochlear or fourth nucleus, and the abducent or sixth nucleus. The first two of these are closely applied to its inner and dorsal aspect, whilst the abducent nucleus is placed on its outer side. Into each of these nuclei it sends many collaterals, and probably also some of its constituent fibres, and these end in terminal arborisations around the nuclear cells. It would appear, therefore, that one of the most important functions of this strand is to bind together these nuclei, and thus enable them to act in harmony with each other. Fibres also enter the posterior longitudinal fasciculus from the auditory system and perhaps, also, from the facial and other motor nuclei. The results obtained by degeneration would seem to indicate that, to a large extent, it is formed of fibres which run a short course within it.

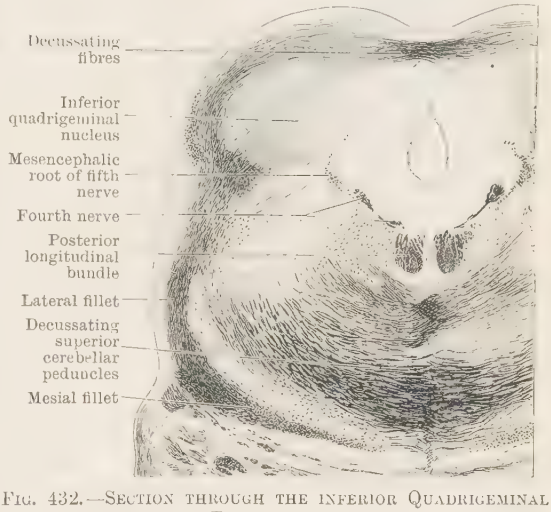

FIG. 432.—SECTION THROUGH THE INFERIOR QUADRIGEMINAL BODY AND THE TEGMENTUM OF THE MESENCEPHALON BELOW THE LEVEL OF THE NUCLEUS OF THE FOURTH NERVE IN THE ORANG. (The decussation of the superior cerebellar peduncles and the course of the fourth nerve in the Sylvian gray matter are seen.)

In spite of the large amount of attention which has been given to the study of the posterior longitudinal bundle, it must be admitted that there is little unanimity of opinion regarding its connexions and functions. That it is a brain tract of high importance, is evident from the fact that it is present in all vertebrates, and, further, that its fibres assume their medullary sheaths at an extremely early period. In fish, amphibians, and reptiles, it is one of the most powerful bundles of the medulla. In man its fibres medullate between the sixth and seventh months of fœtal life, and at the same time as the fibres of the anterior basis-bundle of the cord, with which it stands in connexion.

According to Van Gehuchten and Edinger, it extends upwards beyond the level of the oculo-motor nucleus, and in the subthalamic region its fibres take origin from a special nucleus of its own in the gray matter of the third ventricle, immediately below the level of the corpora mammillaria. Fibres also enter the posterior longitudinal bundle from a nucleus common to it and the posterior commissure of the brain. This nucleus is placed in the fore-part of the Sylvian gray matter of the mid-brain. Held asserts that numerous fibres, arising from cells in the superior quadrigeminal body, curve in an arcuate manner in the tegmentum outside the Sylvian gray

matter, to take part on the ventral aspect of this in what is called the "fountain decussation." Reaching the opposite side these fibres turn downwards and join the posterior longitudinal fasciculus. The same authority considers that fibres from the ventral part of the posterior commissure can also be traced downwards into the posterior longitudinal bundle. Edinger, on the other hand, places these fibres as a distinct tract on the ventral and lateral aspect of the posterior longitudinal bundle, although in apposition with it.

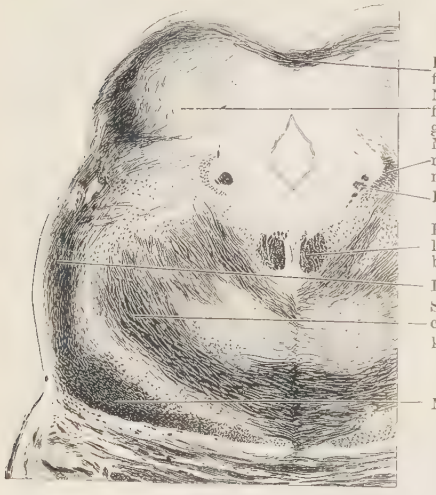

FIG. 433.—SECTION THROUGH THE INFERIOR QUADRIGEMINAL BODY AND THE TEGMENTUM OF THE MESENCEPHALON, AT A SLIGHTLY LOWER LEVEL THAN FIG. 432.

Mendel believes that fibres from the oculo-motor nucleus are carried down in the posterior longitudinal bundle, and, from this, into the facial nerve for the supply of the orbicularis palpebrarum and the corrugator supercilii, bringing these muscles therefore under the control of the same nucleus as the levator palpebræ superioris muscle. This view has received corroboration at the hands of Tooth and Turner. It has been further suggested that fibres from the hypoglossal nucleus may, by the posterior longitudinal fasciculus, reach the facial nerve, and through it the orbicularis oris. In this manner the same nucleus would hold sway over the tongue and the sphincter muscle of the lips. The close relation which exists between the ascending part of the intrapontine portion of the facial nerve and the posterior longitudinal bundle would render the passage of fibres from one to the other a matter which could easily be understood. Another interchange of fibres through the posterior longitudinal bundle has been described by Duval and Laborde. According to these authorities, fibres from the abducent nucleus ascend in the posterior longitudinal bundle into the mesencephalon, and establish connexions with that part of the oculo-motor nucleus from which the nerve for the internal rectus of the opposite side derives its fibres. If this view be correct, it affords a ready and simple anatomical explanation of the harmonious action of the external and internal recti muscles in producing movements of the two eyeballs simultaneously to the right and to the left. From the investigations of E. H. Fraser it would appear that no fibres from the abducent nucleus go directly into the oculo-motor nerve. The same observer has shown that many fibres from Deiters' nucleus, through the path afforded by the posterior longitudinal bundle, enter the third and the fourth nuclei.

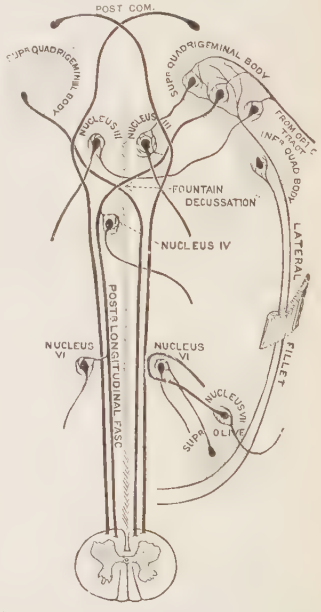

FIG. 434.—DIAGRAM OF THE CONNEXIONS OF THE POSTERIOR LONGITUDINAL BUNDLE (after Held—modified).

**Lateral Fillet** (lemniscus lateralis).—The lateral fillet is a definite tract of longitudinal fibres, which extends upwards through the lateral part of the tegmental substance of the upper portion of the pons and the mesencephalon. It is formed by the fibres of the corpus trapezoides in the lower part of the pons, abruptly turning upwards and taking a course towards the quadrigeminal region. Entering into its constitution, therefore, are fibres from several sources, viz. (1) from the terminal cochlear nuclei of the opposite side; (2) from the terminal cochlear nuclei of the same side; (3) from the superior olivary nuclei. As the tract proceeds upwards a continuation of the gray matter of the superior olivary nucleus is carried up in connexion with it to form the nucleus of the lateral fillet, and from this fibres are also added to the strand. In the mesencephalon the fibres of the lateral fillet end in the nucleus of the inferior quadrigeminal body (p. 534) and in the gray substance of the corpus geniculatum internum, whilst a few are carried into the superior quadrigeminal body. The fibres which go to the inferior quadrigeminal body sweep outwards round the outer side of the superior cere-

bellar peduncle, and to some extent appear on the surface of the mesencephalon (p. 533).

But the lateral fillet cannot be considered as a tract composed entirely of ascending fibres belonging to the auditory system. It also contains descending fibres, the connexions and functions of which are not fully understood. These have been traced by Ferrier and Turner through the pons and medulla into the lateral column of the cord.

**Mesial Fillet** (lemniscus mesialis).—The mesial fillet has already been followed through the medulla and pons, and its position in each of these portions of the brain-stem has been defined (pp. 493 and 504). In the tegmentum of the lower part of the mesencephalon it is carried up in the form of a more or less flattened band on the ventral aspect of the decussating superior cerebellar peduncles. To its outer side, and forming an angle with it (as seen in transverse section), is the lateral fillet (Figs. 432 and 433), and at this level there is no clear demarcation between these two tracts. In the upper part of the mesencephalon the appearance of the red nucleus in the tegmentum causes the mesial fillet to take up a more lateral and dorsal position, so that it now comes to lie subjacent to the corpus geniculatum internum (Fig. 431, p. 536). At this level it exhibits a crescentic outline in transverse section, and the lateral fillet has to a large extent disappeared from its outer side.

The mesial fillet takes origin in the lower part of the medulla oblongata from the gracile and cuneate nuclei of the opposite side (p. 493). Seeing that the posterior column of the cord ends in these nuclei, the fillet may be considered to continue that column upwards into the brain. In the mesencephalon a considerable contribution of fibres is given by the mesial fillet to the superior quadrigeminal body, and then the remainder of the tract proceeds through the subthalamic tegmental region into the hinder part of the lateral nucleus of the optic thalamus. Here its fibres end in terminal arborisations around the thalamic cells.

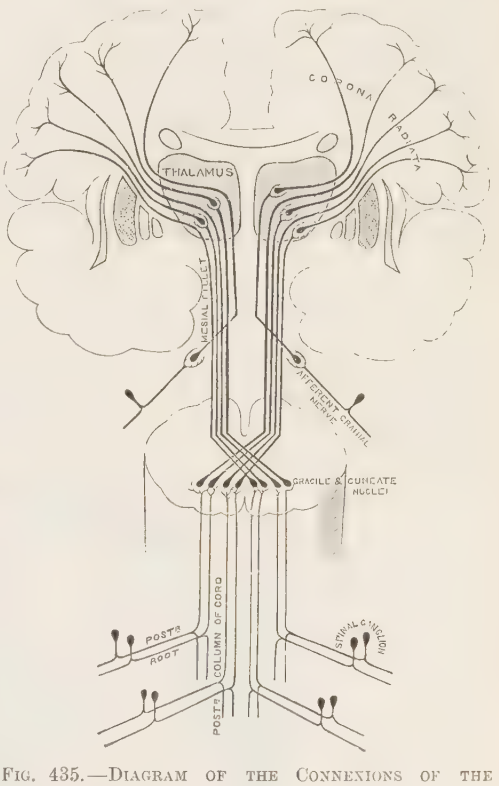

FIG. 435.—DIAGRAM OF THE CONNEXIONS OF THE MESIAL FILLET AND ALSO OF CERTAIN OF THE THALAMO-CORTICAL FIBRES.

**Ganglion Interpedunculare and Fasciculus Retroflexus.**—On the ventral aspect of the tegmentum, close to the surface and to the mesial plane, there is a small group of cells in the lower part of the gray matter which forms the locus perforatus posticus. This is termed the *ganglion interpedunculare.*

The *fasciculus retroflexus* is a small band of fibres which arises above in the ganglion habenulæ—a nuclear mass which will be studied in connexion with the diencephalon—and which runs downwards and forwards in the tegmentum of the upper part of the mesencephalon between the inner aspect of the nucleus ruber and the mesial plane, to end in the ganglion interpedunculare.

**Fountain Decussation.**—If the region in front of the posterior longitudinal bundles be examined in the upper part of the mesencephalon a very close decussation of fibres in the mesial plane will be observed in the interval between the two red nuclei. This is the "fountain decussation." According to Held, the fibres which take part in the dorsal portion of the fountain decussation (decussation of Meynert) come from the superior quadrigeminal bodies, and, after they have gained the opposite side, they turn downwards in the posterior longitudinal fasciculus. The ventral part of the decussation (decussation of Forel) would appear to be formed by arcuate fibres of the tegmentum which arise in the gray matter of the Sylvian aqueduct.

**Crusta or Pes of the Crus Cerebri** (basis pedunculi).—The crusta presents a

somewhat crescentic outline when seen in section, and it stands quite apart from its fellow of the opposite side. It is composed of a compact mass of longitudinally directed fibres, all of which, as Déjerine has shown, arise in the cortex of the cerebrum and pursue an unbroken corticifugal course into and through the crusta of the crus cerebri. These fibres may be classified into two distinct sets, viz. cortico-pontine and pyramidal.

The **cortico-pontine fibres** possess this leading peculiarity: in their course downwards they are all arrested in the ventral part of the pons Varolii and end in fine terminal arborisations around the cells of the nucleus pontis. They come from certain well-defined areas of cerebral cortex, viz. (1) the cortex of the prefrontal part of the frontal lobe, and (2) the cortex of the middle portion of the temporal lobe. These tracts would appear to hold a very definite position within the crus. Thus it has been satisfactorily established that the *temporo-pontine strand* forms the outer or lateral fifth of the crusta, whilst the researches of Ferrier and Turner render it more than likely that the *fronto-pontine strand* holds a similar position in the inner or mesial part of the crusta.

The **pyramidal fibres** constitute the great motor tract from the cerebral cortex. They occupy a position corresponding to the middle three-fifths of the crusta. The pyramidal tract differs from the cortico-pontine strands in being carried downwards through the ventral part of the pons and on the ventral aspect of the medulla into the cord, which it enters in the form of the crossed and direct pyramidal tracts. On its way through the pons and medulla it sends fibres to the various motor nuclei in those sections of the brain-stem.

## Deep Origin of the Cranial Nerves which arise within the Mesencephalon.

Two of the motor cranial nerves, viz. the oculo-motor and the trochlear nerves, as well as the mesencephalic root of the trigeminal nerve, obtain origin within the mesencephalon. The nuclei from which they spring are all situated within the gray matter of the Sylvian aqueduct.

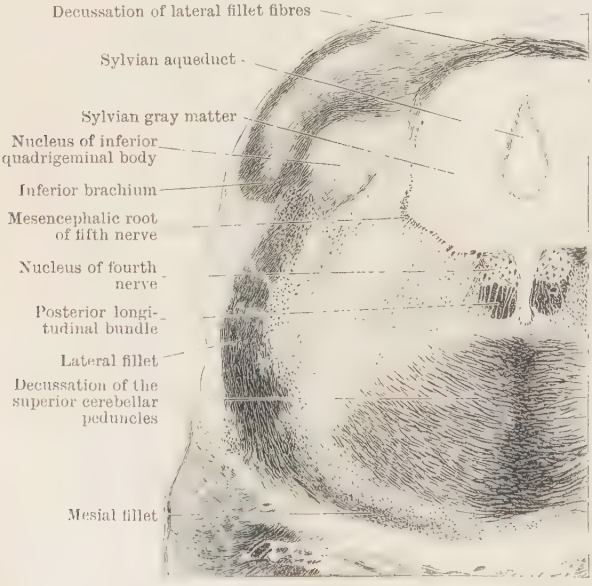

Fig. 436.—Section through the Inferior Quadrigeminal Body and the Tegmentum of the Mesencephalon at the Level of the Middle Part of the Nucleus of the Trochlear Nerve (Orang).

**Mesencephalic Root of the Trigeminal Nerve** (radix descendens).—The fibres of this root arise from a column of large, sparsely-arranged cells, which extends throughout the entire length of the mesencephalon. These cells lie in the outer part of the Sylvian gray matter, close to the tegmentum. The axons which emerge from the cells run downwards close to the outer surface of the Sylvian gray matter in the form of a small, gradually-increasing tract. In the lower part of the mesencephalon this tract assumes a crescentic outline, and ultimately comes to lie on the inner aspect of the superior cerebellar peduncle (Fig. 406, p. 504). The further course of the mesencephalic root of the fifth nerve through the upper part of the pons, to the point where it joins the emerging motor root of the trigeminal nerve, has already been traced (p. 526).

**Trochlear or Fourth Nerve** (nervus trochlearis).—The trochlear nerve supplies

the superior oblique muscle of the eyeball. It emerges from the brain, on its dorsal aspect, at the upper part of the superior medullary velum, immediately below the lower border of the inferior quadrigeminal body (Fig. 438, p 543). The nucleus from which it arises is a small oval mass of gray matter, placed in the ventral part of the Sylvian gray matter at the level of the upper part of the inferior quadrigeminal body. The close association of this nucleus with the posterior longitudinal bundle has already been alluded to. It is sunk deeply in a bay, which is hollowed out on the dorsal and inner aspect of that tract. The nerve has a course of some length within the mesencephalon. The axons of the cells leave the outer aspect of the nuclear mass, and curve backwards and outwards in the Sylvian gray matter until they reach the concave inner surface of the mesencephalic root of the trigeminal nerve. Here they are gathered together into one or two round bundles, which, bending sharply, turn downwards at a right angle and descend on the inner side of the trigeminal root. When the region below the inferior quadrigeminal body is reached, the nerve makes another sharp bend. This time it turns inwards, enters the upper end of the superior medullary velum, in which it decussates with its fellow of the opposite side. Having thus crossed the mesial plane, the trochlear nerve emerges at the inner border of the superior cerebellar peduncle. The course pursued by the fourth nerve within the Sylvian gray matter may be traced by examining in succession Fig. 437; Fig. 432, p. 537; Fig. 433, p. 538; and Fig. 407, p. 505.

**Oculo-motor or Third Nerve** (nervus oculo-motorius). The oculo-motor nerve supplies the levator palpebræ superioris, all the ocular muscles, with the exception of the superior oblique and the external rectus, and also two muscles within the eyeball, viz. the sphincter iridis and the musculus ciliaris. The nucleus of origin is placed in the ventral part of the Sylvian gray matter subjacent to the superior quadrigeminal body (Fig. 431, p. 536). In length it measures from 5 to 6 mm. Its lower end is partially continuous with the nucleus of the trochlear nerve, whilst its upper end extends upwards for a short distance beyond the mesencephalon into the gray matter on the lateral wall of the third ventricle. Its relation to the posterior longitudinal bundle is even more intimate than that of the trochlear nucleus. It is closely applied to the dorsal and inner aspect of this strand; many of its cells occupy a position in the intervals between the nerve-bundles of the tract, and some even are seen on its ventral or tegmental aspect. The axons of the nuclear cells leave the nucleus in numerous bundles, which describe a series of curves as they proceed forwards through the posterior longitudinal bundle, the tegmentum, red nucleus, and inner margin of the substantia nigra, to finally emerge from the brain-stem along the bottom of the sulcus oculo-motorius on the inner aspect of the crus cerebri.

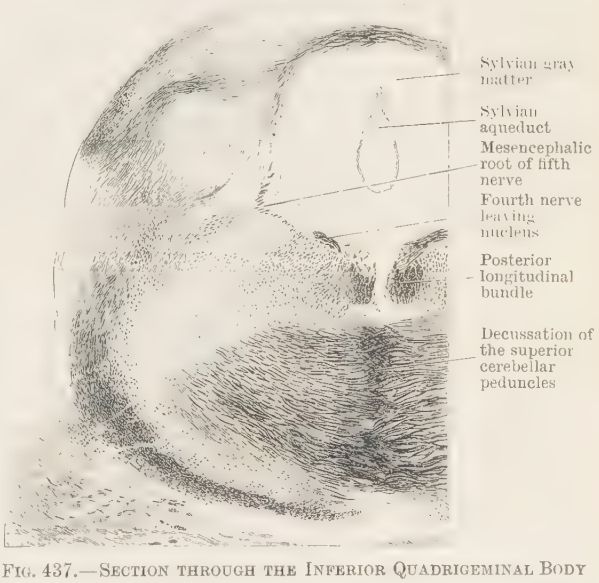

Fig. 437.—Section through the Inferior Quadrigeminal Body and the Tegmentum of the Mesencephalon at the Level of the Lower Part of the Nucleus of the Trochlear Nerve (Orang).

The cells of the oculo-motor nucleus are not uniformly distributed throughout it. They are grouped into several more or less distinct collections or clumps, some of which possess cells which differ in size and appearance from the others. These cell-clusters are very generally believed to possess a definite relation to the several branches of the nerve and the muscles which they supply. Perlia recognises no less than seven such cell-clusters in each nucleus, with a small

median nucleus placed accurately on the middle line, and from which fibres for both nerves spring. Whilst the majority of the fibres in the oculo-motor nerve arise from the cell-groups which lie on its own side of the mesial plane, it has been satisfactorily established that a certain proportion of its fibres are derived from the nucleus of the opposite side, thus forming a crossed connexion and giving rise to a median decussation. These crossed fibres are supposed by some to supply the internal rectus muscle; and we have seen that there is reason to believe that the part of the nucleus from which these fibres are derived stands in connexion through the posterior longitudinal fasciculus with the abducent or sixth nucleus from which proceeds the nerve of supply for the external rectus muscle. The harmonious action of the internal and external recti in producing the conjugate movements of the eyeballs is thus explained.

The oculo-motor nucleus is connected—(1) with the occipital part of the cerebral cortex by fibres which reach it through the optic radiation; (2) with the trochlear and abducent nuclei (and probably with other nuclei) by fibres which come to it through the posterior longitudinal bundle; (3) possibly with the facial nerve by fibres which pass out from it into the posterior longitudinal bundle (p. 538); (4) with the visual system by fibres which enter it from the cells of the superior quadrigeminal body.

### Development of the Mesencephalon.

Even in the early embryo the mesencephalon constitutes the smallest section of the brain-tube, although the disproportion in size between it and the other primitive subdivisions of the brain is not nearly so marked as in the adult. Owing to the cephalic flexure, the mid-brain for a time occupies the highest part of the summit of the head. Later on it becomes completely covered over by the expanding cerebral hemispheres.

The corpora quadrigemina are derived from the alar laminæ of the lateral walls of the brain-tube, whilst the basal laminæ thicken and ultimately form the tegmenta and crustæ of the two crura cerebri. The original cavity of the mid-brain is retained as the aqueduct of Sylvius.

For a considerable time the cavity of the mesencephalon remains relatively large, and the lower part of its dorsal wall is carried downwards in the form of a diverticulum or recess, which overlaps the cerebellar plate. About this time, also, the dorsal wall shows a median fold or ridge. Both of these conditions are transitory. As the corpora quadrigemina take shape, the median ridge disappears and is replaced by the median longitudinal groove, which separates the quadrigeminal bodies. Only its lower part is retained, and this is represented by the frenulum veli of the adult brain. The diverticulum of the cavity gradually becomes reduced, and finally disappears as the aqueduct assumes form.

## FORE-BRAIN.

### Parts derived from the Diencephalon.

Under this heading we have to consider: (1) the **thalamus**; (2) the **epithalamus**, which comprises the pineal body and the habenular region; (3) the **metathalamus**, or the corpora geniculata; and (4) the **hypothalamus**.

The hypothalamus consists of two portions, viz. the **pars mammillaris hypothalami**, which comprises the corpus mammillare and the portion of the central gray matter which forms the floor of the third ventricle in its immediate vicinity; and the **pars optica hypothalami**, which embraces the tuber cinereum, the infundibulum, the pituitary body, and the lamina cinerea. Strictly speaking, the optic part of the hypothalamus does not belong to the diencephalon, but it is convenient to study the parts which it represents at this stage. It is also convenient to examine, at the same time, the **subthalamic tegmental region**, although a very considerable part of this is apparently developed in connexion with the mesencephalon.

The original cavity of that part of the brain-tube which forms the diencephalon is represented by the greater part of the third ventricle of the brain.

**Optic Thalamus** (thalamus).—The optic thalamus is the principal object in this section of the brain (Fig. 438). It is a large ovoid mass of gray matter, which lies obliquely across the path of the crus cerebri as it ascends into the cerebrum. The smaller anterior end of the thalamus lies close to the mesial plane, and is only separated from the corresponding part of the opposite side by a very narrow interval. The enlarged posterior ends of the two thalami are placed more widely apart, and in the interval between them the corpora quadrigemina are situated. As previously stated, the crusta of the crus cerebri, composed of corticifugal fibres

gradually inclines outwards as it is traced upwards, and thus it assumes a place on the outer aspect of the optic thalamus and passes into the internal capsule of the brain. The tegmental part of the crus, on the other hand, comes into relation with the under surface of the thalamus, and forms in this situation the **subthalamic tegmental region**. To a large extent the longitudinal fibres of the tegmentum are corticipetal. For the most part they enter the thalamus, and end within it in fine arborisations around the thalamic cells.

The two optic thalami, in their anterior two-thirds, lie close together on either side of a deep mesial cleft, which receives the name of the third ventricle of the brain. Each thalamus presents an anterior and a posterior extremity and four surfaces. The inferior and external surfaces are in apposition, and, indeed, directly connected with adjacent parts of the brain, and on this account it is only possible to study them by means of sections through the brain. The superior and internal surfaces are free.

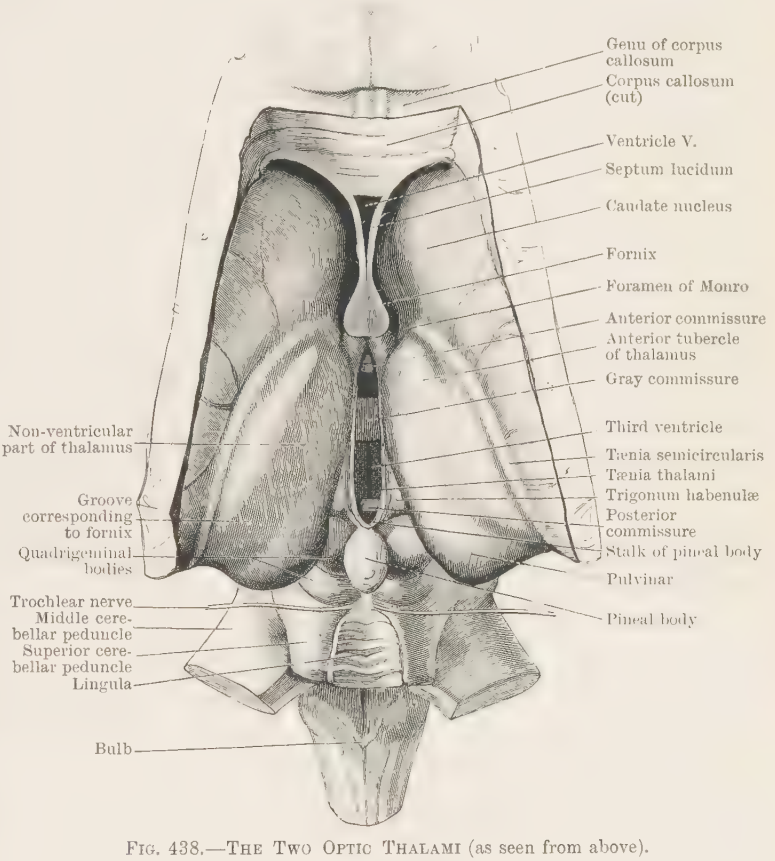

FIG. 438.—THE TWO OPTIC THALAMI (as seen from above).

The *external* or *lateral surface* of the thalamus is applied to a thick layer of white matter interposed between it and the lenticular nucleus, called the **internal capsule**, and composed of fibres passing both upwards towards and downwards from the cerebral cortex. A large proportion of these fibres descend to form the crusta or ventral part of the crus cerebri. From the entire extent of the external surface of the thalamus large numbers of fibres stream out and enter the internal capsule, to reach the cerebral cortex; over the same area other fibres which arise in the cortex of the cerebrum enter the thalamus. Both of these sets of fibres constitute what is termed the **thalamic radiation**, and by this the thalamus establishes a double connexion with the entire extent of the cerebral cortex. As the fibres leave and enter the thalamus they intersect each other at acute angles, and over the whole of the external surface of the ganglionic mass they form a very distinct reticulated zone or stratum, which is termed the **external medullary lamina**.

The *inferior* or *ventral surface* of the thalamus rests chiefly on the subthalamic tegmental region and the corpus mammillare. In front, however, as the tegmental substance gradually disappears, the thalamus comes to lie over the outer part of the tuber cinereum. From the subthalamic region many fibres enter the thalamus on its under aspect, whilst other fibres leave this surface of the thalamus to take part in the thalamic radiation.

The *superior* or *dorsal surface* of the thalamus is free. Externally it is bounded by a groove, which traverses the floor of the lateral ventricle of the brain and intervenes between the thalamus and the caudate nucleus. In this groove are placed a slender band of longitudinal fibres, termed the tænia semicularis, and in its fore-part the vein of the corpus striatum. Internally, the superior surface of the thalamus is separated from the internal or mesial surface in its anterior half by a sharp edge or prominent ledge of the ependyma of the third ventricle. This is termed the **tænia thalami**, and the ridge which it forms is accentuated by the fact that, subjacent to it, there lies a longitudinal strand of fibres called the **stria medullaris**. When these two structures, viz. the ependymal ridge and the subjacent tract, are traced backwards, they are seen to turn inwards and become continuous with the stalk or peduncle of the pineal body. Behind the portion of the tænia thalami which turns inwards towards the pineal body a small depressed triangular area, the **trigonum habenulæ**, situated in front of the superior quadrigeminal body, forms a very definite inner boundary for the hinder part of the superior surface of the thalamus.

The superior surface of the thalamus is slightly bulging or convex, and is of a whitish colour, owing to the presence of a thin superficial covering of nerve-fibres, termed the **stratum zonale**. It is divided into two areas by a faint oblique groove, which begins in front at the inner border, a short distance behind the anterior extremity of the thalamus, and extends outwards and backwards to the outer part of the hinder end. This groove corresponds to the outer edge of the fornix. The two areas which are thus mapped out are very differently related to the ventricles of the brain, and also to the parts which lie above the thalamus. The *outer area*, which includes the anterior extremity of the thalamus, forms a part of the floor of the lateral ventricle. It is covered with ependyma, overlapped by the choroid plexus of this ventricle, and lies immediately subjacent to the corpus callosum. Along the line of the groove the epithelial lining of the lateral ventricle is reflected over the choroid plexus of this cavity. The *inner area*, which includes the hinder end of the thalamus, intervenes between the lateral and third ventricles of the brain, and takes no part in the formation of the walls of either. It is covered by a fold of pia mater, termed the velum interpositum, above which is the fornix, and these two structures intervene between the thalamus and the corpus callosum.

The *anterior extremity* of the thalamus, called the **anterior tubercle** (tuberculum anterius thalami), forms a marked bulging. It projects into the lateral ventricle, behind and to the outer side of the free portion of the anterior pillar of the fornix. The foramen of Monro, a narrow aperture of communication between the lateral and third ventricles of the brain, is bounded in front by the anterior pillar of the fornix and behind by the anterior tubercle of the thalamus.

The *posterior extremity* of the thalamus is very prominent and forms a cushion-like projection, which overhangs the brachia of the corpora quadrigemina. This prominence is called the **pulvinar**. Another oval bulging on the hinder part of the thalamus receives the name of the **corpus geniculatum externum**. It is situated below, and to the outer side of, the pulvinar, and presents a very intimate connexion with the optic tract.

The *mesial surfaces* of the two thalami are placed close together, and are covered not only by the lining ependyma of the third ventricle, but also by a tolerably thick layer of gray matter, continuous below with the central gray substance which surrounds the aqueduct of Sylvius in the mesencephalon. A band of gray matter, termed the **gray** or **soft commissure** (commissura mollis), crosses the third ventricle and joins the inner surfaces of the two thalami together.

**Intimate Structure and Connexions of the Optic Thalamus.**—The upper surface of the thalamus is covered by the **stratum zonale**, a thin coating of white fibres derived to some extent from the optic tract, and probably also from the optic radiation. The inner surface has a thick coating of central gray matter, whilst intervening between the internal capsule and the outer surface is the **lamina medullaris externa**. The lower surface merges into the subthalamic region.

The gray matter of the optic thalamus is marked off into three very apparent parts—termed the anterior, the mesial, and the lateral thalamic nuclei—by a thin

vertical sheet of white matter, continuous with the stratum zonale, termed the **lamina medullaris interna.** The **lateral nucleus** (nucleus lateralis thalami) is by far the largest of the three. It is placed between the internal and the external medullary laminæ, and it stretches backwards beyond the mesial nucleus, and thus includes the whole of the pulvinar (Fig. 440). The **mesial nucleus** (nucleus medialis thalami) only reaches as far back as the habenular region. It is placed between the central gray matter of the third ventricle and the internal medullary lamina. The lateral nucleus is more extensively pervaded by fibres than the mesial nucleus. From the lateral nucleus by far the greatest number of the fibres which form the **radiatio thalami** pass, and these are seen crossing it in various directions towards the lamina medullaris externa. The **anterior nucleus** (nucleus anterior thalami) is the smallest of the three thalamic nuclei. It forms the prominent anterior tubercle, and is prolonged in a wedge-shaped manner, for a short distance, downwards and backwards between the anterior parts of the mesial and lateral nuclei. The internal medullary lamina splits into two parts and partially encloses the anterior nucleus. In connexion with its large cells a very conspicuous bundle of fibres, the **bundle of Vicq d'Azyr** (fasciculus thalamo-mammillaris), which arises in the corpus mammillare, comes to an end.

A diffuse gray mass imperfectly marked off from the under surface of the lateral nucleus receives the name of the *ventral nucleus.* Its lower part is composed of the **central nucleus of Luys** and the **nucleus arcuatus.** In section the former appears as a circular mass of gray matter, which comes into view immediately behind the point where the internal medullary lamina disappears. It would seem to be intimately connected with fibres which reach it from the red nucleus and from the posterior commissure. These fibres pass round it so as to mark it off from the rest of the thalamus, and in front of the nucleus many of them enter the internal medullary lamina. The **nucleus arcuatus** is a small semilunar mass of gray matter placed below and to the outer side of the central nucleus of Luys.

The **connexions of the thalamus** are of an extremely intricate kind. It would appear to be a ganglionic mass interposed between the tegmental corticipetal tracts and the cerebral cortex. In its hinder part, and through its stratum zonale, it also has important connexions with the optic tract. The corticipetal tegmental tracts, which enter it from below, will be noticed in connexion with the subthalamic region. Suffice it to say, for the present, that these fibres end in the midst of the thalamus in connexion with the thalamic cells. In addition to these, enormous numbers of fibres, arising within the thalamus as the axons of its cells, stream out from its outer and under surfaces to form the thalamic radiation. These **thalamo-cortical fibres** pass to every part of the cortex; and although there is no separation of them into distinct groups as they leave the thalamus, it is customary to regard them as constituting a frontal stalk, a parietal stalk, an occipital stalk, and a ventral stalk. But fibres from the cortex, **cortico-thalamic fibres**, likewise stream into the thalamus in large numbers, and end in fine arborisations around its cells. A double connexion with the cerebral cortex is thus established by the thalamus.

The **frontal stalk** of the thalamic radiation emerges from the anterior part of the lateral surface of the thalamus and passes through the anterior limb of the internal capsule, to reach the cortex of the frontal lobe. Many of these fibres end in the caudate and lenticular nuclei, between which they proceed. The **parietal stalk** issues from the lateral surface of the thalamus, and, passing through the internal capsule (and to some extent, also, through the lenticular nucleus and the external capsule), gains the cortex of the hinder part of the frontal lobe and of the parietal lobe. The **occipital stalk** emerges from the outer aspect of the pulvinar and constitutes the so-called optic radiation. These fibres sweep outwards and backwards round the outer side of the posterior horn of the lateral ventricle to gain the cortex of the occipital lobe. The **ventral stalk** streams out from the under aspect of the anterior part of the thalamus, in front of the subthalamic tegmental region and the corpus mammillare. Its fibres arise in both the mesial and lateral nuclei, and sweep downwards and outwards to reach the region below the lenticular nucleus. One very distinct band which lies dorsal to the other fibres (ansa lenticularis) enters the lenticular nucleus, whilst the remainder (ansa peduncularis) continue in an outward direction below the lenticular nucleus and gain the cortex of the temporal lobe and of the insula or island of Reil.

Flechsig divides the thalamo-cortical fibres of ordinary sensation into three sensory systems. These he has been able to distinguish by studying the order in which they assume their sheaths of myelin in the fœtus and infant.

Ferrier and Turner, by the degenerative method of investigation, corroborate Flechsig's results. They confirm the observation of Flechsig that, while thalamic fibres are distributed to

the several regions of the cerebral cortex to an almost equal extent, there is one district, viz. the frontal pole, to which the supply is scanty. Another very important result has been obtained by these authors. They have established the fact that many of the thalamic fibres cross the mesial plane in the corpus callosum, and thus gain the cortex of the opposite cerebral hemisphere. Hamilton's crossed callosal tract thus receives conformation.

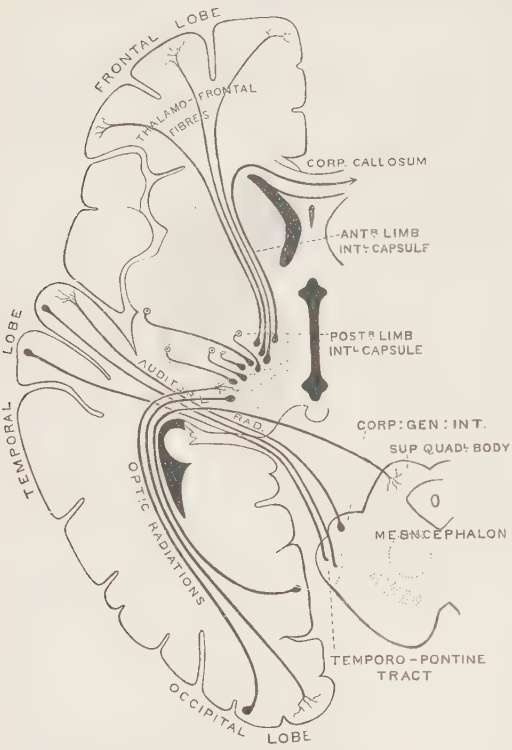

FIG. 439.—SCHEMA. Founded on the observations of Flechsig, and Ferrier and Turner.

**Intimate Structure of the Corpus Geniculatum Externum.** — Sections through the external geniculate body reveal the fact that it is composed of a series of alternately placed gray and white curved laminæ. This gives it a very characteristic appearance. The white laminæ are composed of fibres which enter the body from the optic tract and the optic radiation. The connexions of the geniculate bodies will be studied with the optic tract.

**Subthalamic Tegmental Region.** —The tegmental part of the crus cerebri is prolonged upwards and assumes a position below the hinder part of the thalamus. The **red nucleus** is a conspicuous object in sections through the lower part of this region (Fig. 440). It presents the same appearance as lower down in the mesencephalon, and, gradually diminishing, it disappears before the level of the corpus mammillare is reached. Carried up around it are the same longitudinal tracts of fibres which have been studied in relation to it in the tegmental part of the mesencephalon. Certain of these fibres, placed in immediate relation to the red nucleus, form a coating or capsule for it. This coating is partly derived from those fibres of the superior cerebellar peduncle which pass directly up into the thalamus and also partly from fibres which issue from the nucleus itself. The **mesial fillet**, also, which in the upper part of the mesencephalon is observed to take up a position on the lateral and dorsal aspect of the red nucleus, maintains a similar position in the subthalamic region. When the red nucleus comes to an end these various fibres are continued onwards and form, in the position previously occupied by the nucleus, a very evident and dense mass of fibres. The fibres of the mesial fillet, of the superior cerebellar peduncle, and of the red nucleus are prolonged upwards into the ventral part of the thalamus, where they end in connexion with the thalamic cells.

The **substantia nigra** is likewise carried into the subthalamic region, where it maintains its original position on the dorsal aspect of the crusta of the crus cerebri. As it is traced upwards, it is seen to gradually diminish in amount. It shrinks from within outwards, and finally disappears when the hinder part of the corpus mammillare is reached.

In coronal sections through the subthalamic region, the most conspicuous object which comes into view is the **corpus subthalamicum** or the **nucleus of Luys** (Fig. 440). It is a small mass of gray matter, shaped like a biconvex lens, which makes its appearance on the dorsal aspect of the crusta of the crus cerebri immediately to the outer side of the substantia nigra. At first it lies in an angle, which is formed by the meeting of the crusta and the internal capsule; but, rapidly enlarging in an inward direction, it takes the place of the diminishing substantia nigra on the dorsal surface of the crusta at the level of the lower part of the corpus mammillare. The corpus subthalamicum is rendered all the more evident by the fact that it is

sharply defined by a thin capsule of white fibres. On its mesial aspect these fibres proceed inwards and form a very evident decussation across the middle line in the floor of the third ventricle, immediately above the hinder ends of the corpora mammillaria.

The corpus subthalamicum, in the fresh condition, presents a brownish colour, partly from the fact that its cells are pigmented, and partly also on account of the numerous capillary blood-vessels which pervade its substance.

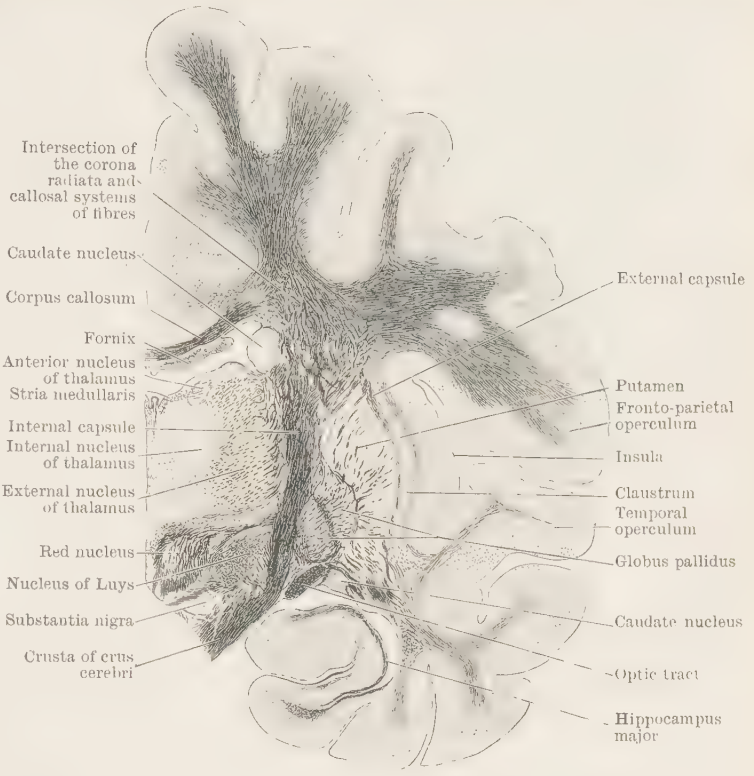

FIG. 440.—CORONAL SECTION THROUGH THE CEREBRUM OF AN ORANG PASSING THROUGH THE SUBTHALAMIC TEGMENTAL REGION.

**Pineal Body** (corpus pineale).—This is a small, dark, reddish body, about the size of a cherry-stone and shaped after the fashion of a fir-cone. Placed between the hinder ends of the two thalami, it occupies the depression on the dorsal aspect of the mesencephalon, which intervenes between the two superior quadrigeminal bodies. Its base, which is directed upwards, is attached by a hollow stalk or peduncle. This stalk is separated into a dorsal and a ventral part by the prolongation backwards into it of a small pointed recess of the cavity of the third ventricle. The dorsal part of the stalk curves outwards and forwards, and on each optic thalamus becomes continuous with the tænia thalami and the subjacent stria medullaris; the ventral part is folded round a narrow but conspicuous cord-like band of white matter, which crosses the mesial plane immediately above the base of the pineal body and receives the name of the **posterior commissure** of the cerebrum (Fig. 438, p. 543).

The pineal body is not composed of nervous elements. The only nerves in its midst are the sympathetic filaments which enter it, with its blood-vessels. It is composed of spherical and tubular follicles, filled with epithelial cells, and containing a variable amount of gritty, calcareous matter.

The pineal body is a rudimentary structure, but in certain vertebrates it attains a much higher degree of development than in man. In the lizard, blind-worm, etc., it is present in the form of the so-called pineal eye. In structure it resembles, in these animals, an invertebrate eye, and it possesses a long stalk, in which nerve-fibres are developed. Further, it is carried through an aperture in the cranial wall, and consequently lies close to the surface on the dorsum of the head between the parietal bones.

**Trigonum Habenulæ.**—The small, triangular, depressed area which receives this name is placed immediately in front of the superior quadrigeminal body in the interval between the peduncle of the pineal body and the hinder end of the thalamus (Fig. 438, p. 543). It marks the position of an important collection of nerve-cells, which constitute the **ganglion habenulæ**. The axons of these cells are collected on the ventral aspect of the ganglion into a bundle, called the **fasciculus retroflexus**, which takes a curved course downwards and forwards in the tegmentum of the

mesencephalon. The fasciculus retroflexus lies close to the inner side of the red nucleus, and finally comes to an end in a group of cells termed the **ganglion interpedunculare**, situated in the lower part of the locus perforatus posticus (see p. 539).

The ganglion habenulæ is likewise intimately connected with the stria medullaris and the dorsal part of the stalk of the pineal body.

As previously stated, the **stria medullaris**—a very evident band of white matter—lies on the optic thalamus, subjacent to the ependymal ridge termed the tænia thalami. When traced backwards, many of the fibres of the stria medullaris are observed to end amongst the cells of the ganglion habenulæ, whilst others are continued past the ganglion to enter the peduncle of the pineal body, and, through it, to reach the ganglion habenulæ of the opposite side, in connexion with the cells of which they terminate. The stria medullaris, therefore, ends partly in the ganglion habenulæ of its own side and partly in the corresponding ganglion of the opposite side. The decussation of fibres across the middle line forms the dorsal part of the pineal stalk or peduncle, and is frequently termed the **commissura habenularum**.

When the stria medullaris is traced in the opposite direction, it is noticed to split into a dorsal and ventral part near the anterior pillar of the fornix. The *dorsal part* turns abruptly upwards, and, joining the fornix, is carried in it to the hippocampus major or cornu ammonis from cells in which its fibres take origin. The *ventral part* turns downwards and appears to spring from a collection of cells in the gray matter on the base of the brain close to the optic chiasma. The stria medullaris is believed to form a part of the olfactory apparatus.

**Commissura Posterior.**—The posterior commissure is a slender band of white matter, which crosses the middle line under cover of the stalk of the pineal body and overlies the entrance of the aqueduct of Sylvius into the third ventricle. The fibres which enter into the formation of the posterior commissure are believed to arise in a special nucleus, which is placed in the central gray matter immediately above the oculo-motor nucleus. They decussate with each other across the mesial plane and thus the commissure is formed. The other connexions of this little band are not satisfactorily established, but Held believes that some of its ventral fibres pass downwards into the posterior longitudinal bundle.

**Locus Perforatus Posticus** (substantia perforata posterior).—This has already been described on p. 475. Some delicate bands of white matter, termed the **tænia pontis**, may frequently be seen emerging from the gray matter of this region; they then curve round the crura cerebri in close relation to the upper border of the pons, into which they ultimately sink (Fig. 390, p. 484).

**Corpora Mammillaria.**—The corpora mammillaria are two round white bodies, each about the size of a pea, which lie side by side in the interpeduncular space on the base of the brain, immediately in front of the locus perforatus posticus.

Each corpus mammillare is coated on the outside by white matter derived from the anterior pillar of the fornix, and contains, in its interior, a composite gray nucleus with numerous nerve-cells. Several important strands of fibres are connected with the corpus mammillare: (1) The **anterior pillar of the fornix** curves downwards in the lateral wall of the third ventricle to reach the corpus mammillare, and its fibres end amidst the cells of that body. (2) A bundle of fibres, called the **bundle of Vicq d'Azyr**, which at first sight appears to be continuous with the anterior pillar of the fornix, takes origin in its midst and extends upwards into the optic thalamus, to end in fine arborisations around the large cells in the anterior thalamic nucleus. (3) Another bundle of fibres, the **pedunculus corporis mammillaris**, takes form within the corpus mammillare and extends downwards in the gray matter of the floor of the third ventricle, to reach the tegmentum of the mesencephalon. The ultimate destination of these fibres is doubtful.

**Tuber Cinereum and Infundibulum.**—The tuber cinereum is a small, slightly prominent field of gray matter, which occupies the anterior part of the interpeduncular space between the corpora mammillaria behind and the optic chiasma in front. From its fore-part the **infundibulum**, or stalk of the pituitary body, projects downwards and connects that body with the base of the brain. In its

upper part the infundibulum is hollow, a small, funnel-shaped diverticulum of the cavity of the third ventricle being prolonged downwards into it.

**Pituitary Body** (hypophysis).—This is a small oval structure, flattened from above downwards, and with its long axis directed transversely, which occupies the pituitary fossa in the floor of the cranium. It is composed of two lobes—a large anterior lobe and a smaller posterior lobe, which are closely applied the one to the other. The infundibulum, which extends downwards from the tuber cinereum, is attached to the posterior lobe.

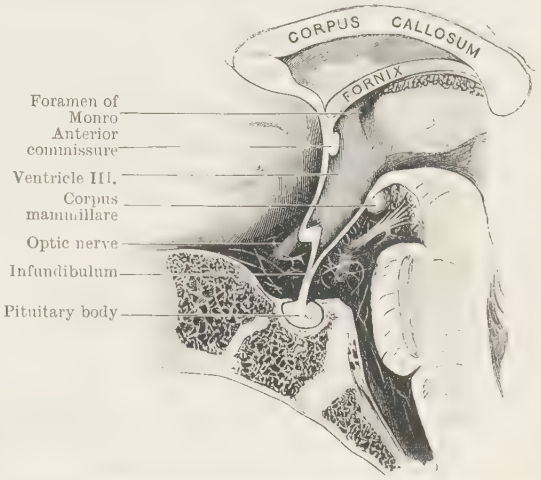

Fig. 441.—Mesial Section through the Pituitary Region in a Child of Twelve Months old.

In this section, as well as in the section figured in Fig. 442, the infundibulum has the appearance of being attached to the anterior lobe. This is due to the way in which the larger anterior lobe grows backwards so as to embrace the smaller posterior lobe. The latter is, as it were, accommodated in a hollow in the hinder aspect of the anterior lobe.

From a photograph by Professor Symington.

The infundibulum and posterior lobe of the pituitary body are developed in the form of a hollow diverticulum, which grows downwards from the floor of that part of the embryonic brain which afterwards forms the third ventricle. The original cavity of this diverticulum becomes obliterated, except in the upper part of the infundibulum. In structure, the posterior lobe of the pituitary body shows little trace of its origin from the wall of the brain-tube. It is chiefly composed of connective tissue and blood-vessels, with branched cells scattered throughout it.

The anterior lobe has quite a different origin, and may be regarded as the functional part of the pituitary body. It is derived from a tubular diverticulum, which grows upwards from the primitive buccal cavity or stomodæum. Its connexion with the latter (canalis cranio-pharyngeus) is in the course of time cut off, and the diverticulum becomes encased within the cranial cavity in intimate association with the cerebral portion of the organ. Structurally, it consists of tubules or alveoli, lined by epithelial cells and surrounded by capillary vessels. Its structure is in some respects not unlike that of the parathyroid bodies. In giants, and in cases of acromegaly, the pituitary body is usually greatly enlarged.

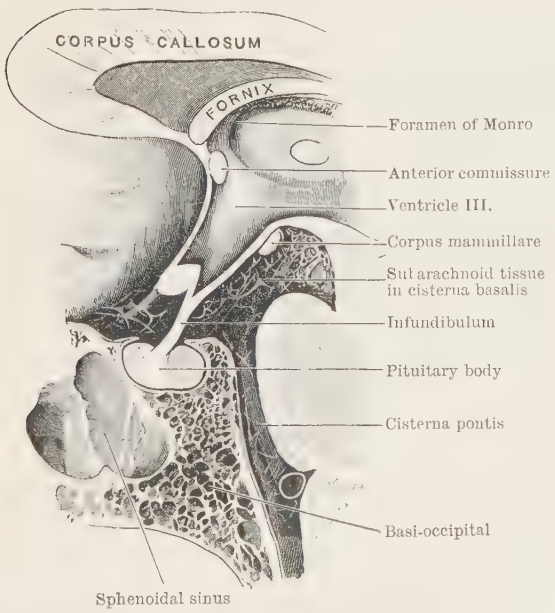

Fig. 442.—Mesial Section through the Pituitary Region in the Adult.

**Lamina Cinerea.**—This is a thin, delicate lamina which may be seen on the basal aspect of the brain, stretching from the upper aspect of the optic chiasma in an upward direction to become connected with the rostrum of the corpus callosum.

**Anterior Commissure of the Cerebrum.**—In the anterior part of the cleft, between the two optic thalami and immediately in front of the anterior pillars of the fornix, a round bundle of fibres crosses the mesial plane. This is the anterior commissure. It is much larger than the posterior commissure.

**Third Ventricle** (ventriculus tertius). — This is the narrow cleft which separates the two optic thalami. Its depth rapidly increases from behind forwards, and it may be said to extend from the pineal body behind to the lamina cinerea in front. Its *floor* is formed by the structures already studied within the area of the interpeduncular space on the base of the brain, viz. the tuber cinereum, the corpora mammillaria, the gray matter of the locus perforatus posticus, and also to some extent behind this by the tegmenta of the crura cerebri. It is interesting to note that the central gray matter which surrounds the Sylvian aqueduct is directly continuous with the gray matter of the locus perforatus posticus and tuber cinereum, and in this way it comes to the surface in the base of the brain. The optic chiasma crosses the floor in front and marks the place where the latter becomes continuous with the anterior wall of the cavity. The *front wall* of the third ventricle is formed by the lamina cinerea, which extends upwards from the optic chiasma. The anterior commissure, as it crosses from one side to the other, projects into the ventricle, but of course it is excluded from the cavity by the ventricular epithelial lining. It may be taken as indicating the place where the roof joins the anterior wall. The *roof* of the third ventricle is formed by a thin epithelial layer, continuous with the thin epithelial lining of the cavity, which stretches across the mesial plane from one tænia thalami to the other. Applied to the upper surface of the epithelial roof is the fold of pia mater, termed the velum interpositum, and the roof is invaginated into the cavity along its whole length by two delicate choroid plexuses, which hang down from the under surface of this fold. When the velum interpositum is removed the thin epithelial roof is torn away with it, leaving only the lines of attachment in the shape of the tænia thalami.

The *lateral wall* of the third ventricle is formed for the greater part of its extent by the inner surface of the optic thalamus, covered by a thick layer of

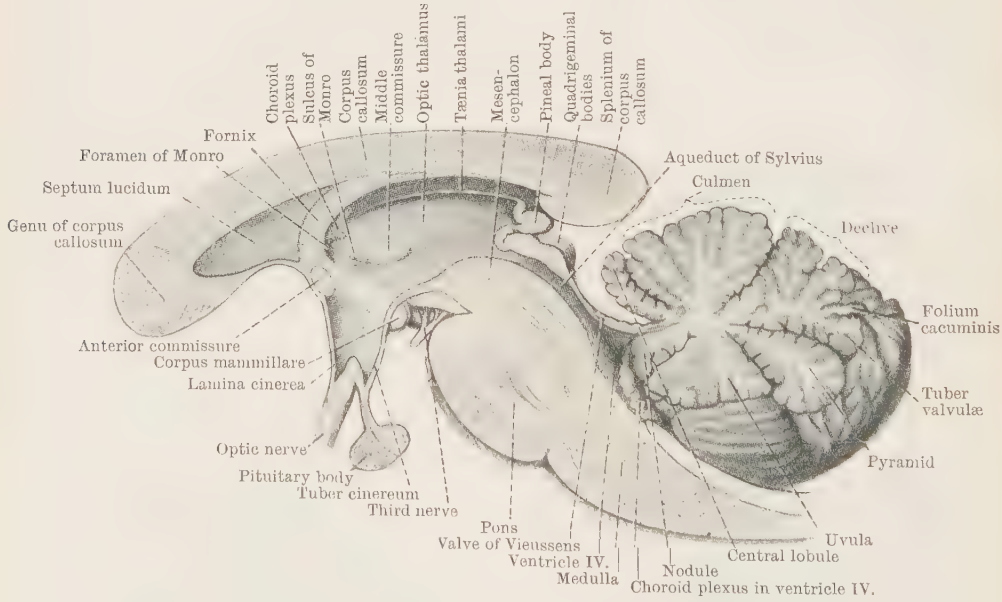

FIG. 443.—MESIAL SECTION THROUGH THE CORPUS CALLOSUM, DIENCEPHALON, ETC.
Shows the third and fourth ventricles connected by the aqueduct of Sylvius.

central gray matter continuous with the Sylvian gray matter of the mesencephalon. A little in front of the middle of the ventricle the cavity is crossed by the **middle** or **soft commissure**, which connects the thalami with each other, and in front of this the anterior pillar of the fornix is seen curving downwards and backwards in the lateral wall. At first the bulging which it forms is distinctly prominent, but it gradually subsides as the strand, on its way to end in the corpus mammillare, becomes more and more sunk in the gray matter on the side of the ventricle.

The third ventricle communicates with both of the lateral ventricles, and also with the fourth ventricle. The **aqueduct of Sylvius**, the narrow channel which tunnels the mesencephalon, brings it into communication with the fourth ventricle. The opening of this aqueduct is placed at the posterior part of the floor of the third ventricle, immediately below the posterior commissure. The **foramina of Monro**

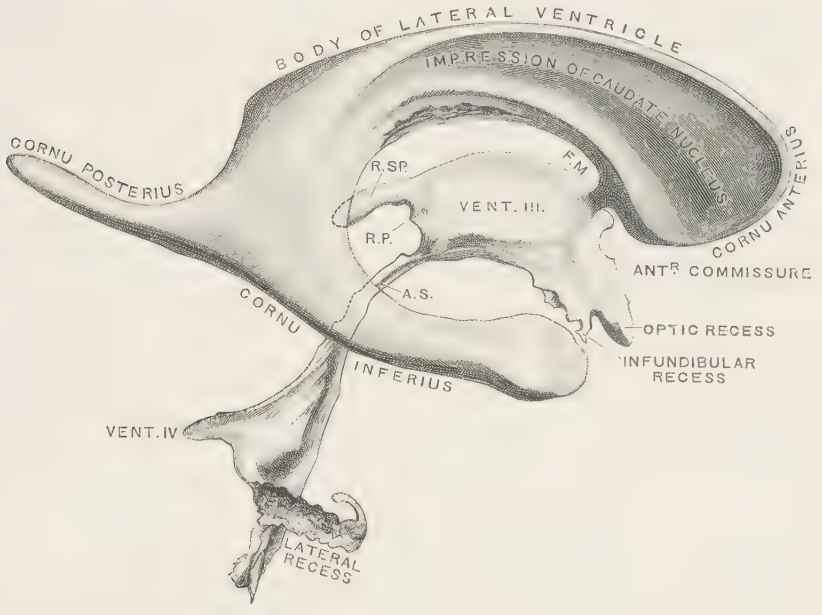

FIG. 444.—PROFILE VIEW OF A CAST OF THE VENTRICLES OF THE BRAIN (from Retzius).

bring it into communication with the lateral ventricles. These apertures are placed at the upper and fore parts of the lateral walls, and lead outwards and slightly upwards between the most prominent parts of the anterior pillars of the fornix and the anterior tubercles of the optic thalami. They are just large enough to admit a crow-quill, and through these passages the epithelial lining of the three ventricles becomes continuous. From the foramen of Monro a distinct groove on the lateral wall of the ventricle leads backwards towards the mouth of the Sylvian aqueduct. It is termed the **sulcus of Monro**, and is of interest, inasmuch as it is considered by His to represent in the adult brain the furrow which divides the lateral wall of the embryonic brain-tube into an alar and a basal lamina.

The outline of the third ventricle, when viewed from the side in a mesial section through the brain, or as it is exhibited in a plaster cast of the ventricular system of the brain, is seen to be very irregular (Fig 444). It presents several diverticula or recesses. Thus, in the fore-part of the floor there is a funnel-shaped pit or recess, leading down through the tuber cinereum into the infundibulum of the pituitary body. Another recess, the *recessus opticus*, leads forwards immediately in front of this, above the optic chiasma. Posteriorly two diverticula are present. One, the *recessus pinealis*, passes backwards above the posterior commissure and the mouth of the Sylvian aqueduct for a short distance into the stalk of the pineal body. The second is placed above this and is carried backwards for a greater distance. It is a diverticulum of the epithelial roof, and, therefore, is difficult to demonstrate. It is termed the *recessus suprapinealis*

## CEREBRAL CONNEXIONS OF THE OPTIC TRACT.

One nerve, the optic nerve or the nerve of sight, is connected with this section of the brain. At the optic chiasma the optic nerves of the two sides are joined together and a partial decussation of fibres takes place. The fibres which arise in the mesial half of each retina cross the mesial plane and join the optic tract of the

opposite side. The optic tract proceeds backwards round the crus cerebri, and in the neighbourhood of the corpora geniculata divides into two roots, viz. a lateral and a mesial (p. 532).

**Mesial Root of the Optic Tract—Commissure of Gudden.**—The mesial root of the optic tract disappears under cover of the corpus geniculatum internum and a large proportion of its fibres arise or end in this nuclear body. As to the connexions of the other fibres, we possess at present no precise information. The mesial root, although it is composed of fibres which run in the optic tract, has absolutely nothing to do with the optic nerve. These fibres, when traced forwards, cross the mesial plane in the posterior angle of the optic chiasma and are carried backwards in the opposite optic tract, to form on that side its mesial root. The fibres, therefore, are commissural, and constitute a bond of union, called the **commissure of Gudden**, between the internal geniculate bodies.

**Lateral Root of the Optic Tract.**—The lateral or true visual root of the optic tract is composed of fibres which come—(1) from the lateral half of the retina of its own side; and (2) from the mesial half of the retina of the opposite side, and which have crossed the mesial plane in the optic chiasma. But in addition to the afferent retinal fibres there are a certain number of efferent fibres in the optic tract, fibres which take their origin in the brain and end in the retina. These are distinguished from the afferent retinal fibres by their exceeding fineness.

The fibres of the lateral root of the optic tract end in the superior quadrigeminal body, in the external geniculate body, and in the pulvinar of the optic thalamus. The fibres to the **superior quadrigeminal body** reach it through the superior brachium (p. 435), and for the most part spread out on its surface in the stratum zonale before they sink into its substance, to end in terminal arborisations around its cells. The **corpus geniculatum externum** receives the largest contribution of fibres from the lateral root of the optic tract. These partly sink into its interior and partly spread out over its surface. The former enter into the construction of the curved lamellæ of white matter which traverse this nuclear mass, and to a large extent end in the gray matter which intervenes between these lamellæ. The deep fibres which are not exhausted in this way proceed onwards through the external geniculate body and enter the pulvinar. Of the superficial fibres which spread over the surface of the external geniculate body some dip into its substance and end there, but the majority are carried over it and enter the stratum zonale of the pulvinar. The fibres of the lateral root of the optic tract, which end in the **pulvinar**, therefore reach their destination by passing either over or through the external geniculate body.

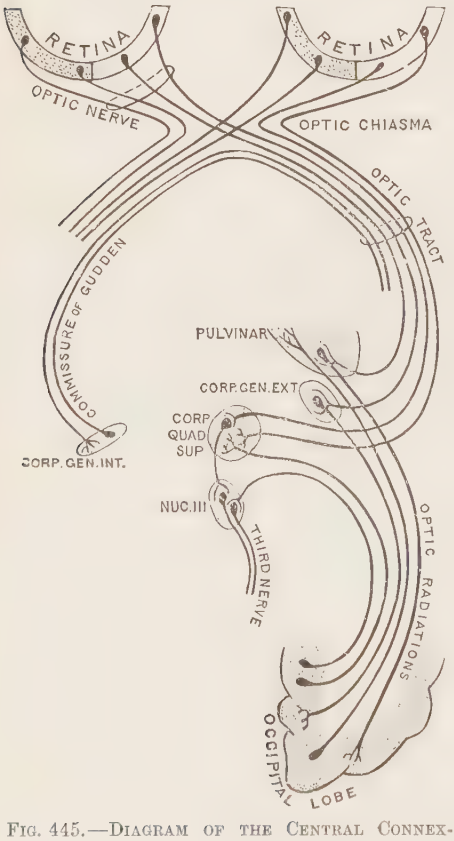

FIG. 445.—DIAGRAM OF THE CENTRAL CONNEXIONS OF THE OPTIC NERVE AND OPTIC TRACT.

**Cortical Connexions of the Optic Nerve.**—The superior quadrigeminal body, the external geniculate body, and the pulvinar constitute the lower visual centres or terminal nuclei of the visual part of the optic tract. The higher visual centre is placed in the cortex of the occipital lobe of the cerebral hemisphere, and the connexions between this and the lower centres are established by a large strand of fibres which runs in the central white matter of the hinder part of the cerebral hemisphere, and which

constitutes the **optic radiation**. The optic radiation is composed both of corticipetal and corticifugal fibres. The former arise as the axons of the cells in the external geniculate body and the pulvinar, around which the retinal fibres end, and they terminate in the cortex of the occipital lobe. The corticifugal fibres take origin in the cortex of the occipital lobe and end in the pulvinar and superior quadrigeminal body (Ferrier and Turner). Thus constituted, the optic radiation forms a conspicuous strand (Figs. 462, p. 576; 465, p. 579; 473, p. 592), which, reaching the retrolenticular part of the internal capsule, sweeps backwards into the occipital lobe of the cerebral hemisphere on the outer side of the posterior horn of the lateral ventricle. Its connexions will be studied more fully at a later stage.

Flechsig does not believe that the pulvinar is an internode interposed in the path of the optic nerve as it proceeds towards the visual area of the cerebral cortex. He states that he has not been able to convince himself that any fibres of the optic tract end in the optic thalamus.

**Other Connexions of the Lower Group of Visual Centres.**—(1) The nuclei of the nerves which supply the muscles which move the eyeball would appear to stand in intimate connexion with the lower group of visual centres. Most probably this connexion is established through the posterior longitudinal bundle. As previously stated, Held believes that axons of certain of the cells of the superior quadrigeminal body enter this tract. (2) Through the mesial fillet, the superior quadrigeminal body is connected with the medulla and cord.

## THE PARTS DERIVED FROM THE TELENCEPHALON.

### Cerebral Hemispheres.

The cerebral hemispheres form the largest part of the fully-developed brain. When viewed from above they form an ovoid mass, the broadest end of which is directed backwards, and the longest transverse diameter of which will be found in the vicinity of the parts which lie subjacent to the parietal eminences of the cranium. The massive rounded character of the anterior or frontal end of each cerebral hemisphere constitutes a leading human characteristic; but the hinder or occipital end is narrow and pointed, and is directed somewhat downwards. The two cerebral hemispheres are separated from each other by a deep mesial cleft, termed the great longitudinal fissure.

**Great Longitudinal Fissure** (fissura longitudinalis cerebri). In front and behind the great longitudinal fissure passes from the dorsal to the ventral aspect of the cerebral hemispheres, so as to separate them completely from each other. In its middle part, however, the fissure is interrupted and floored by the corpus callosum, a white commissural band, which passes between the hemispheres and connects them together. The upper surface of the corpus callosum can be displayed by gently drawing asunder the contiguous mesial surfaces of the cerebral hemispheres. The great longitudinal fissure is occupied by a mesial fold of dura mater, termed the falx cerebri, which partially subdivides the part of the cranial cavity allotted to the cerebrum into a right and left chamber.

**External Configuration of each Cerebral Hemisphere.**—Each cerebral hemisphere presents an external, an internal, and an inferior surface. The *external surface* is convex and is adapted accurately to the deep surface of the cranial vault. The *internal* or *mesial surface* is flat and perpendicular, and bounds the great longitudinal fissure. In great part it is in contact with the falx cerebri; and where that partition is deficient, it is applied to the corresponding portion of the internal surface of the opposite hemisphere. The *inferior surface* is irregular and is adapted to the anterior and middle cranial fossæ of the cranial floor and, behind these, to the upper surface of the tentorium cerebelli. Traversing this surface in a transverse direction, nearer the anterior end of the hemisphere than the posterior end, is the stem of the Sylvian fissure. This deep cleft divides the inferior surface into an anterior or *orbital area*, which rests on the orbital plate of the frontal bone, and is consequently concave from side to side, and a more extensive posterior or *tentorial area*, which lies on the floor of the lateral part of the middle cranial fossa and upon the upper surface of the tentorium cerebelli. This surface is arched from before backwards, and looks inwards as well as downwards. In its hinder two-thirds it lies above the cerebellum, from which it is separated by the tentorium cerebelli.

The borders which intervene between these surfaces are the supero-mesial, the superciliary, the infero-lateral, and the internal occipital. The *supero-mesial border*, convex from before backwards, intervenes between the convex external surface and the flat internal surface of the hemisphere. The *superciliary border* is highly arched and separates the orbital surface from the external surface. The *infero-lateral border* marks off the tentorial surface from the external surface. The *internal occipital border* can only be seen in cases where the brain has been hardened *in situ* and faithfully retains the natural form. It extends from the posterior end of the hemisphere towards the hinder extremity of the corpus callosum, and intervenes between the mesial and tentorial surfaces. It is the border which lies along the straight blood sinus, and it therefore occupies the angle which is formed by the attachment of the posterior part of the falx cerebri to the upper surface of the tentorium cerebelli.

The most projecting part of the anterior end of the cerebral hemisphere is called the **frontal pole**, whilst the most projecting part of the hinder end is termed the **occipital pole**. On the under surface of the hemisphere the prominent point of cerebral substance which extends forwards below the Sylvian fissure receives the name of the **temporal pole**. In a well-hardened brain a broad groove is usually present on the inner and lower aspect of the occipital pole of the right hemisphere. This corresponds to the commencement of the right lateral venous sinus. A less distinct groove on the occipital pole of the left hemisphere frequently indicates the commencement of the left lateral sinus. On the tentorial surface, a short distance behind the temporal pole, a well-marked depression is always visible. This corresponds to the elevation on the anterior surface of the petrous portion of the temporal bone over the superior semicircular canal.

**Cerebral Gyri and Sulci.**—The surface of the cerebral hemispheres is rendered highly irregular by the presence of convolutions or gyri, separated from each other by intervening furrows of very varying depth, termed sulci or fissures. The surface pattern which is presented by these gyri and sulci is, in its general features, the same in all normal human brains; but when the comparison is pushed into detail many differences become manifest, not only in the brains of different individuals, but also in the two cerebral hemispheres of the same individual.

There are two varieties of furrows, viz. complete and incomplete. The **complete fissures** are few in number, and are formed by inwardly-directed infoldings involving the entire thickness of the cerebral wall. They consequently show in the interior of the cerebral cavity or lateral ventricle in the form of internal elevations on its wall. The complete fissures are the following: (1) the dentate or hippocampal fissure; (2) the anterior part of the calcarine fissure; and (3) a portion of the collateral fissure. The **incomplete fissures** are merely surface furrows of varying depth, which do not produce any effect on the inner surface of the ventricular wall.

**General Structure of the Cerebral Hemispheres.**—Each cerebral hemisphere is composed of an outside coating of gray matter, spread in a continuous and uninterrupted layer over its surface, and an internal mass of white matter, which forms a considerable part of the immediate wall of the ventricular cavity. The gray coating is termed the **cerebral cortex**, and the internal white matter is called the **medullary centre**. Each convolution shows a corresponding structure. On transverse section it is seen to present an external covering of gray cortex, supported by a central core of white matter.

But, in addition to the gray matter on the outside, there are certain large deposits of gray matter embedded in the basal part of each cerebral hemisphere. These cerebral nuclei constitute the **corpus striatum**, and, although to some extent isolated from the gray matter on the surface, it can be easily shown that at certain points they are directly continuous with it.

By means of the convolutions and sulci, the gray matter on the surface of the hemisphere is enormously increased in quantity without unduly adding to the bulk of the organ; and, further, the vascular pia mater, which dips into every fissure, is increased in extent to a like degree. Opportunity is, therefore, afforded to the cortical vessels of breaking up into twigs of exceeding fineness before they enter the

substance of the hemisphere. The distribution of blood to the gray cortex is, in this way, equalised and rendered uniform.

**Cerebral Lobes and Interlobar Fissures.**—Certain of the fissures which traverse the surface of the cerebrum are more or less arbitrarily chosen for subdividing the surface into districts or areas, which are termed lobes. These fissures are termed **interlobar**, and are the following: (1) the fissure of Sylvius; (2) the fissure of Rolando; (3) the parieto-occipital; (4) the calloso-marginal; (5) the collateral; and (6) the limiting sulcus of Reil.

The lobes which are mapped out by these fissures are: (1) the frontal; (2) the parietal; (3) the occipital; (4) the temporal; (5) the insula, or the island of Reil; (6) the limbic. To these may be added a seventh lobe, in no way related to the interlobar fissures, viz. the olfactory lobe. With the exception of the occipital and olfactory lobes and the insula, this subdivision of the hemisphere possesses little morphological value, and is chiefly adopted for topographical purposes.

**Fissure of Sylvius** (fissura cerebri lateralis).—This is the most conspicuous

fissure on the surface of the cerebral hemisphere. It is composed of a short main stem, from the outer extremity of which three branches or limbs radiate. The **stem** of the Sylvian fissure is placed on the inferior surface of the hemisphere. It begins at the locus perforatus anticus in a depression termed the **vallecula Sylvii**. From this it passes horizontally outwards, forming a deep cleft between the temporal pole and the orbital surface of the frontal lobe. Appearing on the outer surface of the hemisphere at a point called the **Sylvian point**, the Sylvian fissure immediately divides into three radiating branches. These are: (1) the

ramus horizontalis posterior; (2) the ramus horizontalis anterior; (3) the ramus anterior ascendens.

The **posterior horizontal limb** is the longest and best marked of the three limbs. It extends backwards, with a slight inclination upwards on the outer surface of the hemisphere for a distance which may vary from about two to three inches. It intervenes between the frontal and parietal lobes which lie above it and the temporal lobe which lies below it, and it finally ends in the region subjacent to the parietal eminence of the cranial wall by turning upwards into the parietal lobe in the form of an *ascending terminal piece.*

The **anterior horizontal limb** extends horizontally forwards in the frontal lobe for a distance of about three-quarters of an inch immediately above and parallel to the posterior part of the superciliary margin of the hemisphere.

The **ascending limb** proceeds upwards, with a slight inclination forwards, into the lower part of the outer surface of the frontal lobe for a distance of about an inch. In many cases the two anterior limbs spring from a common stem of greater or less length, and not infrequently both are replaced by a single anterior limb.

**Limiting Sulcus of Reil** (sulcus circularis Reilii).—If the lips of the posterior horizontal limb of the Sylvian fissure be widely pulled asunder from each other, the insula or island of Reil will be seen at the bottom. The insular district of the cortex is completely hidden from view when the Sylvian fissure is closed by overlapping portions of the cerebral hemisphere, and, when brought into view in the manner indicated, it is observed to present a triangular outline and to be surrounded by a limiting sulcus, of which three parts may be recognised, viz.: an *upper part,* bounding it above and separating it from the parietal and frontal lobes; a *lower part,* marking it off below from the temporal lobe; and an *anterior part,* separating it in front from the frontal lobe.

**Opercula Insulæ.**—The overlapping portions of the cerebral substance which cover over the insula are termed the insular opercula, and they form, by the apposition of their margins, the three limbs of the Sylvian fissure. The opercula are four in number and are named: (1) temporal; (2) fronto-parietal; (3) frontal; and (4) orbital. The limbs of the Sylvian fissure cut right through between the different opercula and extend from the exposed surface of the hemisphere to the submerged surface of the insula, and, in this manner, separate the opercula from each other.

The **temporal operculum** extends upwards over the insula from the temporal lobe, and its upper margin forms the lower lip of the posterior horizontal limb of the Sylvian fissure.

The **fronto-parietal operculum** is carried downwards from the parietal and frontal regions over the insula, and its lower margin, meeting the temporal operculum, forms the upper lip of the posterior limb of the Sylvian fissure.

The **frontal operculum** is the small triangular piece of cerebral substance which intervenes between the ascending and anterior horizontal limbs of the Sylvian fissure. It covers over a small part of the anterior portion of the insula, and is sometimes termed the **pars triangularis.**

The **orbital operculum** is, for the most part, on the under surface of the hemisphere. It lies below and to the inner side of the anterior horizontal limb of the Sylvian fissure, and proceeds backwards from the orbital aspect of the frontal lobe over the fore-part of the insula.

**Development of the Sylvian Fissure and of the Insular District of the Cerebral Hemisphere.**—It is only during the latter half of the intrauterine period of development that the opercula take shape and grow over the insula, so as to shut it out from the surface. In its early condition the insula presents the form of a depressed area on the side of the cerebral hemisphere, surrounded by a distinct boundary wall formed by the surrounding more elevated surface of the hemisphere (Fig. 447, A). After a time this depressed area, which is called the Sylvian fossa, assumes a triangular outline, and then the bounding wall is observed to be composed of three distinct parts, viz.: an upper or fronto-parietal, a lower or temporal, and an anterior or orbital part (Fig. 447, B). The rounded angle, formed by the meeting of the upper and anterior portions of the boundary, now becomes flattened, and a short oblique part of the limiting wall, termed the frontal portion, assumes shape in this position. Each of these four portions of the bounding wall of the Sylvian fossa becomes a line of growth, from which an operculum takes origin, and by the approximation of these opercula, as they grow over the surface of the Sylvian fossa, the insula becomes closed in and the limbs of the Sylvian fissure are formed (Fig. 448).

The temporal and fronto-parietal opercula make their appearance somewhere about the end of the fifth month of fœtal development, long before the other two opercula show any indication of growth. The temporal operculum grows more rapidly than the fronto-parietal; so that, when the margins of these two opercula come together to form the posterior limb of the Sylvian fissure, there is a greater extent of the Sylvian fossa covered by the temporal operculum than by the fronto-parietal operculum. This accounts for the more oblique direction of the Sylvian fissure in the fœtal brain. But at this stage a growth-antagonism between the two opercula takes place, and in this the fronto-parietal operculum proves the victor. The contiguous lips of the two opercula become, in the first instance, tightly pressed together, and then, as the upper operculum proves the stronger and the more vigorous in its growth, the posterior limb of the Sylvian fissure becomes gradually depressed until it assumes the inclination characteristic of the adult. It would appear that the opercular growth-antagonism which produces this effect in the human brain does not occur to the same extent, if indeed it occurs at all, in the ape. This is evident from the oblique direction of the posterior limb of the Sylvian fissure in the simian brain. The greater growth-energy of the fronto-parietal operculum in the human brain is not confined to the fœtal stage of development, but is carried into the earlier stages of infantile growth, and it is probable that it is due to an extension of that district of the cortex in which the centres for the skilled movements of the upper limbs reside, and also to an extension of Flechsig's parieto-occipital association area.

FIG. 447.—THREE STAGES IN THE DEVELOPMENT OF THE INSULA AND THE INSULAR OPERCULA.

A, Right cerebral hemisphere from a fœtus in the latter part of the fourth month of development; B, Right cerebral hemisphere from a fœtus in the fifth month of development; C, Right cerebral hemisphere from a fœtus in the latter part of the eighth month of development.

In C the temporal operculum has been removed, and thus a large part of the insula is exposed. The outline of the temporal operculum is indicated by a dotted line.

F.P. Fronto-parietal operculum. F, Frontal operculum. O, Orbital operculum.

The orbital and frontal opercula are late in appearing and very tardy in their growth. Indeed, it is only during the course of the first year of infantile life that they come into apposition

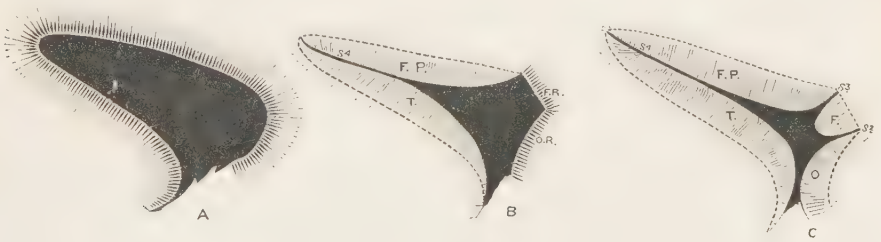

FIG. 448.—DIAGRAM TO ILLUSTRATE THE DEVELOPMENT OF THE OPERCULA WHICH COVER THE INSULA.

with each other and with the other two opercula, so as to close in the fore-part of the Sylvian fossa and form the anterior limbs of the Sylvian fissure. They do not begin to take shape until more than half of the Sylvian fossa has already been closed by the fronto-parietal and the temporal opercula. The orbital operculum appears first and is much more constant in its growth than the frontal operculum, which indeed frequently fails altogether, and, even when present, shows the greatest amount of variability in the degree to which it is developed.

Variations in the degree of development of the frontal operculum influence greatly the form presented by the two anterior limbs of the Sylvian fissure, between which it lies. When strongly developed, it separates the two Sylvian limbs from each other to such an extent that they assume the appearance of the letter U; when the frontal operculum is less strongly marked, the anterior Sylvian limbs may assume a V form or a Y form. In the latter case, the orbital and the fronto-parietal opercula meet below the frontal operculum to form the stem of the Y. In those cases

where the frontal operculum is absent altogether, a single anterior limb of the Sylvian fissure is the result.

The late appearance, the slow growth, the variability of these two opercula, and also the tendency to abortive growth or complete suppression of the frontal operculum, all bespeak the fact that, from a phylogenetic point of view, the frontal and orbital opercula are, comparatively speaking, recent productions in the evolution of the human brain. In the anthropoid ape they are absent, and, consequently, the fore-part of the island of Reil is exposed on the surface of the simian brain. The same condition is not at all an uncommon occurrence in the brain of the microcephalic idiot.

**Fissure of Rolando** (sulcus centralis). The fissure of Rolando takes an oblique course across the outer convex surface of the cerebral hemisphere, and intervening between the frontal and parietal lobes it forms the immediate posterior boundary of the motor area of the cortex. Its upper end cuts the supero-mesial border of the hemisphere a short distance behind the mid-point between the frontal and occipital poles, whilst its lower end terminates above the middle of the posterior horizontal limb of the fissure of Sylvius. Its superior extremity, as a rule, turns round the supero-mesial border of the hemisphere, and is then continued backwards for a short distance on the mesial surface. Although, in its general direction, the fissure is oblique, it is very far from being straight. It takes a sinuous course across the hemisphere. This is largely due to the area of cortex which represents the motor centre for the arm, and which lies in front of the sulcus, growing backwards in the course of its development so as to produce a bay in the fissure within which this portion of the cortex is accommodated. The bends in the fissure which indicate the upper and lower limits of the arm centre (Grünbaum and Sherrington) are termed respectively the *superior* and *inferior genua*. The angle which the general direction of the fissure of Rolando makes with the mesial plane is termed the **Rolandic angle**. In the adult brain the average Rolandic angle is 71° 7′, and the limits of variation would appear to be 69° and 74°.

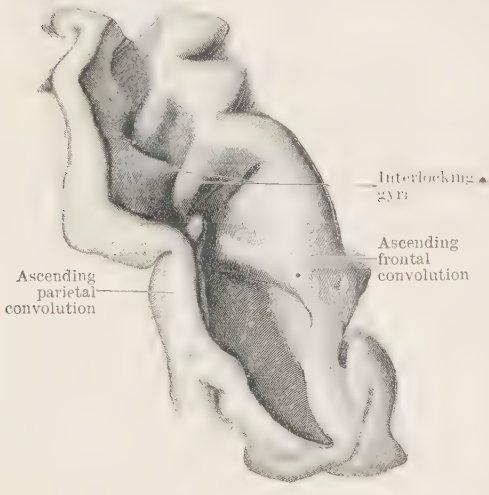

Fig. 449.—Fissure of Rolando fully opened up, so as to exhibit the interlocking gyri and deep annectant gyrus within it.

When the fissure of Rolando is widely opened up, so that its bottom and its opposed sides may be fully inspected, it will be seen that, between the two genua, the two bounding convolutions are dovetailed into each other by a number of interlocking gyri, which do not appear on the surface (Fig. 449). Further, two of these, placed on opposite sides of the fissure, are frequently joined across the bottom of the sulcus in the form of a sunken bridge of connexion, which constitutes what is termed a *deep annectant gyrus*. The continuity of the fissure is thus, to some extent, interrupted. This condition is rendered interesting when considered in connexion with the development of the sulcus. The deep interlocking gyri indicate a great exuberance of cortical growth in this situation in the early stages of the development of the fissure; and the presence of the deep annectant gyrus is explained by the fact that the fissure of Rolando generally develops in two pieces, which run into each other to form the continuous sulcus of the adult, viz. a part corresponding to the lower two-thirds, and an upper part, which represents the upper third and which appears at a slightly later date. In certain very rare cases the fissure of Rolando is found to remain double throughout life, through a failure of its two pieces to unite. In such cases the deep annectant gyrus, which is frequently seen at the bottom of the furrow, remains on the surface. Heschl, who examined 2174 cerebral hemispheres, only found this anomaly six times; Eberstaller met with it twice in 200 brains.

**Parieto-occipital Fissure.**—A small part of this fissure appears on the outer face of the cerebral hemisphere. For the most part it is situated on the internal surface. It is customary, therefore, to describe an external parieto-occipital and an internal parieto-occipital fissure. It must be clearly understood, however, that they are directly continuous with each other round the supero-mesial border of the

hemisphere. The parieto-occipital fissure intervenes between the parietal and occipital lobes.

The **external parieto-occipital fissure** cuts the supero-mesial border of the hemisphere in a transverse direction at a distance of from one and a half to two inches in front of the occipital pole. It is, as a rule, not more than about a half an inch long, and it is brought to an abrupt termination by an arching convolution, which winds round its extremity and receives the name of **arcus parieto-occipitalis.**

The **internal parieto-occipital fissure** is carried downwards on the inner surface of the hemisphere in a nearly vertical direction as a conspicuous and deep cleft. A short distance behind the hinder end of the corpus callosum its lower extremity runs into the calcarine fissure.

O. Orbital wall.

The parieto-occipital fissure is developed, as a rule, after the manner of a complete fissure. In the fœtal brain it forms a very evident infolding of the cerebral wall. In the adult brain, however, it does not form any eminence on the inner wall of the ventricle, because it does not extend downwards as far as the cavity. The wall of the ventricle during the growth of the hemisphere has thickened to such an extent that the part corresponding to the fissure has become solid.

**Collateral Fissure** (fissura collateralis).—The collateral sulcus is a strongly-marked fissure on the tentorial face of the cerebral hemisphere. It begins near the occipital pole and extends forwards towards the temporal pole. In its posterior part it is placed below, and parallel to, the calcarine fissure, whilst in front it is

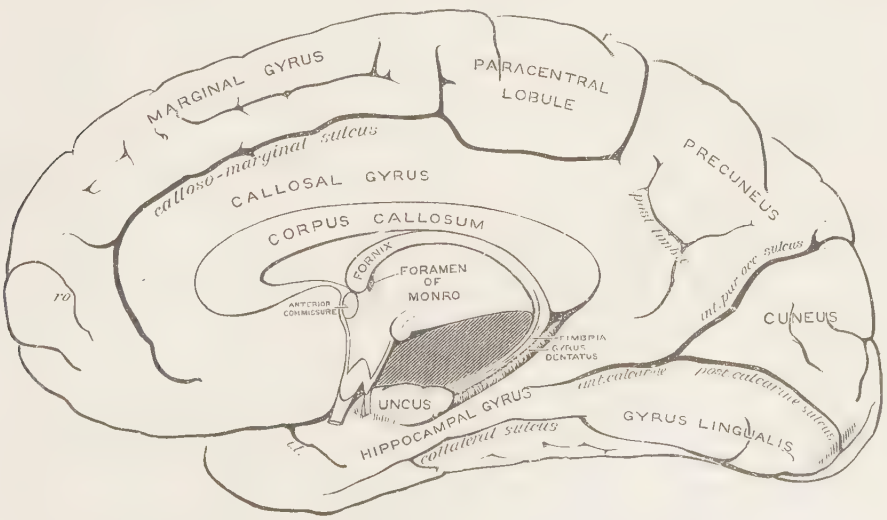

FIG. 451.—THE GYRI AND SULCI ON THE MESIAL ASPECT OF THE CEREBRAL HEMISPHERE.
*r.* Fissure of Rolando. *r.o.* Rostral sulcus. *i.t.* Incisura temporalis.

separated from the hippocampal or dentate fissure by the hippocampal gyrus, which is the innermost convolution on the tentorial surface of the hemisphere.

In front of the anterior extremity of the collateral fissure a shallow sulcus turns round the anterior end of the temporal lobe, so as to intervene between the temporal

pole and the uncinate or hook-like extremity of the hippocampal convolution. This is the **incisura temporalis**, or **ecto-rhinal fissure**. The collateral fissure and the incisura temporalis intervene between the limbic and temporal lobes.

The collateral fissure is developed, as a rule, in three portions—a hinder or occipital, an intermediate, and an anterior or temporal part. These ultimately run into each other and form the continuous fissure. The middle part is usually a complete fissure and responsible for the production of the *eminentia collateralis posterior* in the floor of the trigonum of the lateral ventricle; the temporal part is sometimes a complete fissure, forming when it is so the *eminentia collateralis anterior*; the occipital part is always incomplete.

**Calloso-marginal Fissure.**—This fissure is a strongly-marked sulcus on the fore-part of the mesial surface of the hemisphere. It divides the front portion of the mesial surface into an upper marginal and a lower callosal convolution, and intervenes between the frontal and limbic lobes. Beginning below the fore-end of the corpus callosum, close to the locus perforatus anticus, the calloso-marginal fissure curves round in front of the genu of the corpus callosum, and then extends backwards to a point a short distance behind the middle of the mesial surface. It then turns upwards and cuts the supero-mesial border of the hemisphere, immediately behind the upper end of the fissure of Rolando. The relation presented by the two extremities of these fissures is such that they can both be readily recognised either when examined on the outer or mesial aspect of the cerebrum.

The calloso-marginal sulcus is developed in two or three separate pieces, which, as growth proceeds, run into each other and form the continuous fissure. The numerous cases of irregular arrangement met with in connexion with this fissure can generally be explained by this interrupted mode of development.

Frontal Lobe.—The frontal lobe is the largest of the cerebral lobes. On the outer surface of the hemisphere, it is bounded behind by the fissure of Rolando and below by the posterior horizontal limb of the fissure of Sylvius. On the mesial face it is limited by the calloso-marginal fissure, whilst on the inferior surface of the hemisphere the stem of the Sylvian fissure forms its posterior boundary. It presents an outer surface, a mesial surface, and an inferior or orbital surface.

On the *outer surface of the frontal lobe* the following sulci and gyri may be recognised:—

- Sulci
  - Sulcus præcentralis inferior.
  - Sulcus præcentralis superior.
  - Sulcus paramedialis.
  - Sulcus frontalis superior.
  - Sulcus frontalis medius.
  - Sulcus frontalis inferior.
  - Sulcus diagonalis.
  - Sulcus fronto-marginalis.
- Gyri
  - Gyrus frontalis ascendens or gyrus centralis anterior.
  - Gyrus frontalis superior
    - pars superior.
    - pars inferior.
  - Gyrus frontalis medius
    - pars superior.
    - pars inferior.
  - Gyrus frontalis inferior
    - pars basilaris.
    - pars triangularis.
    - pars orbitalis.

The **inferior præcentral sulcus** consists of a vertical and a horizontal part, and when developed in a typical manner, it presents a figure like the letter T or F. The *vertical portion* lies in front of the lower part of the fissure of Rolando, whilst the *horizontal part* extends obliquely forwards and upwards into the middle frontal convolution.

The **superior præcentral sulcus** is a short vertical sulcus which lies at a higher level than the inferior præcentral furrow, in front of the upper part of the fissure of Rolando. It is almost invariably connected with the hinder end of the superior frontal sulcus.

The **anterior central convolution** (ascending frontal gyrus) is a long continuous gyrus, which is limited in front by the two præcentral furrows and behind by the fissure of Rolando. It extends obliquely across the hemisphere from the supero-mesial margin above to the posterior horizontal limb of the Sylvian fissure below.

The **superior frontal sulcus** extends forwards in a more or less horizontal direction from the sulcus præcentralis superior.

The **gyrus frontalis superior** is the narrow convolution between the supero-mesial

border of the hemisphere and the superior frontal sulcus. It takes a horizontal course to the frontal pole.

The **inferior frontal sulcus** occupies a lower level than the superior frontal furrow. Its hinder end is placed in the angle between the vertical and horizontal parts of the inferior præcentral sulcus, and is not infrequently confluent with one or other of these. It proceeds forwards towards the superciliary margin of the hemisphere and ends a short distance from this in a terminal bifurcation.

The **gyrus frontalis medius** is the name given to the broad convolution which lies between the superior and inferior frontal sulci.

The **gyrus frontalis inferior** is that portion of the outer surface of the frontal lobe which is placed in front of the inferior præcentral sulcus and below the inferior frontal sulcus. The inferior frontal convolution is cut into three pieces by two anterior limbs of the Sylvian fissure. These are termed the pars basilaris, the pars triangularis, and the pars orbitalis.

The **pars basilaris** is that part which lies between the vertical limb of the inferior præcentral sulcus and the ascending limb of the Sylvian fissure. It forms the anterior part of the fronto-parietal operculum, and it is traversed in an oblique direction by a shallow but constant furrow, termed the **sulcus diagonalis**. The **pars triangularis** is simply another name for the frontal operculum. It is triangular in form, and lies between the anterior ascending and the anterior horizontal limbs of the Sylvian fissure. The **pars orbitalis** is placed below the anterior horizontal limb of the Sylvian fissure.

The inferior frontal convolution possesses a special interest on account of the localisation within it, on the left side, of the speech centre. From it, also, the front part of the fronto-parietal and the whole of the frontal operculum are developed. This opercular development in connexion with the inferior frontal gyrus constitutes a leading point of difference between the brain of man and that of the ape. Even in the highest ape the inferior frontal convolution is not opercular. The frontal operculum is not present and the anterior part of the insula is exposed on the surface. Probably the excess of growth which determines the formation of the frontal operculum in man has some connexion with the development of the speech centre.

The **sulcus paramedialis** is the term applied to a series of short irregular depressions or furrows, arranged longitudinally, close to the supero-mesial border of the hemisphere. These rudimentary sulci partially subdivide the superior frontal convolution into an upper and a lower part, and they are of interest in so far that they are not as a rule developed in the higher apes, and are deeper and better marked in the higher than the lower types of human brain.

The **sulcus frontalis medius** (Eberstaller) proceeds horizontally forwards in the forepart of the middle frontal convolution, so as to subdivide it into an upper and a lower part. When the furrow reaches the superciliary margin of the hemisphere it bifurcates, and its terminal branches spread out widely and constitute a transverse furrow, called the *fronto-marginal sulcus*. The sulcus frontalis medius is only found in man and the anthropoid apes. It is not present in any of the lower apes.

Owing to the subdivision of the superior and middle frontal convolutions in the manner indicated, the typical arrangement of the convolutions in the anterior part of the outer surface of the frontal lobe is in five horizontal tiers, and not in three tiers, as formerly described.

As a rule, the sulci on the outer surface of the frontal lobe during the process of development appear in the following order: (1) sulcus præcentralis inferior; (2) sulcus frontalis inferior; (3) sulcus præcentralis superior and sulcus frontalis superior; (4) sulcus frontalis medius; (5) sulcus paramedialis. This gives some indication of the relative morphological importance of these sulci, although it should be borne in mind that the period at which sulci appear on the fœtal brain cannot in every case be taken as affording an infallible guide in our attempts to assign to them their relative morphological value.

On the *mesial aspect of the frontal lobe* there is an elongated more or less continuous convolution, called the **gyrus marginalis**. It lies between the supero-mesial margin of the hemisphere and the calloso-marginal fissure. In the fore-part of this gyrus one or two curved sulci are usually present. They are termed the **sulci rostrales**. The posterior part of the marginal convolution is more or less completely cut off from the portion which lies in front. This part is called the

**paracentral lobule**, and into it the upper end of the fissure of Rolando is prolonged as it turns over the supero-mesial border of the hemisphere.

On the *orbital aspect of the frontal lobe* there are two sulci, viz. the olfactory and the orbital.

The **olfactory sulcus** is a straight furrow which runs parallel to the mesial border of the hemisphere. It is occupied by the olfactory tract and bulb, and it cuts off a narrow strip of the orbital surface close to the mesial border, which receives the name of **gyrus rectus**.

The **orbital sulcus** is a composite furrow which assumes many different forms. As a general rule it presents a shape similar to that of the letter H, and is then composed of three parts, viz. an external limb, an internal limb, and a transverse limb. The **external limb** (sulcus orbitalis externus) curves round the orbital part of the inferior frontal convolution, so as to limit it on this aspect of the brain. The **internal limb** (sulcus orbitalis internus) is frequently broken up into two pieces. It marks off a convolution between itself and the olfactory sulcus, called the **gyrus orbitalis internus**. The **transverse limb** (sulcus orbitalis transversus) takes a curved course between the internal and external limbs. The district in front is termed the **gyrus orbitalis anterior**, and that behind the **gyrus orbitalis posterior**. The latter, in its outer part, corresponds with the orbital operculum.

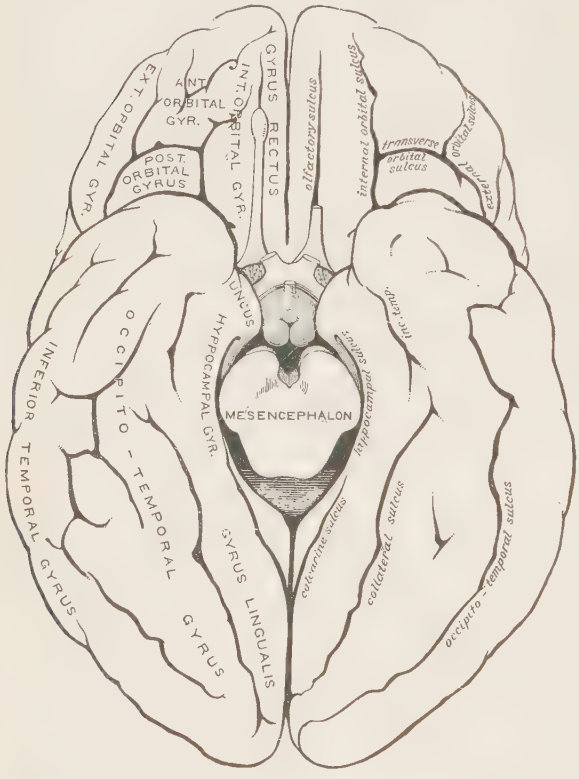

FIG. 452.—GYRI AND SULCI on the tentorial and orbital aspects of the cerebral hemispheres.

PARIETAL LOBE. — The parietal lobe forms a considerable part of the external surface of the cerebral hemisphere, and it also appears on the inner surface in the form of the præcuneus or the quadrate lobule. *In front*, it is bounded by the fissure of Rolando, which separates it from the frontal lobe. *Below*, it is limited in its fore-part by the posterior horizontal limb of the fissure of Sylvius. Behind the upturned end of this fissure the surface of the parietal lobe is continuous inferiorly with that of the temporal lobe, and an arbitrary line drawn backwards on the surface of the brain, in continuation of the horizontal part of the posterior limb of the Sylvian fissure, is taken as its inferior limit. *Posteriorly*, it is separated from the occipital lobe at the supero-mesial border of the hemisphere by the external parieto-occipital fissure. Below this fissure the surface of the parietal lobe is continuous with that of the occipital lobe; and an arbitrary line drawn across the outer surface of the hemisphere, from the extremity of the external parieto-occipital fissure to an indentation on the infero-lateral border of the hemisphere, termed the **præoccipital notch**, may be regarded as furnishing a posterior limitation.

The præoccipital notch is, as a rule, only visible in brains that have been hardened *in situ*. It is placed on the infero-lateral border of the hemisphere, about an inch and a half in front of the occipital pole, and is produced by a vertical fold or wrinkle of the dura mater on the deep aspect of the parieto-mastoid suture, and immediately above the highest part of the lateral blood-sinus.

There is great variability in the degree to which this fold of dura mater projects in different

individuals. In the child it is always very salient, and often produces a deep cleft in the brain, but as the full size of the cranium is gradually attained it becomes much less projecting. In the young skull two or three such folds in this locality are frequently apparent. Related to the præoccipital notch there are likewise some cerebral veins which turn round the infero-lateral margin of the hemisphere to join the lateral blood-sinus.

On the *mesial surface of the hemisphere* the parietal lobe is represented by the **præcuneus** or **quadrate lobule**. This district, which is somewhat quadrilateral in form, lies between the upturned end of the calloso-marginal sulcus and the internal parieto-occipital fissure. It is imperfectly separated below from the limbic lobe by a somewhat variable furrow called the **post-limbic sulcus**.

The gyri and sulci, on the *outer surface of the parietal lobe*, are the following:—

- Sulci
  - Sulcus intraparietalis (of Turner).
    - Sulcus postcentralis inferior.
    - Sulcus postcentralis superior.
    - Ramus horizontalis.
    - Ramus occipitalis.
  - Upturned ends of—
    - (*a*) Sylvian fissure.
    - (*b*) Parallel fissure.
    - (*c*) Second temporal fissure.
- Gyri
  - Gyrus ascendens parietalis or gyrus postcentralis.
  - Gyrus parietalis superior.
  - Gyrus parietalis inferior
    - Gyrus supramarginalis.
    - Gyrus angularis.
    - Gyrus postparietalis.

The **intraparietal sulcus** (of Turner) is a composite furrow, and is built up of four originally distinct factors. Two of these, termed the sulcus postcentralis inferior and the sulcus postcentralis superior, take a more or less oblique course across the hemisphere, and are most frequently united into one continuous fissure. The other two factors are placed horizontally, one behind the other, and are termed the ramus horizontalis and the ramus occipitalis.

The **sulcus postcentralis inferior** lies behind the lower part of the fissure of Rolando, whilst the **sulcus postcentralis superior** occupies a similar position in relation to the upper part of that fissure. When confluent they form a long, continuous fissure, which stretches across the hemisphere behind the fissure of Rolando and parallel to it.

The **ramus horizontalis** is continuous, as a rule, with the upper end of the sulcus postcentralis inferior, and extends backwards, with a slight inclination upwards between the superior parietal gyrus, which lies above it, and the inferior parietal gyrus, which is placed below it. With the two confluent postcentral sulci it presents a figure like the letter ⊣ placed on its side.

The **ramus occipitalis** is a curved sulcus which bounds externally the arcus parieto-occipitalis, or, in other words, the arching convolution which surrounds the external parieto-occipital fissure. The ramus occipitalis lies behind the ramus horizontalis, and is generally linked on to it; less frequently it is separate. The posterior end of the ramus occipitalis enters the occipital lobe, and, behind the arcus parieto-occipitalis, bifurcates into two widely spread-out branches. These form a short transverse fissure in the occipital lobe, termed the **sulcus occipitalis transversus**

In the human brain the intraparietal sulcus is usually developed in four separate pieces, corresponding to the four portions of the fissure which have been described as being present in the adult brain. The sulcus postcentralis inferior appears first (somewhere about the end of the sixth month), then the ramus occipitalis and the ramus horizontalis; last of all the sulcus postcentralis superior comes into view. The further development of the sulcus consists in the running together of these early pieces. This takes place in different ways, and not infrequently union fails at one or more points, and thus a great variety of combinations may be noted in different individuals; indeed, it may be said that every possible kind of combination may be met with. The most common form which the fissure assumes, however, is that in which all its factors have become confluent and one continuous furrow results. When such an intraparietal furrow is widely opened up, certain deep annectant gyri, which cross the bottom of the sulcus, come into view. These interrupt the sulcus at the points of union between its several pieces and indicate its original multiple formation.

There is reason to believe that three of the elements of the human intraparietal sulcus, viz. the sulcus postcentralis inferior, the ramus horizontalis, and the ramus occipitalis, are disrupted portions of the primitive single continuous fissure which is seen in certain of the lower apes (Cebus), whilst one, the sulcus postcentralis superior, is a superadded element.

There is a strong analogy between the postcentral sulcus, the fissure of Rolando, and the

præcentral sulcus. They form a group of radial sulci on the outer surface of the fœtal cerebrum above the Sylvian region. The fissure of Rolando makes its appearance first, then the præcentral sulcus, and, lastly, the postcentral sulcus. Each assumes shape in the first instance in two pieces, viz. an upper and lower. The two pieces of the fissure of Rolando join early, and only in very rare instances remain separate; the two pieces of the postcentral furrow usually join, but in 19 per cent of cerebral hemispheres they remain separate; the two pieces of the præcentral furrow, as a rule, remain separate and distinct.

The **sulcus transversus occipitalis**, or bifurcated extremity of the ramus occipitalis, has been

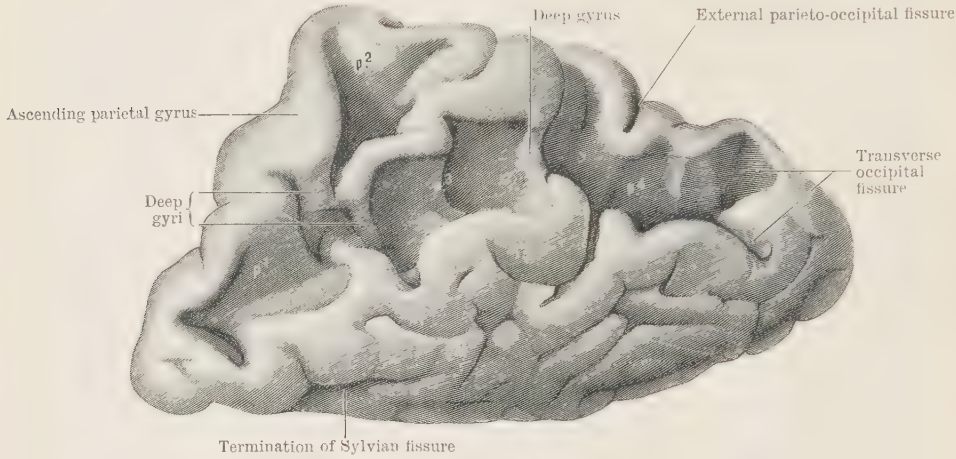

FIG. 453.—THE INTRAPARIETAL SULCUS FULLY OPENED UP, so as to show its several parts and the deep annectant gyri intervening between them.

$p^1$. Sulcus postcentralis inferior.

until lately generally believed to be the representative in the human brain of the conspicuous "Affenspalte," in the cerebrum of the ape. The accuracy of this view was challenged in 1892 (*Cunningham Memoir*, No. vii. Roy. Irish Acad.), and recently Elliot Smith has brought forward evidence of a very convincing kind which seems to show that in the human brain the "Affenspalte" is represented by the sulcus occipitalis lateralis of Eberstaller.

The intraparietal sulcus maps out three districts or gyri on the external surface of the parietal lobe, viz. the posterior central convolution, the superior parietal gyrus, and the inferior parietal gyrus.

The upturned ends of the fissure of Sylvius, of the first temporal or parallel sulcus, and of the second temporal sulcus ascend for a short distance, one behind the other, into the inferior parietal gyrus.

The **posterior central convolution** (ascending parietal convolution) is a long gyrus which extends obliquely across the hemisphere from the supero-mesial border above to the Sylvian fissure below. It is bounded in front by the fissure of Rolando and behind by the superior and inferior postcentral sulci.

The **superior parietal gyrus** is the area of cerebral cortex which lies between the supero-mesial border of the hemisphere above and the ramus horizontalis below. In front it is bounded by the superior postcentral sulcus, whilst behind it is connected with the occipital lobe by the arcus parieto-occipitalis. It is continuous round the supero-mesial border with the præcuneus.

The **inferior parietal gyrus** lies below the ramus horizontalis and the ramus occipitalis and behind the inferior præcentral sulcus. It is more or less directly continuous with the occipital lobe behind and the temporal lobe below. From before backwards it presents three arching convolutions, viz. the supra-marginal, the angular, and the postparietal. The **supramarginal convolution** is bent round the upturned end of the posterior limb of the Sylvian fissure, and stands in continuity behind and below this, with the first temporal gyrus. The **angular convolution** arches over the upturned end of the parallel sulcus and becomes continuous with the second temporal convolution. The **postparietal convolution** winds round the upturned end of the second temporal sulcus and runs into the third temporal gyrus.

OCCIPITAL LOBE.—The occipital lobe forms the hinder pyramidal part of the

cerebral hemisphere; and although very imperfectly mapped off from the temporal and parietal lobes, which lie in front of it, it is nevertheless one of the most natural subdivisions of the cerebral hemisphere. It is not developed in the brain of the quadruped. Man and the ape alone possess a well-marked occipital lobe, and it may be defined as being that part of the hemisphere which encloses the posterior horn of the lateral ventricle. Being pyramidal in form, it presents three surfaces and an apex or occipital pole. On the mesial aspect of the hemisphere it is separated from the parietal lobe (*i.e.* the præcuneus) by the internal parieto-occipital fissure. On the tentorial or inferior surface it is not marked off in any way from the temporal lobe and the limbic lobe, which lie in front of it. It is necessary, therefore, on this aspect to employ an arbitrary line of demarcation; one which extends from the præoccipital notch on the infero-lateral border of the hemisphere to the isthmus of the limbic lobe (*i.e.* the narrow part of the limbic lobe immediately below the hinder end of the corpus callosum) will serve the purpose. On the external surface the external parieto-occipital fissure, and an arbitrary line from this to the præoccipital notch, may be regarded as separating the occipital from the parietal and temporal lobes. The upturned end of the second temporal sulcus may lie in the course of this line.

On the *mesial aspect of the occipital lobe* we find: (1) the calcarine fissure, (2) the cuneus, and (3) the gyrus lingualis.

The **calcarine fissure** begins on the occipital pole by a bifurcated extremity, which lies in the groove which is formed on this part of the brain by the lateral sinus. From this it pursues a slightly arched course forwards, and ends by cutting into the limbic lobe immediately below the splenium or thickened hinder margin of the corpus callosum. The calcarine fissure is joined by the internal parieto-occipital fissure at a point somewhat nearer its anterior than its posterior extremity. Together, the two fissures present a ≺-shaped figure. Between the two limbs of the Y is placed the cuneus.

If the calcarine and internal parieto-occipital fissures are opened up so as to expose the bottom in each case, three well-marked deep or submerged annectant gyri will usually be displayed. One of these, the best marked, called the **gyrus cunei**, marks off the parieto-occipital from

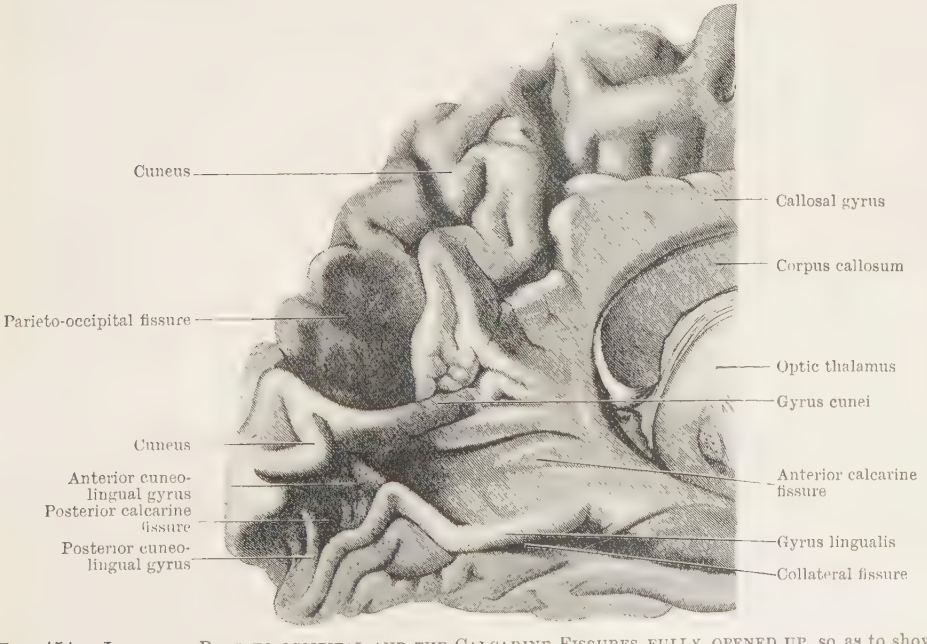

FIG. 454.—INTERNAL PARIETO-OCCIPITAL AND THE CALCARINE FISSURES FULLY OPENED UP, so as to show the deep annectant gyri marking off the several elements of the ≺-shaped system.

the calcarine fissure and joins the cuneus with the limbic lobe. In the chimpanzee and in the lower apes the gyrus cunei is on the surface, and there is no communication between the two fissures; in the orang, gibbon, and microcephalic idiot, it may either be submerged or on the

surface. The second deep annectant gyrus, termed the **anterior cuneo-lingual**, crosses the bottom of the calcarine fissure a short distance behind the point where it is joined by the parieto-occipital fissure, and divides it into an anterior and a posterior part. The **anterior calcarine fissure** is slightly longer and much deeper than the posterior part. It includes the whole of the stem of the Y-shaped fissural arrangement and extends backwards for a short distance into the cuneus. It is the complete part of the fissure and gives rise to an elevation on the inner wall of the posterior horn of the lateral ventricle, to which the name of calcar avis or hippocampus minor is given. The **posterior calcarine fissure** is shallower and is usually interrupted by the third deep annectant gyrus, viz. the **posterior cuneo-lingual**; this divides it into two parts, of which the

c.m. Mid-collateral fissure.

hinder is little more than the bifurcated extremity of the fissure. Very frequently this deep gyrus reaches the surface, and then the hinder end of the sulcus is completely cut off. The posterior calcarine fissure is not a complete fissure.

When the manner in which the calcarine fissure is developed is studied, the various appearances which come into view when the bottom of the adult fissure is inspected receive the fullest explanation. The anterior calcarine fissure is formed very early as an infolding of the wall of the cerebral hemisphere. The posterior calcarine fissure is a secondary formation. It appears much later, and usually in two pieces, which run together and then join the anterior calcarine fissure. The points of union are indicated in the adult by the two cuneo-lingual deep gyri.

The **cuneus** is the wedge-shaped or triangular district, on the mesial aspect of the occipital lobe, which lies between the internal parieto-occipital and calcarine fissures.

The **gyrus lingualis** is a well-marked convolution between the calcarine fissure above and the posterior part of the collateral fissure below, which stretches forwards from the occipital pole. Anteriorly, it becomes very narrow and joins the hippocampal part of the limbic lobe. It lies partly on the mesial surface and partly on the tentorial surface of the occipital lobe.

On the *tentorial surface of the occipital lobe* there is only one convolution, viz. the posterior part of the **occipito-temporal gyrus**. It proceeds continuously forwards into the temporal lobe on the outer side of the collateral fissure, and is bounded externally by the **occipito-temporal sulcus**, a furrow which is rarely continuous, but is usually represented by a series of detached pieces.

There are two well-marked sulci on the *external surface of the occipital lobe*, viz. the sulcus occipitalis transversus and the sulcus occipitalis lateralis. The **sulcus occipitalis transversus** extends transversely across the upper part of the lobe, behind the arcus parieto-occipitalis. As already explained, it is the terminal bifurcation of the ramus occipitalis of the intraparietal sulcus. The **sulcus occipitalis lateralis** is a short horizontal, often sharply-curved, furrow, which divides the outer surface of the lobe into an upper and a lower area of very nearly equal extent. These areas are connected by superficial annectant gyri with the parietal and temporal lobes.

Elliot Smith has brought forward very convincing proof in favour of regarding the sulcus occipitalis lateralis as the representative of the "Affenspalte" in the brain of the

ape. He calls it the **sulcus lunatus occipitalis**, and shows that in the brains of Egyptian Fellaheen it not infrequently possesses an operculum, and presents an appearance which closely corresponds with the condition distinctive of the gorilla. The same may occasionally be seen in the brain of the aboriginal Australian.

Temporal Lobe.—The temporal lobe lies behind the stem and below the posterior horizontal limb of the Sylvian fissure. It is somewhat pyramidal in form, and presents an upper, an outer, and a tentorial surface, with a free projecting apex or pole. Above, it is bounded by the posterior horizontal limb of the fissure of Sylvius, together with the artificial line which is drawn backwards from this. On the tentorial face it is separated from the hippocampal part of the limbic lobe by the collateral fissure, whilst behind it is marked off from the occipital lobe by the artificial lines already described. The temporal pole projects forwards on the under surface of the brain beyond the stem of the Sylvian fissure. It should be noticed that the recurved end of the hippocampal part of the limbic lobe (uncus), which lies to the inner side of the temporal pole, does not extend so far forwards as the latter, and is separated from the pole by the incisura temporalis or ecto-rhinal fissure.

The *upper or opercular surface of the temporal lobe* is turned towards the island of Reil and the fronto-parietal operculum. The fissure of Sylvius must, therefore, be widely opened up to expose it. For the most part the surface is smooth, but towards the back part there are a few transverse furrows, which separate two or three weakly-expressed gyri.

The anterior transverse gyrus is much more strongly expressed in the fœtal than in the adult brain. It appears in the early part of the seventh month, and is only subsequently completely hidden within the Sylvian fissure. The fact of the auditory centre being localised in this region of the temporal lobe makes this fact of interest.

On the deep surface of the temporal pole there are also a few feeble furrows.

On the *outer surface of the temporal lobe* there are two horizontal sulci, called respectively the first temporal or parallel and the second temporal sulcus.

The **parallel sulcus** is a long, continuous, and deep fissure, which begins near the temporal pole and proceeds backwards below the posterior limb of the Sylvian fissure. Its hinder end turns upwards into the parietal lobe and is surrounded by the angular gyrus. The **second temporal sulcus** is placed midway between the parallel sulcus and the infero-lateral border of the hemisphere. It is very rare to find it in the form of a continuous cleft; usually it is broken up into several isolated pieces, one behind the other. Its hinder part, which turns upwards into the parietal lobe, lies close to the artificial line of demarcation between the occipital and parietal lobes, and is surrounded by the postparietal gyrus.

By the two temporal sulci the outer surface of the temporal lobe is mapped out into three tiers of horizontal convolutions, which are termed the **first**, **second**, and **third temporal gyri**.

On the *tentorial surface of the temporal lobe* there is one fissure, termed the occipito-temporal sulcus. The **occipito-temporal sulcus** lies to the outer side of the collateral fissure and close to the infero-lateral margin of the hemisphere. It runs in an antero-posterior direction, and is not confined to the temporal lobe, but extends backwards towards the occipital pole. It is usually broken up into two or more separate pieces.

The **occipito-temporal convolution** is situated between the collateral fissure and the occipito-temporal sulcus. It extends from the occipital pole behind to the temporal pole in front.

The narrow strip of surface on the outer side of the occipito-temporal sulcus is continuous, round the infero-lateral margin of the hemisphere, with the third temporal convolution on the outer surface of the cerebrum, and may be reckoned as a part of it.

The three temporal convolutions and the occipito-temporal convolutions run into each other at the temporal pole.

Island of Reil or Insula.—The insula is a triangular and somewhat bulging field of cerebral cortex, which lies on a deeper plane than the general surface of the hemisphere and is hidden from view by the four opercula which overlap it. It is circumscribed by a limiting sulcus (sulcus circularis), already described, and its

dependent apical part, which is directed downwards, is in close relation to the anterior perforated spot and the Sylvian vallecula. Here the limiting sulcus is absent and the gray matter on the surface of the insula passes continuously into the anterior perforated spot. The place of transition is called the **limen insulæ**.

The insula is divided into several diverging convolutions by a series of radiating sulci. Of the latter, one, which presents the same direction and lies in the same plane as the fissure of Rolando, receives the name of the **sulcus centralis insulæ** (Fig. 447, C, p. 557). It divides the insula into an anterior *frontal part* and a posterior *parieto-limbic part.*

Limbic Lobe.—This lobe is seen on the mesial surface of the hemisphere in the form of an elongated ring-like convolution, the extremities of which approach closely to each other at the locus perforatus anticus. These extremities are connected by the roots of the olfactory tract, and in this manner the limbic ring may be considered to be closed. The upper part of the limbic lobe is placed in intimate relation to the extremities and upper surface of the corpus callosum, and receives the name of callosal convolution or gyrus fornicatus. The lower portion of the lobe is termed the hippocampal convolution and forms the inner part of the tentorial surface of the hemisphere. The continuity between the hippocampal gyrus and the callosal convolution is established below the hinder end of the corpus callosum by a narrow portion of the limbic lobe, called the isthmus. From this point the hippocampal convolution extends forwards towards the temporal pole. Finally, on the side of the crus cerebri, the hippocampal gyrus is folded back on itself and ends in a recurved hook-like extremity called the uncus. The uncus does not reach so far forwards as the temporal pole.

The **callosal convolution** begins below the anterior end of the corpus callosum at the locus perforatus anticus, and, winding round the genu of the corpus callosum, it is continued backwards on its upper surface to its hinder thickened extremity or splenium. Curving round this, it becomes greatly narrowed through the calcarine fissure cutting into it. This narrow part is termed the **isthmus**, and constitutes the link of connexion between the callosal gyrus and the hippocampal gyrus. The callosal gyrus is separated from the marginal convolution by the calloso-marginal fissure, and behind this it is imperfectly marked off from the præcuneus by the post-limbic sulcus. The furrow which separates it from the corpus callosum is termed the **callosal sulcus.**

The **hippocampal convolution** is bounded on the outer side by the anterior part of the collateral fissure, and in front of this by the incisura temporalis, which separates its hooked extremity, or **uncus**, from the temporal pole. On the inner side it is limited by the hippocampal or dentate fissure, whilst posteriorly it is divided into two parts by the anterior extremity of the calcarine fissure. Of these, the upper is the isthmus, which connects it with the callosal gyrus, whilst the lower portion brings it into continuity with the gyrus lingualis. The surface of the hippocampal convolution is covered by a white reticular stratum of fibres, termed the *substantia reticularis alba.*

Although the hippocampal convolution and uncus in descriptive anatomy are classed together there is a marked morphological distinction between them. The uncus is the feeble representative in man of the important pyriform lobe in certain of the lower mammals, and consequently it belongs to the *rhinencephalon*; the hippocampal convolution, on the other hand, is to be regarded as forming a part of the *neo-pallium* of Elliot Smith. The unimportant incisura temporalis of the human brain in lower types of brain in which the rhinencephalon bulks largely is represented by the conspicuous *ecto-rhinal fissure.*

**Gyrus Dentatus and the Fimbria.**—If the dentate fissure, which lies along the inner side of the hippocampal convolution, be opened up, the gyrus dentatus and the fimbria, lying side by side, will be brought into view (Fig. 451, p. 559).

The **fimbria** is simply a portion of the posterior pillar of the fornix prolonged into this region. It is a conspicuous band of white matter, which presents a prominent free border. In front it runs into the recurved extremity of the uncus, whilst, if traced backwards, it will be seen to curve upwards behind the posterior end of the optic thalamus and become continuous with the posterior pillar of the fornix below the hinder part of the corpus callosum.

The **gyrus dentatus** is the free edge of gray matter which is placed between the fimbria and the deep part of the upper surface of the hippocampal convolution. The groove between it and the fimbria is termed the **fimbrio-dentate sulcus**, whilst the furrow between it and the hippocampal convolution forms the bottom of the **dentate fissure**. The dentate gyrus is notched along the margin, whilst its surface is scored by numerous parallel and closely-placed transverse grooves. It begins behind in the region of the splenium or thickened posterior margin of the corpus

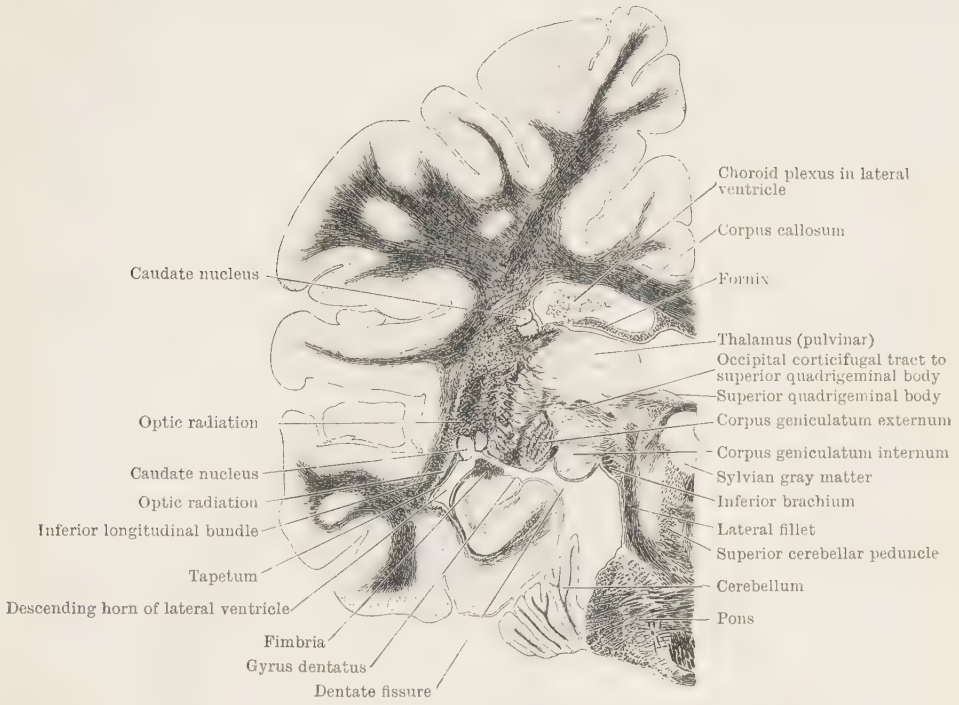

FIG. 456.—CORONAL SECTION THROUGH THE LEFT SIDE OF THE CEREBRUM, MESENCEPHALON, AND PONS, IN THE REGION OF THE PULVINAR OF THE THALAMUS AND THE CORPORA GENICULATA (Chimpanzee; Weigert-Pal specimen).

callosum, and is carried forwards into the cleft of the uncus. From this it emerges in the form of a delicate band, which crosses the surface of the recurved part of the uncus in a transverse direction, thereby constituting the *frenulum Giacomini*.

The **dentate fissure** is a complete fissure, and the elevation on the ventricular wall which corresponds to it is called the hippocampus major. It begins behind the splenium of the corpus callosum, where it is continuous with a shallow part of the callosal fissure, and it proceeds forwards between the gyrus dentatus and the hippocampal convolution. Its anterior end is enclosed within the uncus.

When coronal sections are made through the callosal part of the limbic lobe and the subjacent corpus callosum, the cortical gray matter is seen to be reflected from the bottom of the callosal fissure in the form of an exceedingly fine layer, which forms a thin coating for the upper surface of the corpus callosum. In the midst of this certain delicate strands of longitudinal fibres, the **striæ longitudinales**, are embedded, and, with the gray matter associated with them, they represent an aborted or vestigial convolution, termed the **gyrus supracallosus**. This gyrus is continuous with the gyrus dentatus round the hinder margin of the corpus callosum.

OLFACTORY LOBE.—The olfactory lobe is small and rudimentary in the human brain, and the description which is given here does not include all the parts which, from the morphological point of view, belong to this portion of the cerebral hemisphere (see p. 584). Under this heading we shall study merely: (1) the olfactory bulb and tract, with the two roots of the latter; (2) the trigonum olfactorium.

The **olfactory tract** is a narrow, white, prismatic band, which expands anteriorly into a swollen bulbous extremity, termed the **olfactory bulb.** Both the tract and the bulb lie upon the olfactory sulcus on the orbital surface of the frontal lobe,

whilst the inferior surface of the bulb rests on the cribriform plate of the ethmoid bone, and receives the numerous olfactory nerves which reach it through the foramina in that part of the cranial floor.

Posteriorly, the olfactory tract divides into two diverging roots. The **mesial root** curves abruptly inwards and is continued into the callosal and sub-callosal gyri. The **lateral root** runs outwards and backwards over the outer part of the locus perforatus anticus, and gradually disappears from view. In animals, in which the olfactory apparatus is better developed than in man, it may be traced into what corresponds to the uncinate extremity of the hippocampal convolution in man (Fig. 380, p. 474).

The **trigonum olfactorium** or olfactory tubercle is the small triangular field of gray matter which occupies the interval between the roots of the olfactory tract at the point where they begin to diverge. Some fibres from the posterior end of the olfactory tract enter the trigonum, and, in certain cases, these constitute a more or less distinct **middle root**.

### Corpus Callosum, Septum Lucidum, and Fornix.

**Corpus Callosum.**—The corpus callosum is the great transverse commissure which passes between the two cerebral hemispheres. It is placed nearer the anterior

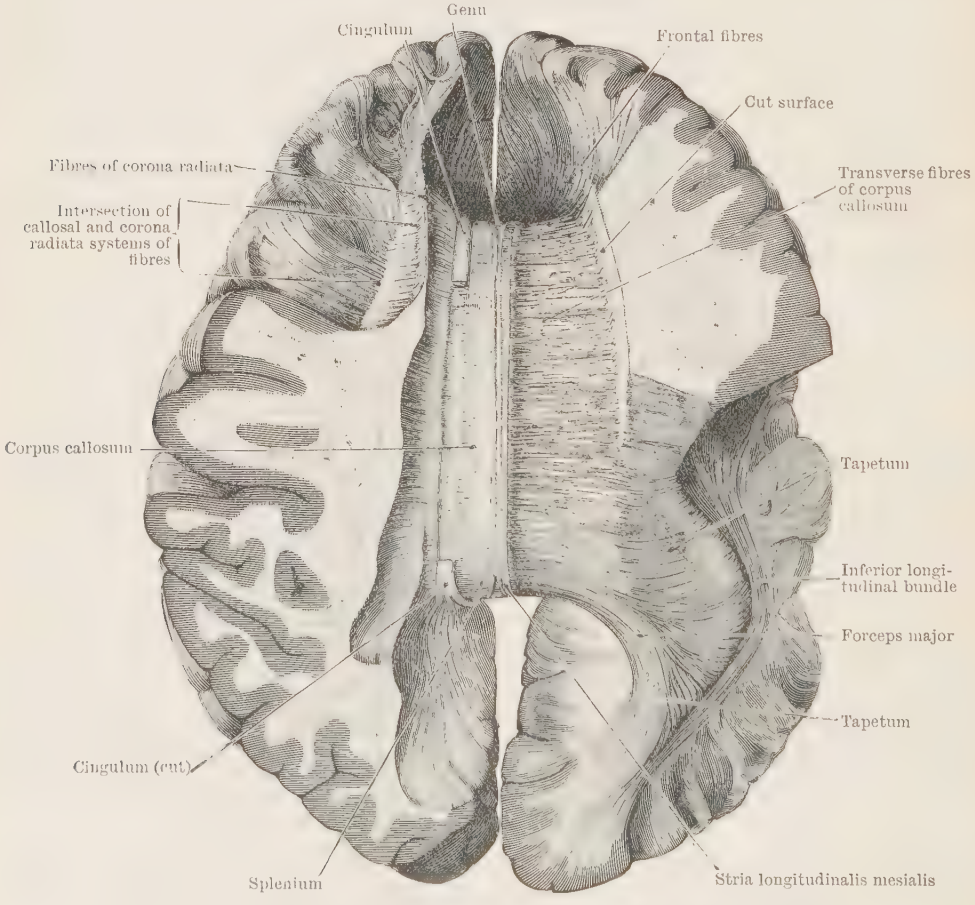

Fig. 457.—The Corpus Callosum, exposed from above and the right half dissected, to show the course taken by its fibres.

than the posterior aspect of the brain, and it unites the inner surfaces of the hemispheres throughout very nearly a half of their antero-posterior length. The corpus callosum is highly arched from before backwards, and presents a convex upper surface and a concave lower surface.

The *upper surface* of the corpus callosum forms the bottom of the great longitudinal fissure, and on each side of this it is covered by the callosal gyrus. Only in its posterior part is it touched by the falx cerebri; in front, this process of dura mater falls considerably short of it. The upper surface of the callosum is covered by a thin layer of gray matter continuous at the bottom of the callosal sulcus with the gray cortex on the surface of the hemisphere. In this there are embedded on either side of the mesial plane two delicate longitudinal bands of fibres, called respectively the stria longitudinalis medialis and lateralis. The **stria longitudinalis medialis** is the more strongly marked of the two, and it is separated from its neighbour of the opposite side by a faint mesial furrow. The **stria longitudinalis lateralis** is placed farther out, under cover of the callosal gyrus. The thin coating of gray matter, with the two striæ, represents an aborted convolution, termed the **gyrus supracallosus.** So thin is the gray coating supplied by this gyrus that the transverse direction pursued by the callosal fibres proper can be easily perceived through it.

The two extremities of the corpus callosum are much thickened, whilst the intermediate part or **body** is considerably thinner. The massive *posterior end*, which is full and rounded, lies over the mesencephalon and extends backwards as far as the highest point of the cerebellum. It is called the **splenium,** and it consists of an upper and a lower part. The latter is bent forwards under the upper part, to the inferior surface of which it is closely applied. The *anterior end* of the corpus callosum is not quite so massive and is folded downwards and backwards on itself. It is termed the **genu.** The recurved lower part of the genu is separated from the part of the corpus callosum, which lies above, by an interval. It rapidly thins as it passes backwards and receives the name of the **rostrum.** The fine terminal edge of the rostrum becomes connected with the lamina cinerea.

The gyrus supracallosus, with its contained medial and lateral longitudinal striæ, when traced backwards, is seen to turn round the splenium and become continuous with the gyrus dentatus. In front the mesial striæ, with the associated gray matter, are carried round the genu and then backwards on the under surface of the rostrum. As they turn round the anterior extremity of the corpus callosum, each stria runs into the corresponding **gyrus subcallosus**—a narrow cortical strip which lies on the mesial surface of the hemisphere immediately below the genu of the corpus callosum. The gyrus subcallosus is often called the peduncle of the corpus callosum, and the fibres of the stria which it contains, emerging from its substance, proceed backwards and outwards along the posterior limit of the anterior perforated spot towards the anterior extremity of the temporal lobe. Elliot Smith has shown that these parts have an important morphological significance.

The *under surface* of the corpus callosum on either side of the mesial plane is for the most part free, and, lined by ependyma, it forms the roof of the anterior horn and body of the lateral ventricle. In the mesial plane, however, it is attached to subjacent parts, viz. to the septum lucidum in front and to the body of the fornix behind.

The transverse fibres of the corpus callosum, as they enter the white medullary centre of the cerebral hemisphere, radiate from each other so as to reach every part of the cerebral cortex. This radiation is termed the **radiatio corporis callosi** and the fibres which compose it intersect the fibres which form the corona radiata, or, in other words, the fibres which extend between the internal capsule and the cerebral cortex (Figs. 440, p. 547; and 468, p. 582). The more anterior of the fibres which compose the genu of the corpus callosum sweep forwards in a series of curves into the prefrontal region of the hemisphere. A large part of the splenium, forming a solid bundle termed the **forceps major**, bends suddenly and abruptly backwards into the occipital lobe (Fig. 463, p. 577). Fibres from the body and upper part of the splenium, curving round the lateral ventricle, form a very definite stratum, called the **tapetum.** This is a thin layer in the medullary centre of the hemisphere, which constitutes the immediate roof and outer wall of the posterior horn and the outer wall of the hinder part of the descending horn of the lateral ventricle. In coronal sections through the occipital and hinder temporal regions the tapetum stands out very distinctly (Figs. 456, p. 569; 462, p. 576; and 465, p. 579).

**Fornix.**—The fornix is an arched bilateral structure composed, for the most part, of longitudinally-directed fibres. In its intermediate part its two lateral

halves are joined together in the mesial plane, and form what is called the body of the fornix; but in front and behind they are quite separate, and constitute the anterior and posterior pillars of the fornix.

The **body of the fornix** is triangular in form. In front, where it is continuous with the anterior pillars, it is narrow; whilst behind it broadens out, becomes flattened, and is finally prolonged into the posterior pillars. The upper surface of the body of the fornix is in contact with the under surface of the hinder part of the body of the corpus callosum, and posteriorly is adherent to it. In front of this adhesion, and in the mesial plane, it is attached to the septum lucidum. Beyond these attachments, on each side, the upper surface of the body of the fornix forms a part of the floor of the lateral ventricle and is clothed by the lining ependyma. It presents a sharp lateral edge or margin, from under which the choroid plexus projects into the cavity of the lateral ventricle and with which the epithelial layer which covers that plexus is continuous. The lower surface of the body of the fornix rests upon the velum interpositum, which separates it from the roof of the third ventricle and the upper surface of the optic thalami. It is not at all an uncommon occurrence to find the two lateral portions of the body of the fornix of unequal size (Fig. 461, p. 575).

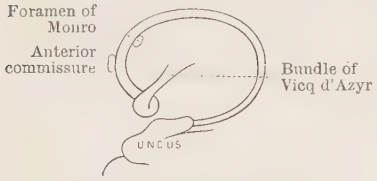

FIG. 458.—DIAGRAMMATIC PROFILE VIEW OF THE FORNIX.

The **anterior pillars of the fornix** (columnæ fornicis) are two rounded strands which emerge from the anterior part of the body of the fornix, and then diverge very slightly from each other as they curve downwards in front of the foramina of Monro. Sinking into the gray matter on the lateral wall of the third ventricle, each anterior pillar proceeds downwards to the base of the brain, and in the interpeduncular space protrudes, to take part in the formation of the corpus mammillare. When the corpus mammillare is dissected it appears to be largely formed of a twisted loop of the anterior pillar of the fornix, in which the pillar bends upon itself, and is then continued upwards and backwards into the optic thalamus. This appearance, however, is misleading. The fibres of the anterior pillar end in the gray nucleus of the corpus mammillare, and the strand which passes from this to the thalamus is the **bundle of Vicq d'Azyr** (p. 548).

The **posterior pillars of the fornix** (crura fornicis) are flattened bands which diverge widely from each other. At first they are adherent to the under surface of the corpus callosum, but soon they sweep downwards round the posterior ends of the optic thalami and enter the descending horns of the lateral ventricles. Here each pillar comes into relation with the corresponding hippocampus major, and a portion of its fibres are spread out on the surface of this prominence, thereby giving it a white coating termed the **alveus**, whilst the remainder of the fibres constitute the **fimbria** or **tænia fornicis**—a narrow but very distinct band of white matter, which is attached by its outer margin along the inner border of the hippocampus major and ends in front by joining the uncus (p. 568).

A certain number of transverse fibres enter into the formation of the fornix. The diverging posterior pillars enclose between them a small triangular space on the under surface of the hinder part of the corpus callosum. This area is crossed by transverse fibres, which form a thin lamina called the **psalterium** or **lyra**. Sometimes the psalterium is not completely fused to the under surface of the corpus callosum, and in these cases a narrow space is left between them, which receives the name of **Verga's ventricle.**

The fornix is intimately connected with the olfactory apparatus. Its fibres for the most part, arise from the pyramidal cells in the cornu ammonis or hippocampus major and ascend in the fimbria and posterior pillar. In the region of the psalterium numerous fibres cross the mesial plane, enter the opposite posterior pillar, and in it proceed to the opposite cornu ammonis. These fibres constitute a commissure between the two cornua ammonis. The remainder of the fibres proceed forwards in the body of the fornix, and by means of the anterior pillar the majority of the fibres are carried downwards, behind the anterior commissure, to the corpus mammillare. Some, however, curve backwards into the stria medullaris (p. 548); whilst others, forming the **olfactory bundle of the cornu ammonis**, pass in front of the anterior commissure and

enter the septum lucidum, through which they reach the subcallosal gyrus and the locus perforatus anticus. Finally, this bundle divides into two parts, of which one joins the inner root of the olfactory tract, whilst the other goes to the uncus.

The greater number of the longitudinal fibres of the fornix must, therefore, be regarded as establishing a connexion between the cornu ammonis and the optic thalamus. The inner portion of the composite nucleus of the corpus mammillare is an internode interposed in the path of this connecting tract. The bundle of Vicq d'Azyr, formed by the relay of fibres which takes origin in this internode, forms the second link in the chain.

The striæ longitudinales in the gyrus supracallosus on the upper surface of the corpus callosum are to be regarded, from a morphological point of view, as forming an outlying part of the fornix system.

There can be little doubt that the gyrus supracallosus represents a wasted portion of the hippocampus formation. In monotremes and marsupials the hippocampus occupies a corresponding position, but, with the greater development of the corpus callosum in higher mammals, atrophy and stretching occur and the structure is reduced to a vestigial condition (Elliot Smith). That fornix fibres therefore should be found in connexion with the supracallosal gyrus is not surprising.

**Septum Lucidum** (septum pellucidum).—The septum lucidum is a thin vertical partition which intervenes between the anterior cornua and foreparts of the bodies of the two lateral ventricles. It is triangular in shape, and posteriorly it is prolonged backwards for a variable distance between the body of the corpus callosum and the fornix, to both of which it is attached by its upper and lower edges. In front it occupies the gap behind the genu of the corpus callosum, whilst below, in the narrow interval between the posterior edge of the rostrum of the corpus callosum and the fornix, it is prolonged downwards towards the base of the brain in the gyrus subcallosus. The septum lucidum is composed of two thin laminæ in apposition with each other in the mesial plane (Fig. 461, p. 575).

**Fifth Ventricle** (cavum septi pellucidi).—This name is applied to the mesial cleft between the two laminæ of the septum lucidum. It varies greatly in size in different brains and contains a little fluid. It is completely isolated and presents no communication with the other ventricles of the brain. Indeed, the term "ventricle," as applied to it, is quite inappropriate, seeing that at no period in the development of the brain has it any connexion with the general ventricular system.

## Lateral Ventricle.

The cavity in the interior of the cerebral hemisphere is called the lateral ventricle. It is lined throughout by ependyma continuous with the ependymal lining of the third ventricle. In many places the walls of the cavity are in apposition, whilst in other localities spaces of varying capacity, and containing cerebrospinal fluid, are left between the bounding walls.

The **lateral ventricle** (ventriculus lateralis) communicates with the third ventricle of the brain by means of a small foramen, just large enough to admit a crow-quill, which is termed the **foramen of Monro**. This aperture is placed in front of the fore end of the optic thalamus and behind the anterior pillar of the fornix.

The highly-irregular shape of the lateral ventricle can be best understood by the study of a cast of its interior (Figs. 459; and 444, p. 551). It is usual to describe it as being composed of a body and three horns, viz. an anterior, a posterior, and a descending horn. The **anterior horn** is that part of the cavity which lies in front of the foramen of Monro. The **body** is the portion of the ventricle which extends from the foramen of Monro to the splenium of the corpus callosum. At this point the posterior and descending horns diverge from the hinder part of the body. The **posterior horn** curves backwards and inwards into the occipital lobe. It is very variable in its length and capacity. The **descending horn** proceeds with a bold sweep round the hinder end of the optic thalamus, and then tunnels in a forward and inward direction through the temporal lobe towards the temporal pole. The early fœtal lateral ventricle is very capacious and presents an arched or semilunar form. It is composed of parts which correspond to the anterior horn, the body, and the descending horn, and there is little or no demarcation between them. The posterior horn is a later production. It comes into existence with the occipital lobe and is produced as a diverticulum or elongated pouch, which grows backwards from the upper and hinder part (*i.e.* the convexity) of the primitive cavity.

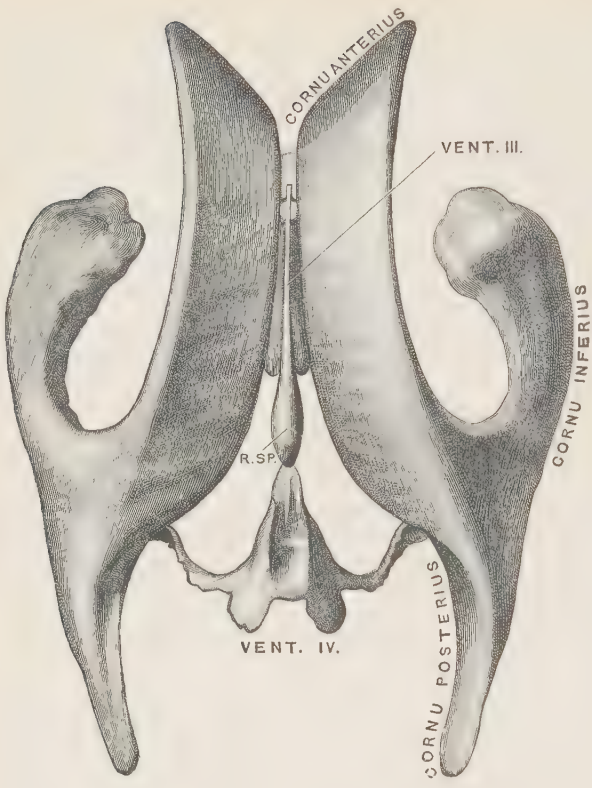

FIG. 459.—DRAWING TAKEN FROM A CAST OF THE VENTRICULAR SYSTEM OF THE BRAIN, as seen from above (after Retzius).

Vent. III. Third ventricle. Vent. IV. Fourth ventricle.
R.SP. Recessus suprapinealis.

**Anterior Horn of the Lateral Ventricle** (cornu anterius). — The anterior horn forms the foremost part of the cavity, and extends in a forward and outward direction in the frontal lobe. When seen in coronal section (Fig. 460) it presents a triangular outline, the floor sloping upwards and outwards to meet the roof at an acute angle. It is bounded *in front* by the posterior surface of the genu of the corpus callosum; the *roof* is also formed by the corpus callosum. The *inner wall*, which is vertical, is formed by the septum lucidum; whilst the sloping *floor* presents a marked elevation or bulging, viz. the smooth, rounded, and prominent extremity of the pear-shaped caudate nucleus.

**Body of the Lateral Ventricle** (pars centralis).—The body of the cavity is likewise *roofed* by the corpus callosum. On the *inner* or *mesial side* it is bounded by the attachment of the fornix to the under surface of the corpus callosum and by the hinder part of the septum lucidum. On the *outer side* it is closed, as in the case of the anterior horn, by the meeting of the floor and the roof of the cavity. On the *floor* a number of important objects may be recognised. From without inwards these are met in the following order: (1) the caudate nucleus; (2) a groove which extends obliquely from before backwards and outwards between the caudate nucleus and the optic thalamus, and in which are placed the vein of the corpus striatum and a white band called the tænia semicircularis; (3) a portion of the upper surface of

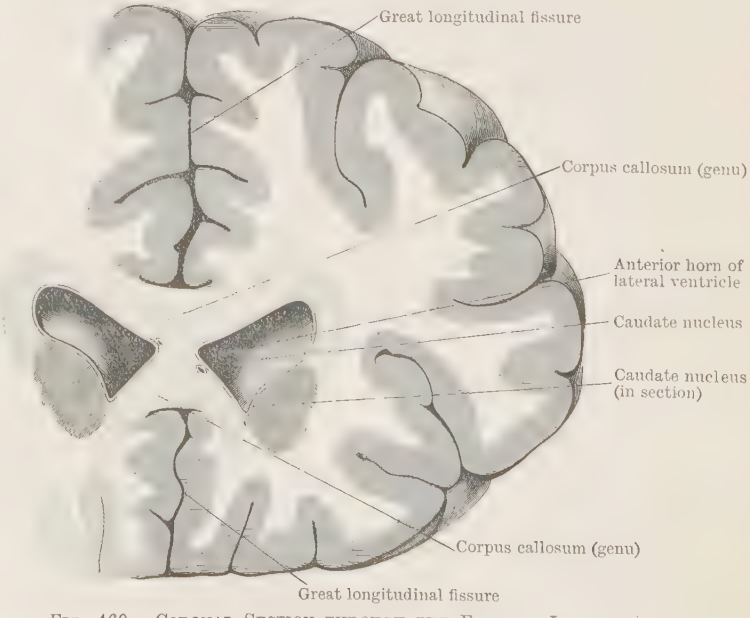

FIG. 460.—CORONAL SECTION THROUGH THE FRONTAL LOBES AND THE ANTERIOR HORNS OF THE LATERAL VENTRICLES.

the optic thalamus; (4) the choroid plexus; (5) the thin, sharp lateral edge of the fornix.

The **caudate nucleus** narrows rapidly as it proceeds backwards on the outer part of the floor of the body of the lateral ventricle. The **vein of the corpus striatum** is covered over by ependyma. It joins the vein of Galen close to the foramen of Monro. The connexions of the **tænia semicircularis** will be dealt with later. The portion of the upper surface of the **optic thalamus** which appears in the floor of the

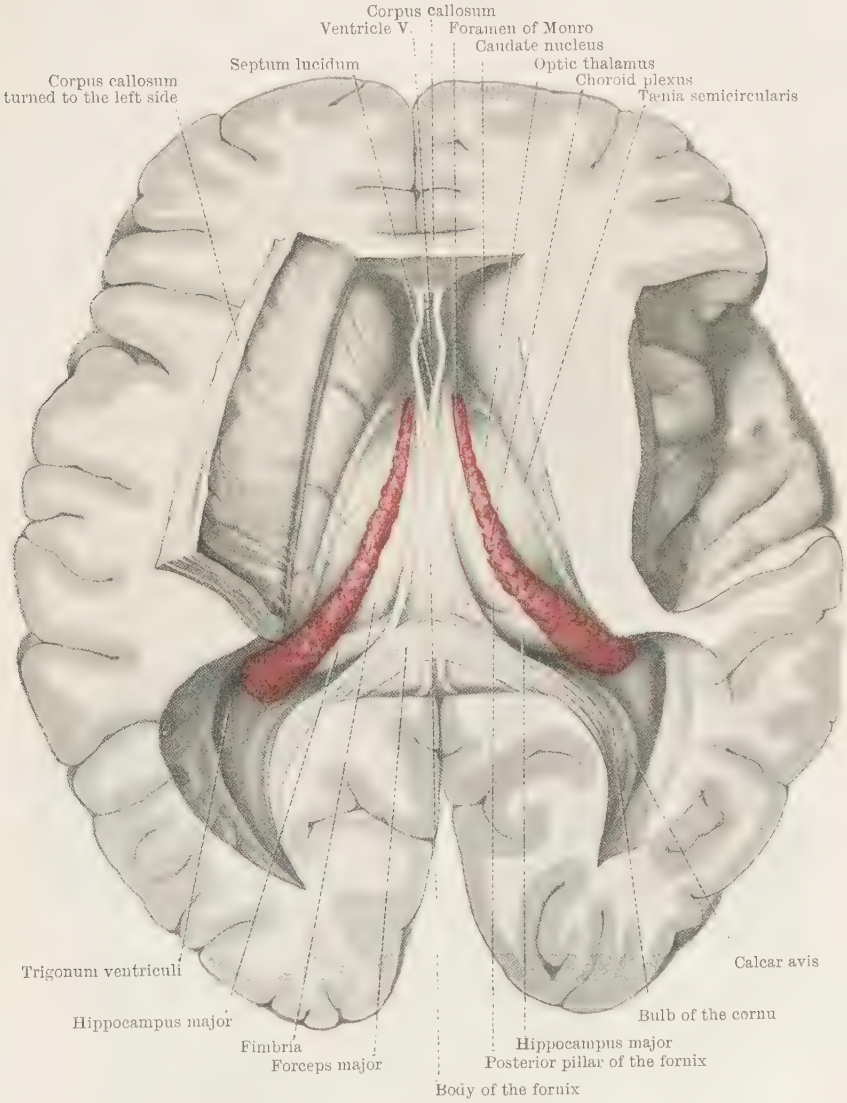

FIG. 461.—DISSECTION, to show the fornix and lateral ventricles; the body of the corpus callosum has been turned over to the left.

ventricle is in great part hidden by the choroid plexus, which lies upon it. The **choroid plexus** is a rich vascular fringe which appears from under cover of the sharp lateral edge of the fornix. In front it is continuous, behind the foramen of Monro, with the corresponding choroid plexus of the opposite side, whilst behind, it is carried into the descending horn of the ventricle. Although the choroid plexus has all the appearance of lying free within the ventricle, it must be borne in mind that it is invested by an epithelial layer which represents a portion of the hemisphere wall and excludes it from the cavity. This thin layer is continuous on the

one hand with the sharp edge of the fornix, and on the other it is attached to the upper surface of the optic thalamus.

**Posterior Horn of the Lateral Ventricle** (cornu posterius).—The posterior horn is an elongated diverticulum carried backwards into the occipital lobe from the hinder end of the body of the ventricle. It tapers to a point and describes a gentle curve, the convexity of which is directed outwards. The *roof* and *outer wall* of this portion of the ventricular cavity are formed by the tapetum of the corpus callosum. In coronal sections through the occipital lobe this is seen as a thin but distinct layer of white fibres, which lies immediately outside the ependyma and to the inner side of a much larger strand of fibres in the medullary substance of the occipital lobe, viz. the optic radiation.

On the *inner wall* two elongated curved elevations may be observed. The uppermost of these is termed the **bulb of the cornu** (bulbus cornu posterioris), and is produced by the fibres of the forceps major of the corpus callosum as they curve abruptly backwards from the lower part of the splenium of the corpus callosum into the occipital lobe. Below this is the elevation known as the **calcar avis**. It varies greatly in size in different brains, and is caused by an infolding of the ventricular wall in correspondence with the anterior calcarine fissure on the exterior of the hemisphere.

**Descending Horn of the Lateral Ventricle** (cornu inferius).—The descending horn is the continuation of the cavity into the temporal lobe. At first directed backwards and outwards the descending horn suddenly sinks downwards behind the optic thalamus into the temporal lobe, in the centre of which it takes a curved course forwards and inwards to a point about an inch behind the extremity of the temporal pole.

In the angle between the diverging posterior and descending horns the cavity of the ventricle presents an expansion of a somewhat triangular shape. To this the name of **trigonum ventriculi** is sometimes given.

The *roof* of the descending horn is formed for the most part by the tapetum of

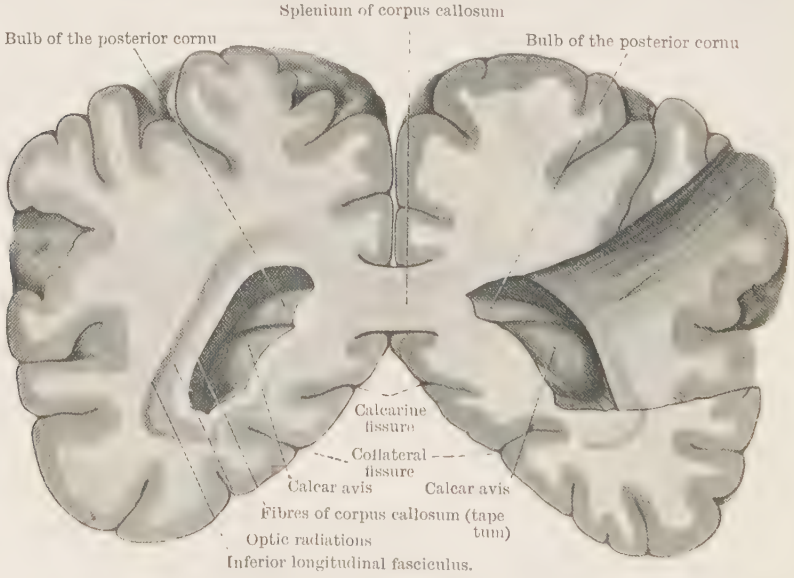

FIG. 462.—CORONAL SECTION THROUGH THE POSTERIOR HORNS OF THE LATERAL VENTRICLES.

the corpus callosum. At the extremity of the horn the roof presents a bulging into the cavity. This is the **amygdaloid tubercle**, and it is produced by a superjacent collection of gray matter termed the amygdaloid nucleus. The **tænia semicircularis** and the attenuated **tail of the caudate nucleus** are both prolonged into the descending horn and are carried forwards, in its roof, to the amygdaloid nucleus.

On *the floor* of the descending horn the following structures are seen: (1) hippocampus major, or the cornu ammonis; (2) the choroid plexus; (3) the fimbria; and (4) the eminentia collateralis.

The **hippocampus major** (hippocampus) is for the most part covered by the

choroid plexus. It is a prominent elevation on the floor of the descending horn of the lateral ventricle and is strongly curved, in conformity with the course taken by the horn in which it lies. It therefore presents an internal concave margin and an external convex border. Narrow behind, it enlarges as it is traced forwards, and it ends below the amygdaloid tubercle in a thickened extremity, which presents some faint grooves or notches on its surface. In consequence of this, the anterior end of the hippocampus major receives the name of the **pes hippocampi.** The hippocampus major is the internal elevation which corresponds to the dentate fissure on the exterior of the hemisphere (Fig. 464).

If an incision be made along the outer convex edge of the hippocampus major, and the surface lamina be raised, the central core will be seen to present the curious appearance of two corrugated layers dove-tailed into each other (M'Carthy).

The **fimbria** (fimbria hippocampi) is the narrow band of white matter which is attached by its outer margin along the inner concave border of the hippocampus major. The white matter composing it is continuous with the thin white layer (the alveus) which is spread over the surface of the hippocampus major, and it presents two free surfaces and a sharp free inner border. The fimbria has already been examined in connexion with the hippocampal fissure and the gyrus dentatus

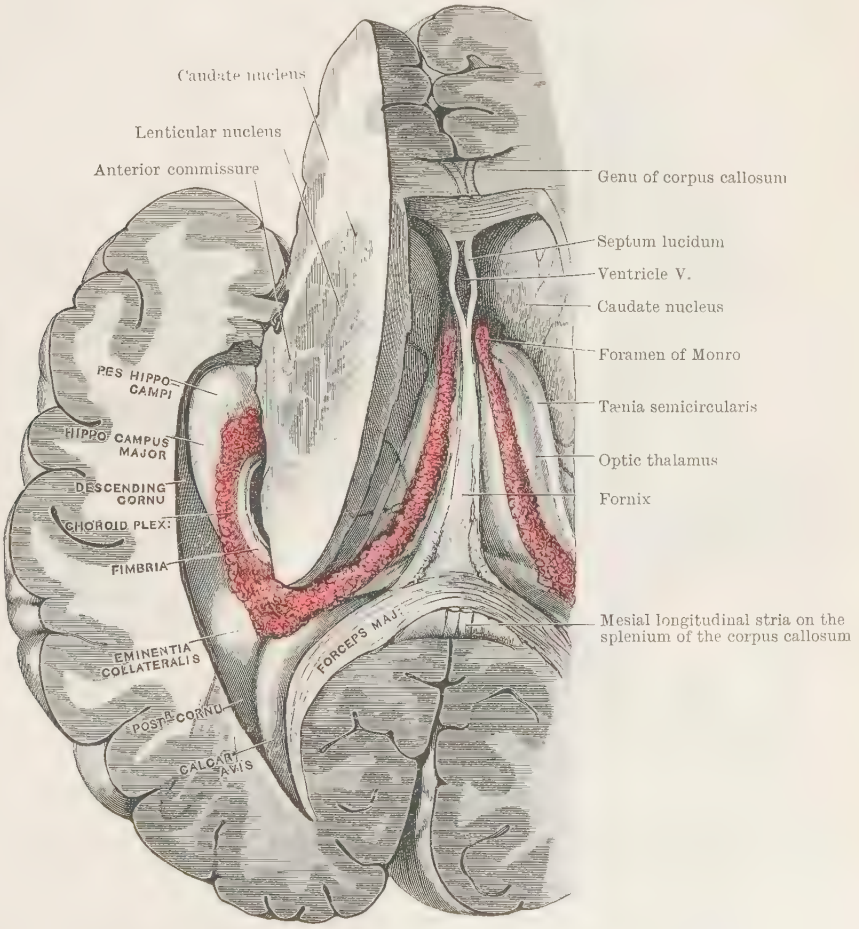

Fig. 463.—Dissection, to show the fornix and the posterior and descending cornua of the lateral ventricle of the left side.

(p. 568), and the relations which it presents to the fornix and the uncus have been pointed out.

When the pia mater in the region of the hippocampal fissure is removed from the surface of the brain, the choroid plexus in the interior of the descending horn

of the lateral ventricle is usually withdrawn with it, and a fissure appears between the fimbria and the roof of the ventricular horn. This is the **choroid fissure.** It appears at a very early date in the development of the cerebral hemisphere, and takes an arcuate course upwards and forwards round the hinder end of the optic thalamus. In the region of the body of the lateral ventricle it extends as far forwards as the foramen of Monro, and is formed by the involution of an epithelial part of the wall of the ventricle over the choroid plexus (p. 575). In the region of the descending horn, when the choroid plexus with the involuted epithelial layer which covers it is withdrawn, the choroid fissure is converted into an artificial gap which leads directly into this part of the ventricular cavity.

The **choroid plexus** is a convoluted system of blood-vessels in connexion with a fold of pia mater, which is prolonged into the descending horn of the lateral ventricle. It lies on the surface of the hippocampus major and is continuous behind the posterior part of the optic thalamus, with the choroid plexus in the body of the lateral ventricle. But it must not be supposed that the choroid plexus lies free in the ventricular cavity. It is clothed in the most intimate manner by an epithelial layer, which represents the inner or mesial wall of the descending horn involuted into the cavity over the choroid plexus. The ventricle, therefore, only opens on the surface through the choroid fissure when this thin epithelial layer is torn away by the withdrawal of the choroid plexus. From the above, it will be understood that the arcuate choroid fissure, throughout its whole length (viz. from the foramen of Monro to the extremity of the descending horn of the lateral ventricle), is formed by the involution of a portion of the wall of the hemisphere which remains epithelial. In the body of the ventricle this layer is attached, on the one hand, to the sharp lateral margin of the fornix, and on the other to the upper surface of the optic thalamus; in the descending horn it is attached, in like manner, to the edge of the fimbria or posterior pillar of the fornix, whilst above it joins the roof of this portion of the ventricle along the line of the tænia semicircularis.

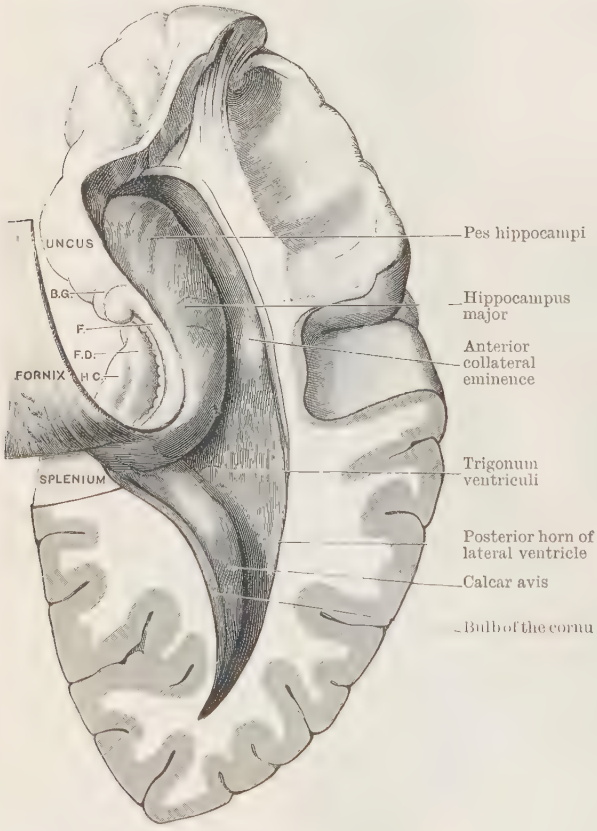

FIG. 464.—DISSECTION from above, to show the posterior and descending cornua of the lateral ventricle.

B.G. Giacomini's band. F.D. Gyrus dentatus.
F. Fimbria. H.C. Hippocampal convolution.

The **eminentia collateralis** shows very great differences in its degree of development, and it may present two distinct forms, which may be distinguished from each other as the eminentia collateralis posterior and the eminentia collateralis anterior.

The *posterior collateral eminence* is a smooth elevation in the floor of the trigonum ventriculi, in the interval which is left between the calcar avis and the hippocampus major as they diverge from each other. In the fœtal brain this is always a very strongly-marked elevation, which corresponds with the mid-collateral fissure, but in the course of growth it is apt to lose much of its prominence.

The *anterior collateral eminence* is only occasionally present. It appears as an elongated elevation of varying length and prominence, on the floor of the descending horn of the lateral ventricle, on the outer side of the hippocampus major. It is formed by the anterior portion of the fœtal collateral sulcus, when this develops as a complete fissure.

## Basal Ganglia of the Cerebral Hemisphere.

Under this heading are included certain masses of gray matter more or less completely embedded in the white medullary substance of the hemisphere, and which are developed in its wall. They compose the caudate and lenticular nuclei, which together form the corpus striatum, the claustrum, and the amygdaloid nucleus.

The **caudate nucleus** bulges into the lateral ventricle. It is a pyriform, highly-arched mass of gray matter, which presents a thick, swollen head, or anterior extremity, and a long, attenuated tail. The head projects into the anterior horn of the lateral ventricle, whilst its narrower part is prolonged outwards and backwards in the floor of the body of the ventricle, where it is separated from the optic thalamus by the tænia semicircularis. Finally, its tail curves downwards with a bold sweep and enters the descending horn of the lateral ventricle. In the roof of this horn it is prolonged forwards to the amygdaloid nucleus, the lower part of which it joins. The caudate nucleus thus presents a free ventricular surface, covered with ependyma, and a deep surface embedded in the white substance of the cerebral hemisphere, and for the most part related to the internal capsule.

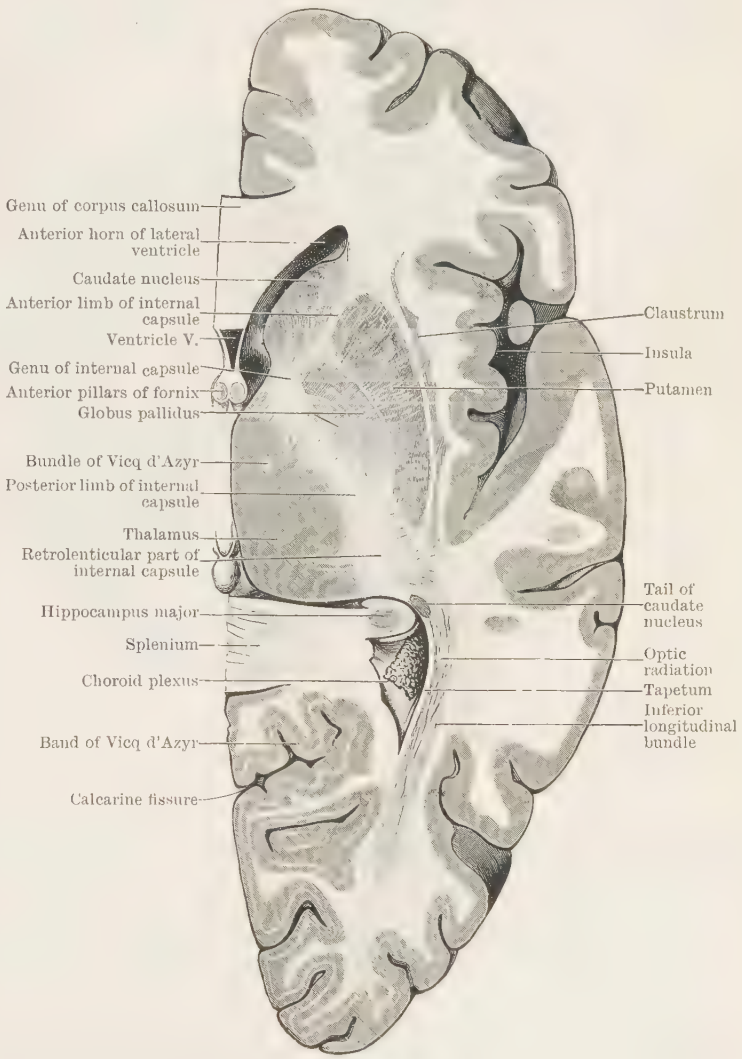

Fig. 465.—Horizontal Section through the Right Cerebral Hemisphere at the Level of the Widest Part of the Lenticular Nucleus.

Owing to its arched form it follows that, in horizontal sections through the cerebral hemisphere below a particular level, it is cut at two points, and both the head and the tail appear on the field of the section (Fig. 465). In coronal sections behind the amygdaloid nucleus, it is also divided at two places (Fig. 440, p. 547).

The anterior extremity of the head of the caudate nucleus coincides very nearly with that of the anterior horn of the lateral ventricle. In the region of the locus perforatus anticus, the head of the caudate nucleus gains the surface and its gray matter becomes continuous with that of the cerebral cortex.

The **lenticular nucleus** lies on the outer side of the caudate nucleus and optic thalamus, and is for the most part embedded within the white medullary substance of the cerebral hemisphere. It does not extend either so far forwards or so far backwards as the caudate nucleus. Indeed, it presents a very close correspondence in point of extent with the insula or island of Reil on the surface. When seen in horizontal section, it presents a shape similar to that of a biconvex lens. Its inner surface bulges more than the outer surface, and its point of highest convexity is placed opposite the tænia semicircularis or the interval between the caudate nucleus and the optic thalamus. In coronal section the appearance presented by the lenticular nucleus differs very much in different planes of section. Fig. 466 represents a section through its anterior portion. Here it is semilunar or crescentic in outline and is directly continuous below with the head of the caudate nucleus; above, also, it is intimately connected with the caudate nucleus by bands of gray matter, which pass between the two nuclei and break up the white matter of the forepart of the intervening internal capsule. It is due to the ribbed or barred appearance, which is presented by such a section as this, that the term **corpus striatum** is applied to the two nuclei. In the region of the locus perforatus anticus both nuclei reach the surface and become continuous with the cortex.

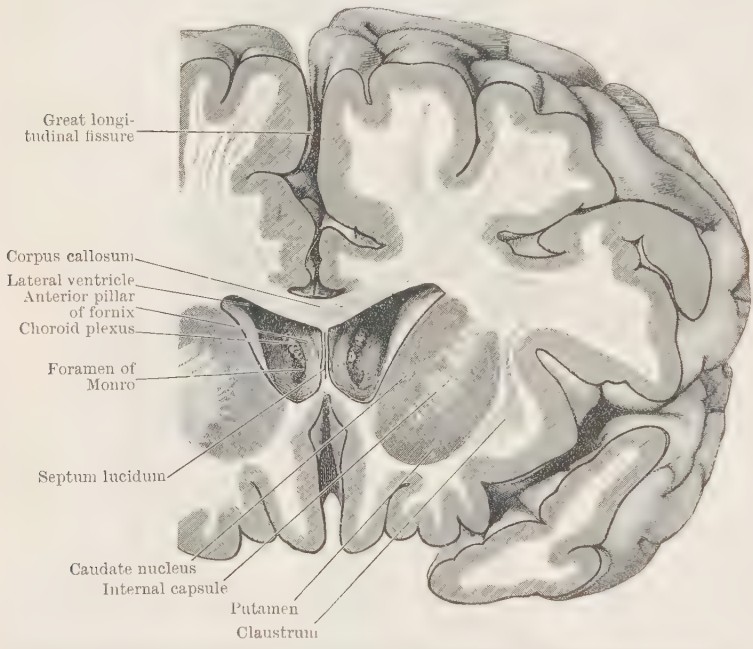

Fig. 466. Coronal Section through the Cerebral Hemispheres so as to cut through the anterior part (putamen) of the lenticular nucleus in front of the globus pallidus.

When a section is made in a plane further back (*e.g.* immediately posterior to the anterior commissure, as in Fig. 467) the divided lenticular nucleus assumes an altogether different shape, and is seen to be completely cut off from the caudate nucleus by the internal capsule. It is now triangular or wedge-shaped. Its *base* is turned towards the island of Reil and is in direct relation to a thin lamina of white matter, termed the external capsule. Its *internal surface* is oblique and is applied to the internal capsule, whilst its *inferior surface* is horizontal and is directed downwards towards the base of the brain. But, further, two white laminæ, the **external** and **internal medullary laminæ**, are now evident, which traverse its substance in a vertical direction and divide it into three zones. The outer, basal, and larger zone is termed the **putamen**; the two inner portions together constitute the **globus pallidus**.

The **putamen** forms much the largest part of the lenticular nucleus. It is darker in colour than the globus pallidus, and in this respect resembles the caudate nucleus. It is traversed by fine radiating bundles of fibres, which enter it from the

external medullary lamina. Both in point of structure and in mode of development it is closely associated with the caudate nucleus, and it is the only part of the lenticular nucleus which is connected by intervening bands of gray matter with the caudate nucleus. The antero-posterior length, as well as the vertical depth of the putamen, is much greater than in the case of the globus pallidus; consequently, in

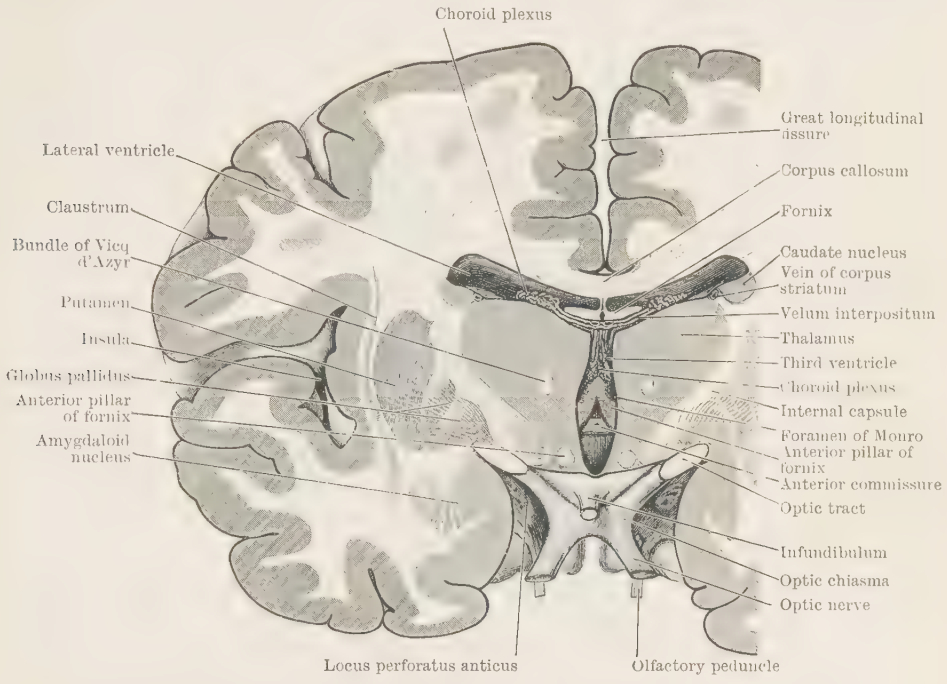

FIG. 467.—CORONAL SECTION THROUGH THE CEREBRUM so as to cut through the three divisions of the lenticular nucleus; posterior surface of the section depicted.

both coronal and horizontal sections through the cerebrum it is encountered before the plane of the globus pallidus is reached.

The external capsule is loosely connected with the outer surface of the putamen, and it can be readily stripped off. This accounts for the tendency, exhibited in hæmorrhages in this locality, for the effused blood to spread out in the interval between these structures.

The **globus pallidus** is composed of the two smaller and inner zones of the lenticular nucleus. They present a faint yellowish tint, and are paler and more abundantly traversed by fibres than the putamen. The zone next the putamen (*i.e.* the intermediate zone) is much larger than the innermost subdivision. It extends forwards to a point a little in front of the plane of the anterior commissure. When the lenticular nucleus is cut in a coronal direction, and in its widest part, the innermost zone shows an indication of a separation into two parts, so that here the globus pallidus appears to consist of three subdivisions. The morphology of the globus pallidus is by no means clear.

**Connexions of the Corpus Striatum.**—(1) Numerous fibres pass from the optic thalamus to the corpus striatum, and in the reverse direction from the corpus striatum into the thalamus through the anterior limb of the internal capsule. These may be termed the **thalamo-striate** and the **strio-thalamic fibres**. (2) Edinger describes a connexion between the caudate nucleus and the substantia nigra. The connecting fibres pass through the subthalamic region and constitute a tract in the mesencephalon, in close apposition with the substantia nigra, called the **stratum intermedium**. (3) The **ansa lenticularis** has previously been mentioned. It is composed of fibres which come from the inferior part of the fore portion of the thalamus and curve outwards under the lenticular nucleus. They stream upwards into this and through its medullary laminæ. Many of them apparently proceed onwards to the cerebral cortex. (4) Fibres from the posterior

limb of the internal capsule (thalamic fibres chiefly) enter the lenticular nucleus and stream through it, and its medullary laminæ, on their way to the cerebral cortex.

**Claustrum.**—This is a thin plate of gray substance embedded in the white matter, which intervenes between the lenticular nucleus and the gray cortex of the insula or island of Reil. Followed in an upward direction, it becomes gradually thinner and ultimately disappears. As it is traced downwards, however, it

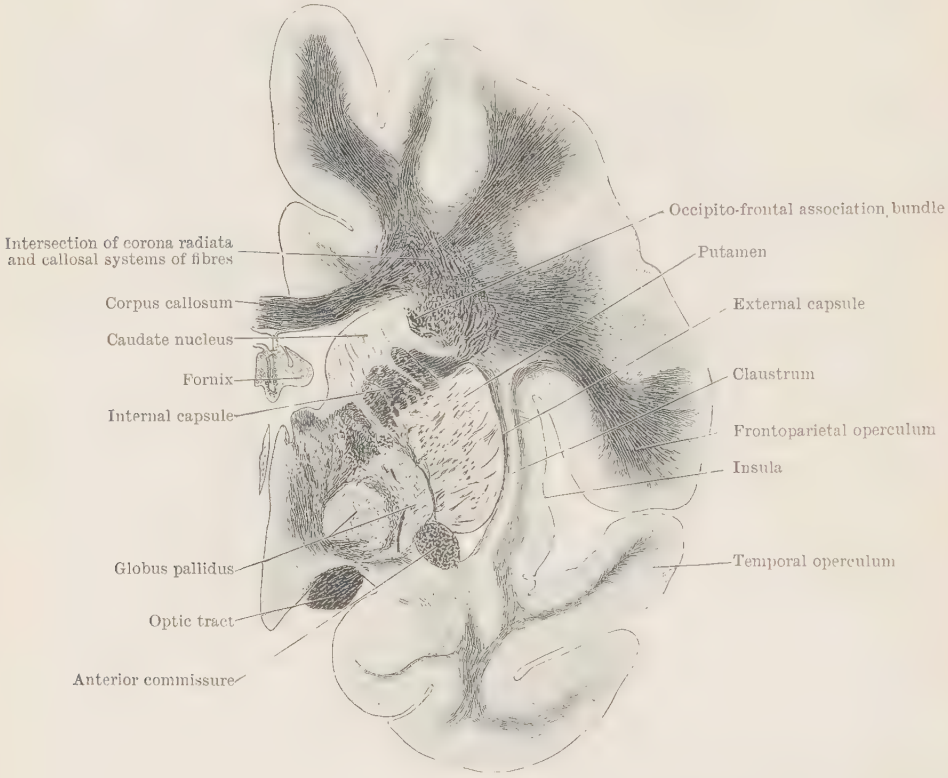

FIG. 468.—CORONAL SECTION THROUGH THE LEFT SIDE OF THE CEREBRUM OF AN ORANG (Weigert-Pal specimen).

The section passes through the middle of the lenticular nucleus.

thickens considerably, and at the base of the brain it comes to the surface at the anterior perforated spot and becomes continuous with the gray matter of the cortex. Its extent corresponds very closely with the area occupied by the insula, and its surface towards this portion of the cerebral cortex shows ridges and depressions corresponding to the insular gyri and sulci.

**Amygdaloid Nucleus.** In the forepart of the temporal lobe, in front of, and to some extent above the extremity of the descending horn of the lateral ventricle, there is a round mass of gray matter, called the amygdaloid nucleus. The tail of the caudate nucleus joins its lower part, whilst above it is carried up into the putamen. In front it is continuous with the gray cortex of the cerebrum.

**Tænia Semicircularis.**—This is a band of fibres which, for the most part, arise in the amygdaloid nucleus. From this it runs backwards in the roof of the descending horn of the lateral ventricle, and then arches upwards and forwards, so as to gain the floor of the body of the lateral ventricle. In both situations it lies close to the inner side of the nucleus caudatus, and finally, at the foramen of Monro, it bends downwards towards the anterior commissure. Some of its fibres pass in front and others behind the commissure, and ultimately they end in the locus perforatus anticus (Kölliker).

**Internal Capsule.**—This term is applied to the broad band of white matter which intervenes between the lenticular nucleus, on the outside, and the optic

thalamus, tænia semicircularis, and caudate nucleus on the inner side. It presents many different appearances, according to the plane in which the brain is cut. In the region of the mesencephalon, a coronal section through the brain shows that in great part the internal capsule is directly continuous with the crusta of the crus cerebri (Fig. 440, p. 547). In horizontal section the internal capsule is observed to be bent upon itself opposite the tænia semicircularis, or the interval between the caudate nucleus and the thalamus. This bend, which points inwards, is called the **genu**. About one-third of the internal capsule lies in front of the genu, and is termed the anterior limb; the remaining two-thirds, which lie behind the genu, constitute the posterior limb.

The **anterior limb of the internal capsule** intervenes between the lenticular nucleus and the caudate nucleus. In its lower and forepart it is much broken up by the connecting bands of gray matter which pass between the forepart of the putamen and the lenticular nucleus.

The anterior limb of the internal capsule is largely composed of corticipetal fibres belonging to the thalamic radiation. It likewise contains corticifugal fibres. The *corticipetal fibres* are of two kinds, viz. thalamo-frontal and thalamo-striate. The former, which arise in the optic thalamus, go through the anterior limb of the internal capsule to reach the cortex of the frontal lobe. The thalamo-striate fibres likewise arise in the thalamus and enter the anterior limb, to reach the caudate and lenticular nuclei.

The corticifugal fibres are represented by the fronto-thalamic, the strio-thalamic, and the fronto-pontine tracts.

The **fronto-pontine tract** arises in the cortex of the prefrontal region, traverses the anterior limb of the internal capsule, forms the inner fifth of the crusta of the crus cerebri, and finally ends in the nucleus pontis.

The **posterior limb of the internal capsule** is placed between the optic thalamus and the lenticular nucleus, and it extends backwards for a short distance beyond the hinder end of the putamen on the outer side of the posterior part of the thalamus and of the tail of the caudate nucleus. The posterior limb, therefore, is spoken of as consisting of a lenticular and a retrolenticular part.

The **lenticular part** of the posterior limb is composed of both corticipetal and corticifugal fibres. The *corticipetal fibres* enter the internal capsule from the outer aspect of the optic thalamus, and are composed of fibres which arise within the thalamus, and proceed upwards to the cerebral cortex.

The *corticifugal fibres* consist of the pyramidal tract and the cortico-thalamic fibres.

The great **motor** or **pyramidal tract**, descending from the Rolandic area of the cortex, occupies the anterior half of the lenticular part of the internal capsule. The fibres, which go to the nucleus of the facial nerve, lie close to the genu, and behind these are the fibres which go to the hypoglossal nucleus; still further back are pyramidal fibres which enter the spinal cord and end around the motor cells of the anterior horn of gray matter. This pyramidal tract has been observed occupying the middle part of the crusta of the crus cerebri, into which it passes directly from the internal capsule.

The **retrolenticular part** of the posterior limb contains: (1) the fibres of the optic radiation as they pass to establish their connexions with the thalamus, superior quadrigeminal body, and corpus geniculatum externum; (2) the fibres of the auditory radiation, or those which connect the auditory cortical field in the temporal lobe with the corpus geniculatum internum (Figs. 418, p. 520, and Fig. 439, p. 546); (3) the temporo-pontine tract, which is composed of fibres which take origin in the two upper convolutions of the temporal lobe and pass through this section of the internal capsule to reach the outer part of the crusta of the crus cerebri. Through this they reach the ventral part of the pons, in the gray matter of which they end.

When the fibres of the internal capsule are traced upwards they are found to spread out widely from each other in a radiating or fan-shaped manner, so as to reach the various convolutions of the cerebral hemisphere. This arrangement is termed the **corona radiata**. The callosal system of fibres, as they proceed into the hemisphere, also radiate, and they intersect the fibres of the corona radiata (Fig. 468, p. 582).

**External Capsule.**—The thin lamina of white matter between the outer aspect of the putamen and the claustrum is called the external capsule. This joins with

the internal capsule in front of and behind the putamen, and in this manner the lenticular nucleus is encapsulated by white matter.

**Morphological Subdivision of the Cerebral Hemisphere.**—In many respects the descriptive anatomy of the human cerebral hemisphere is not in accord with the facts which have been acquired regarding its morphological evolution; and of recent years this discrepancy has become more marked through the important researches of Elliot Smith.

From the morphological point of view the cerebral hemisphere may be regarded as being composed of three parts, viz. the rhinencephalon, the corpus striatum, and the neo-pallium.

The **rhinencephalon** is the most archaic part of the hemisphere, and in the brains of the lower vertebrates (fishes, amphibians, reptiles) it constitutes its chief bulk. In the human brain it is represented by the olfactory bulb, olfactory tract and its roots, the anterior perforated space, the uncus, the gyrus subcallosus, the septum lucidum, the hippocampus, fornix, gyrus dentatus, and the gyrus supracallosus.

The uncus, with the aborted lateral stria of the olfactory peduncle, is all that remains in the human brain of the relatively huge pyriform lobe of many of the lower mammals. The hippocampal convolution which lies to the outer side of the dentate fissure, although it runs continuously into the uncus, is not a part of the rhinencephalon. It belongs to the neo-pallium. The feeble furrow, termed the incisura temporalis which separates the uncus from the temporal pole, is one of the most primitive of the cerebral fissures. It represents the rhinal or ecto-rhinal fissure—the bounding fissure of the rhinencephalon.

The **neo-pallium** is represented by the rest of the hemisphere, exclusive of the corpus striatum. It therefore comprises almost the whole of the convoluted cortex on the surface together with its associated white matter. The great development of the neo-pallium in man is one of the most distinctive characters of the human brain.

In their phylogenetic evolution the rhinencephalon and the neo-pallium appear to develop more or less independently of each other. In certain cases the former atrophies, whilst the neo-pallium attains a high degree of development (*e.g.* man, monkey, whale, etc.), in others the reverse development occurs (*e.g.* hedgehog and many other mammals), in which the rhinencephalon forms a large part of the hemisphere and the neo-pallium is relatively small.

## Intimate Structure of the Cerebral Hemisphere.

The cerebral hemisphere is composed of an external coating of gray matter, termed the **cortex**, spread over an internal mass of white matter, which is called the **medullary centre**. The cortex is of peculiar interest, seeing that there is good reason for believing that in it the higher functions of the brain, or those which may be classed under the general designation of the intellectual functions, take place. It is within the same layer of gray matter that the influence of those external impressions, which gain access to the cerebro-spinal axis through the senses, finally take shape as consciousness; and in it also are placed the centres which carry on the psycho-motor functions. The white medullary centre is composed of nerve-fibres which constitute the paths along which the influence of impressions is carried to and from the cortex, and from one part of the cortex to another.

## The Cerebral Cortex.

The gray cortex is spread over the entire surface of the cerebral hemisphere, but it does not form a layer of equal thickness in all localities. At the summit of a convolution it is always thicker than at the bottom of a furrow. The maximum thickness of cortex (about 6 mm.) is attained in the upper parts of the two central convolutions, whilst the minimum (about 2·5 mm.) may be observed in the region of the occipital pole. The amount of gray cortex differs considerably in different individuals, and appreciably diminishes in old age. It is also stated, but upon imperfect evidence, that it is relatively more abundant in the male than in the female.

In structure, likewise, marked differences may be noted in the gray cortex of different regions, and excellent work has been recently done in the direction of connecting these structural peculiarities with the functional characteristics of particular areas and applying them to the determination of morphological problems connected with the cerebral surface (Campbell and Bolton). In certain localities this structural difference is quite apparent to the naked eye when sections are made through the cortex. There are, however, no sharp transitions in structure. One form of cortex passes, as a rule gradually and almost insensibly, into the variety of cortex which is distinctive of an adjoining region, and throughout the whole

mass a general ground type may be recognised. It is only to those general structural features which more or less characterise the entire cortical layer that we shall be able to refer.

When sections are made through the fresh brain, and the cut surface is closely inspected, it will usually be apparent that the cortex is indistinctly stratified. On the outside there is a thin, whitish layer, and beneath this the gray matter presents two strata of very nearly equal thickness, viz. a middle, gray-coloured stratum and an inner, yellowish-red stratum. Between the two latter layers a narrow white band is, in many places, visible. This is termed the **outer band of Baillarger**. When the layers indicated above are present, four strata superimposed on each other are recognised; but in certain regions, as, for instance, in the anterior central convolution, a second white streak traverses the deep or inner gray layer and divides it into two. This is termed the **inner white band of Baillarger**, and, when it is present, the gray cortex becomes divided obscurely into six alternating white and gray layers.

The outer band of Baillarger is strongly marked in the region of the calcarine fissure and gives a characteristic appearance to this portion of the cortex. In this locality it receives the name of the **band of Vicq d'Azyr** or the **stria of Gennari** (Fig. 465, p. 579).

According to Henschen the visual centre is strictly limited to the region in which the stria of Gennari is present. Elliot Smith applies the name of "striated area" to this cortical district, and considers that it affords a means of identifying homologous sulci in the brains of man and the apes.

To obtain a full understanding of the minute structure of the cerebral cortex many different methods must be employed, and it is only by combining the several separate pictures which are thus afforded that the end in view is, in some measure, reached.

The stratification indicated above has little bearing upon the more essential points of the intimate structure of the cortex. The three white layers are brought about by aggregations of fibres running in a tangential direction, or, in other words, in a direction parallel to the surface of the convolution.

**Nerve-cells.**—According to the arrangement and the characters presented by the nerve-cells which are met with at different depths, it is now usual to recognise four layers in the cortex. These are: (1) the stratum zonale; (2) the layer of small pyramidal cells; (3) the layer of large pyramidal cells; and (4) the layer of polymorphic cells.

As the pyramidal cells are specially characteristic of the cerebral cortex, we shall, in the first instance, describe the two layers which contain them. The difference between these two layers largely depends upon the difference in the size of the constituent cells. Taken together, the second and third layers constitute the chief part of the cortex; they merge insensibly into each other, and, in the parietal and frontal lobes, the layer of large pyramidal cells is the thickest of all the layers. In both of these strata the pyramidal cells present the same form, and apparently also similar connexions.

A **pyramidal cell** has a triangular outline. Its apex is directed towards the surface of the convolution and is drawn out into a long, tapering, apical, dendritic process; its base is turned towards the medullary centre of the gyrus, and from this (usually from the centre) a slender axon proceeds. Numerous lateral dendrites are given off from both sides of the cell-body, and particularly from the two basal corners. The apical dendrite varies in length, according to the depth at which the cell is placed in the cortex. In every case it passes straight towards the surface of the convolution. Every here and there fine lateral branches come off from it, and ultimately it enters the stratum zonale, where, close to the surface, it ends by breaking up into a large number of fine terminal filaments, which spread out horizontally in every direction and interlace closely with the corresponding filaments of other pyramidal cells and with the other elements of this layer.

The axon of the cell descends, gives off collaterals, assumes a medullary sheath, and enters the central white core of the gyrus as a nerve fibre.

The **stratum zonale** is chiefly composed of fibres which run in a tangential direction, or, in other words, parallel to the surface. These form an interlacement of considerable density and extreme complexity. The elements which for the most part enter into the formation of this feltwork are: (1) the terminal filaments of the apical dendrites of the pyramidal cells; (2) the terminal filaments of certain corticipetal fibres, which enter the cortex from the white centre of the gyrus; (3) the axons of certain small cells peculiar to this stratum; (4) the axons of the cells of Martinotti. Spread over the surface of this tangential interlacement of fibres, which constitutes the most important part of the stratum zonale, there

is a thin layer of neuroglia which intervenes between it and the pia mater, which covers the convolution. The stratum zonale is not devoid of nerve-cells, although these are small and somewhat indefinite in their connexions. The most characteristic form is a small fusiform cell described by Cajal, which sends out from either end a long process and which lies in the deeper part of the layer. The long filamentous processes of this cell thread their way between the other fibres in a tangential direction and give off minute branches which pass towards the surface.

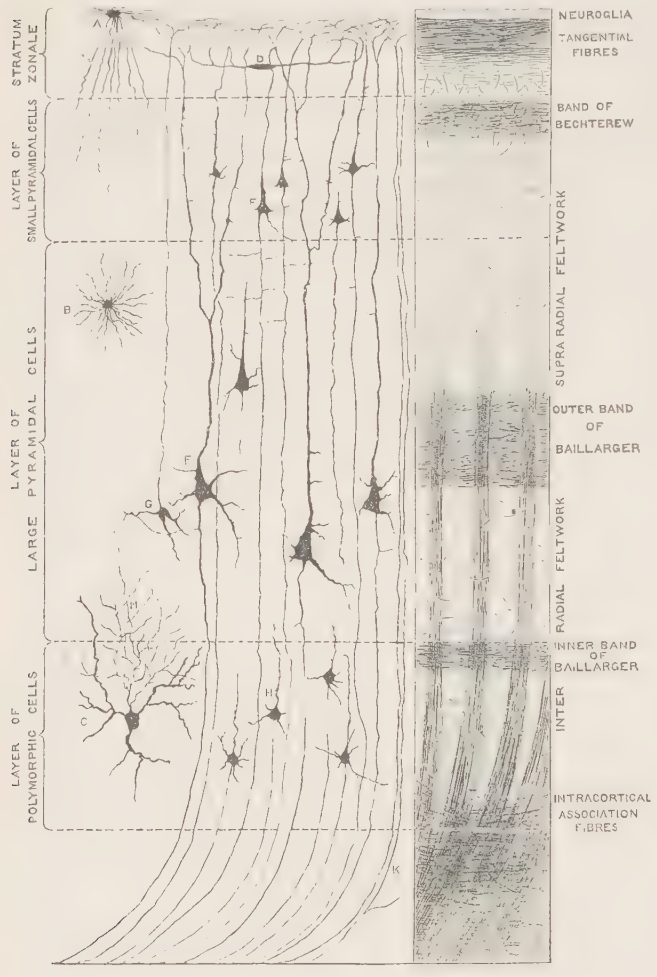

FIG. 469.—DIAGRAM TO ILLUSTRATE MINUTE STRUCTURE OF THE CEREBRAL CORTEX.

A. } Neuroglia cells.
B. }
C. Cell with short axon (N) which breaks up in a free arborisation.
D. Spindle-shaped cell in stratum zonale.
E. Small pyramidal cell.
F. Large pyramidal cell.
G. Cell of Martinotti.
H. Polymorphic cell.
K. Corticipetal fibres.

The **deepest layer of the cortex** contains the polymorphic cells. These cells are not large, and they present many different forms. Numerous dendrites proceed from the cells of this group, but none of these reach the stratum zonale, and in this respect the polymorphic cells offer a marked contrast to the pyramidal cells. The axons of the polymorphic cells, however, like those of the pyramidal cells, enter the white centre of the gyrus in the shape of nerve-fibres.

In addition to the cells characteristic of the several layers, there are two which may be found amongst the pyramidal or amongst the polymorphic cells. These are: (1) the cells of Golgi; (2) the cells of Martinotti.

A **cell of Golgi** has this peculiarity—that its axon, close to its origin, begins to divide, and very soon loses its individuality by breaking up into a perfect maze of branches, none of which pass far from the neighbourhood of the cell-body and none of which enter the stratum zonale.

The **cell of Martinotti** is small and is chiefly found in the deeper part of the cortex. Its leading peculiarity is, that its slender axon runs in a contrary direction to the axons of the pyramidal cells and of the polymorphic cells. In other words, it proceeds towards the surface, and, entering into the stratum zonale, divides into terminal filaments, which spread out in the tangential interlacement characteristic of this layer.

**Nerve-Fibres.**—The arrangement of the nerve-fibres can best be studied in vertical sections through the gray cortex, which have been specially treated with this end in view. In such preparations bundles of nerve-fibres are seen to radiate into the gray cortex from the surface of the white centre of the gyrus. As these proceed through the polymorphic layer into the layer of large pyramidal cells, they gradually become less distinct, and, finally, they disperse and are lost to view before they reach the layer of small pyramidal cells. In the intervals between the radiating bundles the polymorphic and large pyramidal cells are arranged in columns, and in the same intervals an open

feltwork of intercrossing fibres is evident. After the radiating fibre-bundles have disappeared the same feltwork of fibres is visible in the gray matter, and consequently it is convenient to distinguish, with Edinger, an **inter-radial feltwork** and a **supra-radial feltwork** of fibres in the cortex. The fibres which enter into the composition of the different radial bundles vary in number from ten to twenty, and they gradually diminish in number as they proceed onwards. This diminution is due to their joining the various cells that they meet (both polymorphic and pyramidal) as their axons. The fibres in a given bundle also vary much in size, and it may be noticed that the largest fibres disappear in the vicinity of the large pyramidal cells, which shows clearly that it is with these that they are connected. But, in addition to cell-axons, the radial bundles contain fibres of an altogether different type, viz. corticipetal fibres, which pass through all the layers of the cortex and end in fine terminal filaments in the tangential interlacement of the stratum zonale.

The inter-radial and supra-radial feltwork is largely formed of the collaterals which issue from the axons. By a condensation of this feltwork the two bands of Baillarger are formed. The outer band, which is the broader and better marked, occurs in the deeper part of the layer of the large pyramidal cells. The inner band, when present, is formed in the superficial part of the layer of polymorphic cells.

Another condensation of the fibre-feltwork in the superficial part of the supra-radial region may be noted in certain localities. This is termed the **band of Bechterew**.

It has been noted that up to a certain point the tangential fibres increase in quantity as age advances, and there is reason to believe that upon the richness with which the gray cortex is supplied with fibres—more especially of the tangential variety—depends to some extent the intellectual capacity of an individual.

Whilst the general mass of the cortex for the most part conforms more or less closely to the ground-type described above, showing merely deviations characteristic of the different regions, there is one part of the cortex, viz. the cornu ammonis and the fascia dentata, in which the structural arrangement of the elements is very markedly different. To some extent this is due to the complicated manner in which, in this region, the cortex is folded upon itself.

### Olfactory Tract and Bulb.

The olfactory tract and bulb arise as a hollow outgrowth from the primitive cerebral vesicle. In many animals with a well-developed olfactory apparatus, the tract and bulb remain hollow; but in man the central cavity becomes obliterated, although traces of the original hollow persist in the shape of ependymal remains, visible in the centre of both tract and bulb. Outside these ependymal elements is a coating of white matter, upon which is laid the gray matter. The gray matter, however, is by no means uniformly distributed over the surface. In the tract, except along the dorsal edge, it is so thinly spread that it is hardly appreciable. In the bulb, on the other hand, there is very little gray matter on the dorsum, but a considerable quantity on the ventral surface; and it is into this that the delicate nerves which enter the cranium through the cribriform plate of the ethmoid bone sink. A brief description of the structure of this infrabulbar mass of gray matter, as well as of the connexions established by its elements, now becomes necessary.

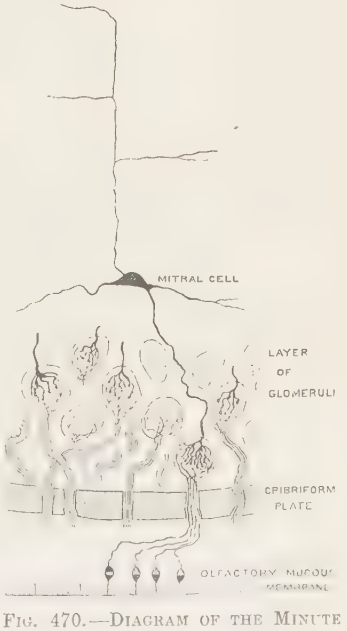

Fig. 470.—Diagram of the Minute Structure of the Olfactory Bulb.

The fibres of the delicate olfactory nerves are to be regarded as the axons of the olfactory cells of the olfactory mucous membrane. They enter the ventral surface of the olfactory bulb, and there each breaks up in an arborescent fashion into a tuft of terminal filaments. A thick dendrite from a mitral cell of the bulb passes down towards this terminal tuft, and, coming into contact with it, breaks up and terminates in a similar manner. In this way a large number of globular bodies, formed by the arborescent terminations of a mitral dendrite and of certain olfactory nerve-fibres, are formed. These are the **olfactory glomeruli** of the bulb. The mitral cells lie deeper in the olfactory bulb. Each gives

off several dendrites and one axon. Only one dendrite enters into the formation of a glomerulus, but several nerve-fibres may be connected with such a body. It thus happens that, through its dendrite, a mitral cell may stand in connexion with several olfactory nerve-fibres. The axon of the mitral cell passes upwards to the white matter of the bulb, enters this, and is conducted through the tract towards the cerebral cortex.

### White Medullary Centre of the Cerebral Hemisphere.

The white matter of the hemisphere which lies subjacent to the gray cortex is composed of medullated nerve-fibres, arranged in a very intricate manner. According to the connexions which they establish these fibres may be classified into three distinct groups, viz. (1) commissural fibres; (2) association fibres; and (3) projection fibres.

**Commissural Fibres.**—These are fibres which link together portions of the gray cortex of opposite cerebral hemispheres. They are arranged in three groups forming three definite structures, viz. the corpus callosum, the anterior commissure, and the psalterium or the hippocampal commissure.

The **corpus callosum** has in a great measure been already studied (p. 570). As it enters each hemisphere, its fibres spread out in an extensive radiation (the radiation of the corpus callosum). It thus comes about that every part of the cerebral cortex, with the exception of the bulbus olfactorii and the under and fore part of the temporal lobe, is reached by the callosal fibres. But it should be clearly understood that all the regions of the cortex do not receive an equal proportion of fibres; in other words, some cortical areas would appear to be more plentifully supplied than others. Another point of some importance consists in the fact that the callosal fibres do not, as a rule, connect together symmetrical portions of the gray cortex. As the fibres cross the mesial plane they become greatly scattered, so that most dissimilar parts of the cortex of opposite hemispheres come to be associated with each other.

Each callosal fibre arises in one hemisphere and ends by fine terminal arborisations in the cortex of the opposite hemisphere. It may arise in any one of three ways, viz. (1) as the axon of one of the cortical cells, either pyramidal or polymorphic; (2) as the collateral of a fibre of association; (3) as the collateral of a fibre of projection.

Many cases have been recorded in which, through congenital defect, the corpus callosum has not been developed. In the description of this structure on p. 570 attention has been called to a layer of callosal fibres which sweep over the posterior and descending horns of the lateral ventricle, so as to form the immediate outer wall of the cavity. This layer is called the **tapetum**, and it has been stated that when the corpus callosum is absent the tapetum is found in a well-developed condition. Further, it has been asserted that in cases where the corpus callosum has been experimentally destroyed the tapetum suffered no degeneration (Muratoff). Certain anatomists are, therefore, inclined to argue that the tapetum has little or no connexion with the corpus callosum. This assertion, however, cannot by any means be regarded as being proved. There is a large amount of evidence on the other side. Thus, Mingazzini has seen a case of failure of the corpus callosum which was accompanied by a corresponding defect in the tapetum, whilst softening of the splenium and the forceps major has been observed by Anton to be accompanied by a secondary degeneration of the tapetum. Further, the recent experimental evidence of Ferrier and Turner would appear to support the older view that the tapetum is associated in the closest manner with the corpus callosum.

The **anterior commissure** (commissura anterior) is a structure supplemental to the corpus callosum. It connects together the two olfactory lobes, and also portions of opposite temporal lobes. It presents a cord-like appearance and is arranged in the form of a horse-shoe, the concavity of which looks backwards. The middle free portion is placed immediately in front of the anterior pillars of the fornix as they curve downwards, and also in intimate relation to the anterior end of the third ventricle. Posteriorly, the small portion of the anterior commissure which appears in the ventricle between the two pillars of the fornix is clothed with the ventricular ependyma; anteriorly, the commissure is connected with the lamina cinerea as it stretches from the optic chiasma upwards towards the rostrum of the corpus callosum.

The lateral part of the anterior commissure penetrates the cerebral hemisphere, and, gaining the lower part of the anterior end of the internal capsule, divides into two portions, viz. a small lower olfactory part and a much larger temporal part.

The **olfactory portion** of the anterior commissure is an exceedingly small fasciculus. It passes downwards and forwards, and finally enters the olfactory tract. It is composed (1) of true commissural fibres, which bind one olfactory bulb to the other; and (2) of other fibres, which connect the olfactory bulb of one side with the temporal lobe of the other side.

The **temporal portion** is formed of almost the whole of the fibres of the commissure. It is carried transversely outwards, under the lenticular nucleus, until it gains the interval between the globus pallidus and the putamen. At this point it

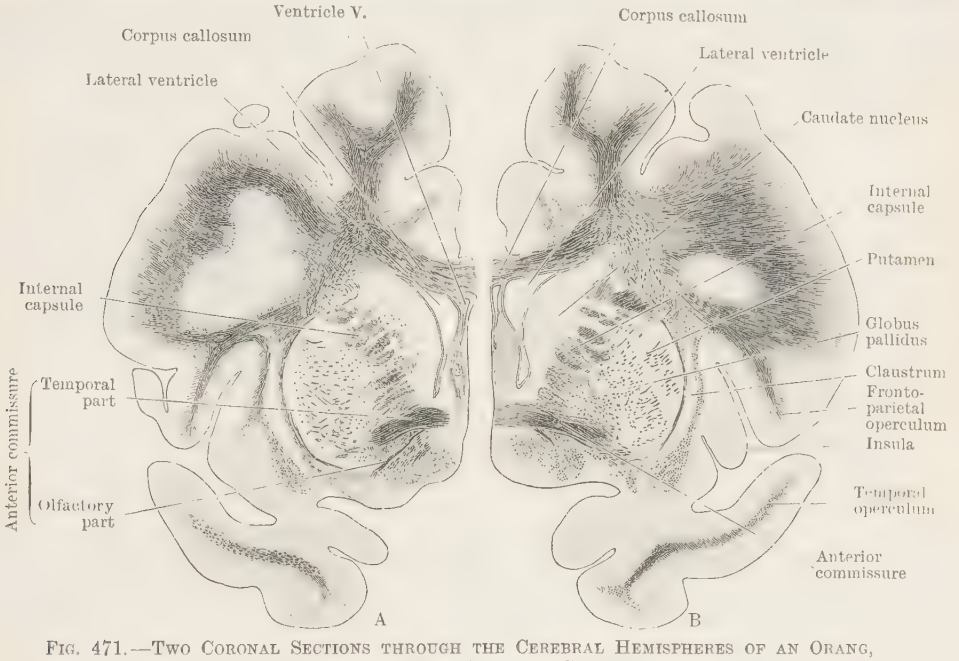

FIG. 471.—TWO CORONAL SECTIONS THROUGH THE CEREBRAL HEMISPHERES OF AN ORANG, IN THE PLANE OF THE ANTERIOR COMMISSURE.

A, Section through the left hemisphere in a plane a short distance behind B, which is a section through the right hemisphere.

changes its direction and sweeps backwards. In coronal sections through the brain, behind this bend, the temporal portion of the anterior commissure appears as an oval bundle of fibres cut transversely and placed in close contact with the under surface of the lenticular nucleus (Fig. 468, p. 582). Finally, it turns sharply downwards on the outer aspect of the amygdaloid nucleus, and its fibres are lost in the white medullary centre of the temporal lobe. The precise part of the cerebral cortex with which these fibres stand in connexion is not known. When the lateral part of the anterior commissure is displayed by dissection, it is seen to be twisted like a rope.

The **psalterium**, or the **hippocampal commissure**, is composed of fibres which connect the cornu ammonis of one side with the corresponding structure of the opposite side. It is described on p. 572.

**Association Fibres.**—The association fibres bind together different portions of the cortex of the same hemisphere. They are grouped into long and short association bundles.

The greater number of the **short association fibres** pass between adjacent convolutions. They curve round the bottom of the sulci in U-shaped loops. Some of these occupy the deepest part of the gray cortex itself, and are termed *intracortical association fibres* (Fig. 469, p. 586): others lie immediately subjacent to the gray matter—between it and the general mass of the white matter—and receive the name of *subcortical fibres*. Many groups of short association fibres, instead of linking together contiguous convolutions, pass between gyri more or less remote. It is only

after birth, when intellectual effort and education have stimulated different portions of the cortex to act in harmony and in conjunction with each other, that these association fibres assume their sheaths of medulla and become functional.

The **long association fibres** are arranged in bundles which run for considerable distances within the white medullary centre of the cerebral hemisphere, and unite districts of gray cortex which may be far removed from each other. The better known of these fasciculi are the following: (1) the uncinate; (2) the cingulum; (3) the superior longitudinal; (4) the inferior longitudinal; (5) the occipito-frontal.

The **fasciculus uncinatus** is composed of fibres which arch over the stem of the Sylvian fissure and connect the frontal pole, and the orbital convolutions of the frontal lobe, with the front portion of the temporal lobe.

The **cingulum** is a very well-marked and distinct band, which is closely associated with the limbic lobe. Beginning in front, in the region of the anterior perforated spot, it arches round the genu of the corpus callosum and is carried backwards on the upper surface of this structure at the place where its fibres pass into the

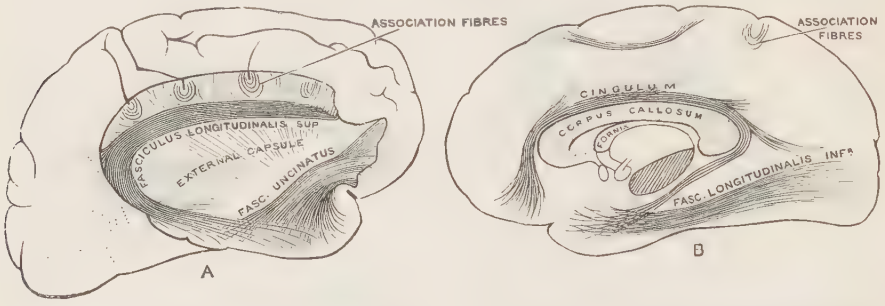

FIG. 472.—DIAGRAM OF THE LEADING ASSOCIATION BUNDLES OF THE CEREBRAL HEMISPHERE. (Founded on the drawings of Déjerine.)

A. Outer aspect of hemisphere. B. Inner aspect of hemisphere.

callosal radiation. The cingulum, therefore, lies under cover of the callosal gyrus and stands in intimate relation to the white centre of this convolution (Fig. 457, p. 570). At the hinder end of the corpus callosum the cingulum turns round the splenium and is carried forwards, in relation to the hippocampal gyrus, to the uncus and the temporal pole. The cingulum is composed of several systems of fibres which only run for short distances within it.

The **fasciculus longitudinalis superior** is an arcuate bundle which is placed on the outer aspect of the foot or basal part of the corona radiata and connects the frontal, occipital, and temporal regions of the hemisphere. It lies in the base of the fronto-parietal operculum and sweeps backwards over the insular region to the posterior end of the Sylvian fissure. Here it bends downwards round the hinder end of the putamen and proceeds forwards in the temporal lobe, to reach its anterior extremity. As it turns downwards to reach the temporal lobe numerous fibres radiate from it into the occipital lobe.

The **fasciculus longitudinalis inferior** is a very conspicuous bundle which extends along the whole length of the occipital and temporal lobes (Fig. 457, p. 570). In the occipital lobe it is placed on the outer aspect of the optic radiation, which takes a similar direction and from which it is distinguished by the greater coarseness of its fibres (Figs. 462, p. 576; 465, p. 578; 473, p. 592). It is not present in the macaque monkey (Ferrier and Turner), but is well developed in the orang and the chimpanzee,

The **fasciculus occipito-frontalis** is a bundle of fibres which runs in a sagittal direction in intimate relation to the lateral ventricle (Fig. 468, p. 582). It has been pointed out (Forel, Onufrowicz, and others) that, in cases where the corpus callosum fails to develop, the tapetum remains apparently unaffected, and Déjerine has endeavoured to prove that the fibres of this layer really belong to the fasciculus occipito-frontalis. According to Déjerine, the fasciculus occipito-frontalis lies on the inner aspect of the corona radiata in intimate relation to the caudate nucleus, and posteriorly it spreads out over the upper and outer aspect of the lateral ventricle, immediately outside the ependyma, where it constitutes the tapetum (see p. 588). There is a considerable amount of literature

dealing with this subject, and the most probable explanation of the difficulty would appear to be that the tapetum is composed of fibres derived from both the corpus callosum and the fasciculus occipito-frontalis of Déjerine.

**Projection Fibres.**—The projection fibres are those which connect the cerebral cortex with nuclear masses placed at a lower level. The great bulk of these fibres are found in the corona radiata. This has already been seen to be formed by the continuation upwards of the internal capsule (p. 583). In the corona radiata the fibres which, lower down, are gathered together in the compact mass which constitutes the internal capsule, radiate in every direction, intersect the radiation of the corpus callosum, and finally reach every region of the cortex. Although the fibres of the corona radiata represent the chief bulk of the projection fibres, it should also be borne in mind that a certain number gain the cortex by a different route, notably through and under the lenticular nucleus and by the path offered by the external capsule.

The projection fibres of the cerebral hemisphere may be classified into (1) corticipetal, and (2) corticifugal groups; and under these headings the following great strands may be arranged:—

| Corticipetal Projection Strands. | Corticifugal Projection Strands. |
|---|---|
| 1. Thalamo-cortical. | 1. The pyramidal or great motor tract. |
| 2. Corticipetal fibres of the optic radiation. | 2. The cortico-thalamic. |
| 3. The auditory radiation. | 3. The fronto-pontine strand. |
| | 4. The temporo-pontine strand. |
| | 5. The corticifugal fibres of the optic radiation. |

The **great motor** or **pyramidal tract** is composed of fibres which arise from pyramidal cells in that portion of the cortex which is spread over the Rolandic area, or, in other words, in the district immediately in front of the fissure of Rolando. The fibres descend through the corona radiata into the posterior limb of the internal capsule. From this point the further course of the pyramidal tract has been traced, viz. through the central part of the crusta of the crus cerebri, the ventral part of the pons, and the pyramid of the medulla oblongata. At the level of the foramen magnum it decussates in the manner already described, and enters the spinal cord as the crossed and direct pyramidal tracts. The fibres composing these end in connexion with the ventral or motor column of cells, from which the fibres of the anterior roots of the spinal nerves arise.

The **fronto-pontine strand** is composed of fibres which arise as the axons of the cells in the cortex which covers the portion of the frontal lobe, which lies in front of the præcentral furrows. It descends in the anterior limb of the internal capsule, enters the mesial part of the crusta of the crus cerebri, through which it gains the ventral part of the pons. In this its fibres end, by forming arborisations around the cells of the nucleus pontis.

The **temporo-pontine tract** consists of fibres which spring from the cells of that part of the cortex which covers the middle portions of the two upper temporal convolutions. It probably represents a corticifugal tract belonging to the auditory system, seeing that it springs to some extent from the auditory cortical area. The temporo-pontine tract passes inwards under the nucleus lenticularis, enters the retrolenticular part of the hinder limb of the internal capsule, and thus gains the outer part of the crusta of the crus cerebri. From this it descends into the ventral part of the pons, in which it ends in the nucleus pontis (Fig. 439, p. 546).

The **optic radiation** forms a very definite and easily demonstrated tract of longitudinally-directed fibres in the white medullary centre of the occipital lobe. It lies on the outer side of the ventricular cavity, from which it is separated by the fibres of the tapetum and the ependyma of the ventricle (Figs. 462, p. 576; and 465, p. 579). To the outer side of, and applied closely to, the optic radiation is another longitudinal tract of fibres in this part of the medullary centre of the cerebral hemisphere, viz. the inferior longitudinal association bundle; but the fibres of the latter fasciculus are coarser and are stained more deeply by the Pal-Weigert method, and thus they can, as a rule, be easily distinguished from the optic radiation. Traced

in a backward direction, the fibres of the optic radiation disperse and pass to the cortex of the occipital lobe on both its mesial and outer aspects. This is a matter of interest, seeing that the visual centre is placed in this cortical district, and more particularly on the mesial aspect in the immediate neighbourhood of the calcarine fissure (Flechsig and Henschen). When the optic radiation is followed in a forward direction it is seen to enter the retrolenticular part of the posterior limb of the internal capsule, from whence its fibres pass to the pulvinar of the optic thalamus, to the corpus geniculatum externum and the superior quadrigeminal body.

As we have noted, the optic radiation is composed partly of corticifugal and partly of corticipetal fibres (p. 552). The former arise from cells in the occipital cortex and end in the pulvinar and the superior quadrigeminal body; the corticipetal fibres arise in the pulvinar and in the corpus geniculatum externum and end in the occipital cortex (Ferrier and Turner).

The system of fibres which belong to the **mesial fillet** and the **superior cerebellar**

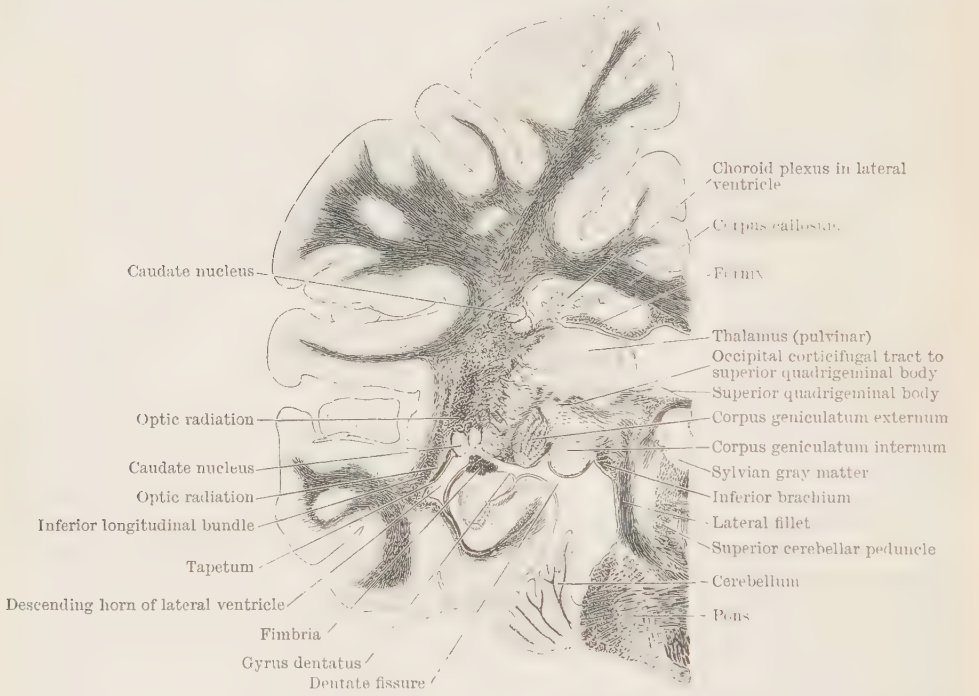

FIG. 473. — CORONAL SECTION THROUGH THE LEFT SIDE OF THE CEREBRUM, MESENCEPHALON, AND PONS, IN THE REGION OF THE PULVINAR OF THE THALAMUS, AND THE CORPORA GENICULATA (Chimpanzee; Weigert-Pal specimen).

**peduncle** have been already more or less fully dealt with (pp. 535 and 539). The **fillet system** represents the continuation upwards of the posterior columns of the cord. The first nuclear internodes in the system are met with in the medulla in the shape of the cuneate and gracile nuclei. It is here that the fillet first takes definite shape, and, as it passes upwards through the tegmental part of the medulla and pons, it receives many additions to its strength in the form of fibres from the nuclei of termination of the afferent cranial nerves. Finally, passing through the tegmentum of the mesencephalon, it reaches the subthalamic region and enters the ventral aspect of the thalamus. This may be looked upon as being the second internode laid across the path of the fillet, and its fibres end in arborisations around the thalamic cells.

The **fibres of the superior cerebellar peduncle** encounter two nuclear internodes as they pass towards the cerebral cortex, viz. the red tegmental nucleus and the optic thalamus (p. 536).

The **fibres of the auditory radiation** arise as the axons of cells situated in the internal geniculate body. They enter the retrolenticular part of the posterior limb of the internal capsule and proceed under the lenticular nucleus towards the

temporal lobe. Here they end in the area of cortex which constitutes the auditory centre. This corresponds to the middle portion of the superior temporal convolution, and also to the rudimentary transverse gyri of Heschl, which are present on the insular surface of the temporal operculum.

The **thalamo-cortical cortico-thalamic systems** include the fibres which constitute a double bond of connexion between the thalamus and all parts of the cortex. They are sufficiently described at p. 545.

The remarkable researches of Flechsig have added greatly to our knowledge of the different tracts of fibres in the cerebral hemisphere. By studying the periods at which these tracts myelinate he has been able to note the manner in which the different areas of the cortex are bound together and also linked on to subjacent centres. He has arrived at a highly important conception regarding the functional value of different districts of the cortex, founded upon their anatomical connexions. He recognises four sense-areas in the cortex, viz. the somæsthetic area, the visual area, the auditory area, and the olfactory area.

The **somæsthetic area** is the field of general sensibility and is the most extensive of all. It includes the two central convolutions, the posterior portions of the three frontal convolutions, the paracentral convolution, and the adjoining part of the callosal convolution.

The **visual area** is placed on the inner aspect of the occipital lobe, and more particularly in the immediate neighbourhood of the calcarine fissure.

The **auditory area** corresponds to the middle third of the superior temporal convolution and to the transverse gyri of Heschl.

The **olfactory area** includes the locus perforatus anticus, the trigonum olfactorium, the anterior part of the callosal convolution, and the uncus.

These sense-areas are peculiarly rich in their supply of projection fibres, and each is provided with an extensive system of both corticifugal and corticipetal fibres. Thus the somæsthetic area

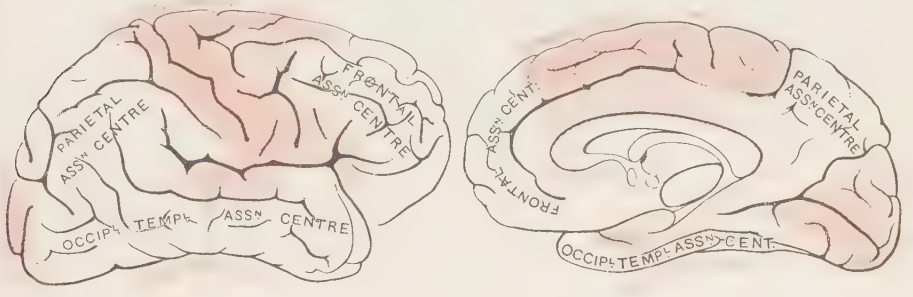

FIG. 474.—DIAGRAMS to show Flechsig's sensory and association areas on the surface of the cerebral hemisphere.

is the field where the motor pyramidal tract takes origin and within which the tracts of general sensibility end. The visual area has the corticipetal and corticifugal fibres of the optic radiation. The auditory area has the corticipetal auditory radiation and also the corticifugal temporopontine tract. In man the olfactory area is feebly developed, and Flechsig has not been able to establish, with certainty, its corticipetal and corticifugal projection tracts.

The sense-areas differ greatly from each other in the extent of cerebral surface which they cover. The size in each case is in strict conformity with the peripheral area with which each is in connexion. It can easily be understood, therefore, how the somæsthetic area, representing as it does on the cortex all the parts of the body outside the special organs of sense, from which sensory nerves proceed, should be so large. Further, it is manifest why the visual sensorial area, which in the cortex is the corresponding part to the retina, should be of greater extent than the auditory field, which represents the cochlea, and the olfactory area, which represents a small amount of olfactory mucous membrane in the nasal chamber.

The four sensorial areas, taken together, only form about one-third of the entire cerebral surface. The remaining two-thirds of the cortex constitute what Flechsig has termed the **association centres**. The great extent of these in man must be regarded as a special human characteristic. These centres differ from the sensorial areas in being poorly provided with projection fibres. They have little direct connexion with the centres which lie at a lower level. Indeed, the only direct bond of union over a very large extent of these association areas with lower centres consists of the thalamo-cortical fibres, which pass to them from the thalamus. But, on the other hand, they are rich in association fibres, and are linked in the most complete and perfect manner by these fibres to the sensorial areas.

Flechsig regards these association areas as constituting the portions of cortex in which the higher intellectual activities are carried on, and he further believes that they exercise an important controlling influence over the sense areas. More particularly is this control exhibited in the case of the great somæsthetic area, within which the influence of all bodily impressions is received and transformed into consciousness, and within which the impulses which are thereby

excited take definite form. These impulses, according to Flechsig, are, in a measure, in all properly-balanced minds, held in subjection by the higher feelings, which assume shape in the association centres.

In his study of the fœtal and infantile brain Flechsig has shown that the fibres of the sensory paths become medullated in the first instance; then the corticifugal fibres which go out from the sense-areas assume their sheaths of myelin; and, further, that it is not until a month after birth, and after the projection fibres in connexion with the sense-areas are myelinated, that the association areas become linked on by medullated association fibres with the sense-areas.

## Development of the Parts derived from the Fore-brain.

It has been previously noted that the fore-brain very early shows an obscure subdivision into a front portion, termed the telencephalon, and a hinder part, called the diencephalon, which corresponds more nearly to the original cavity of the fore-brain. The cavity of third ventricle is derived from both, and stretches forwards, therefore, to the lamina terminalis, which in its lower part is represented in the adult by the lamina cinerea.

The lateral wall of both sections of the primitive fore-brain shows a subdivision into a dorsal or alar and a ventral or basal lamina. The groove which indicates this separation is the sulcus of Monro, and is evident even in the adult brain.

In recognising an alar and basal lamina in the fore-brain the teaching of Professor His is followed. This subdivision, however, is not admitted by all observers, and some hold that the fore-brain is to be regarded as a great diverticular expansion which grows out from the mid-dorsal and alar laminæ of the mesencephalon.

**Alar Lamina.**—The alar part of the lateral wall of the *telencephalon* is pushed out to form the diverticulum, which ultimately constitutes the cerebral hemisphere, and thus from a very early period the primitive position of this part of the lateral wall is indicated by the wide foramen of Monro, or aperture of communication between the cavity of the cerebral hemisphere and the third ventricle.

The alar part of the lateral wall of the *diencephalon* is utilised for the development of the thalamus, the epithalamus, and the metathalamus. Of these the optic thalamus is derived from the anterior and by far the greatest part of the alar wall. It arises as a large oval swelling, which gradually approaches its fellow of the opposite side, and thus diminishes the width of the third ventricle. Finally, the two bodies come into contact in the mesial plane and cohere over an area corresponding to the gray commissure. This occurs about the end of the second month.

From that section of the lateral wall to which the name of metathalamus is given the two geniculate bodies arise. Each of these shows, in the first place, as a depression on the inside, and a slight elevation on the outside, of the wall of the diencephalon. As the thalamus grows backwards, it encroaches greatly upon the territory occupied by the geniculate bodies. It thus comes about that in the adult brain the internal geniculate body seems to hold a position on the lateral aspect of the mesencephalon, whilst the external geniculate body, viewed from the surface, appears to be a part of the thalamus.

From the epithalamic region of the wall of the diencephalon are developed the pineal gland, its peduncle, and the habenular region. These parts are relatively much more evident in the embryonic than in the adult brain. The pineal body is developed as a diverticulum of the posterior part of the roof of the diencephalon. Viewed from the dorsal aspect of the brain-tube, this diverticulum shows in the first instance as a rounded elevation, from either side of which a broad ridge runs forwards. This ridge becomes the tænia thalami, whilst in the region of its junction with the pineal elevation the trigonum habenulæ takes shape. The pineal diverticulum ultimately becomes solid, but a small portion of the original cavity is retained as the recessus pinealis of the third ventricle.

**Basal Lamina.**—The part of the diencephalon and telencephalon which represents the basal lamina lies below the level of the sulcus of Monro, retains its primitive form, and undergoes only slight change. Consequently, when this region in the adult brain is compared with the corresponding region in the embryonic brain, the resemblance between the two is very striking.

In the fore-brain, therefore, it is the alar lamina which plays the predominant part in the formation of the cerebrum. The value, also, of the basal part of the wall of this portion of the neural tube is still further reduced by the fact that it no longer contains the nuclei of origin of efferent nerves. The highest of these nuclei (the oculo-motor) is placed in the mesencephalon.

The region of the fore-brain which lies below the sulcus of Monro is termed the hypothalamus. The part of this which corresponds to the diencephalon is called the pars mammillaris hypothalami, whilst the part in front, which belongs to the telencephalon, receives the name of pars optica hypothalami.

From the pars mammillaris hypothalami are derived the corpus mammillare and a portion of the tuber cinereum. With the pars optica hypothalami are associated the following parts, viz. the tuber cinereum, with the infundibulum and the cerebral part of the pituitary body, the optic chiasma, the optic recess, and the lamina cinerea.

The corpora mammillaria form, in the first instance, a relatively large downward bulging of the floor of the brain-tube. As development goes on this bulging becomes relatively small, and about the fourth month the single projection becomes divided into the two tubercles.

The infundibulum and posterior or cerebral lobe of the pituitary body are developed as a hollow downward diverticulum of the floor of the telencephalon (p. 549). A portion of the original cavity is retained in the upper part of the infundibulum, and constitutes the infundibular recess in the floor of the third ventricle.

The optic nerve is chiefly formed by the passage of fibres backwards from the retina in the wall of the original optic stalk, whilst the chiasma takes form by the transit of fibres across the middle line in front of the infundibulum and behind the optic recess. To a large extent these fibres are derived from the optic nerve. The optic recess of the third ventricle marks the spot where the hollow optic vesicle originally bulged out from the lower and lateral part of the fore-brain, and in the adult it therefore represents a portion of the primitive cavity of the tubular stalk of the optic vesicle. In the course of development the optic nerve fibres, which appear in the stalk of the optic vesicle to form the optic nerve, seek an attachment much further back, and through the optic tract they are even carried as far as the mesencephalon.

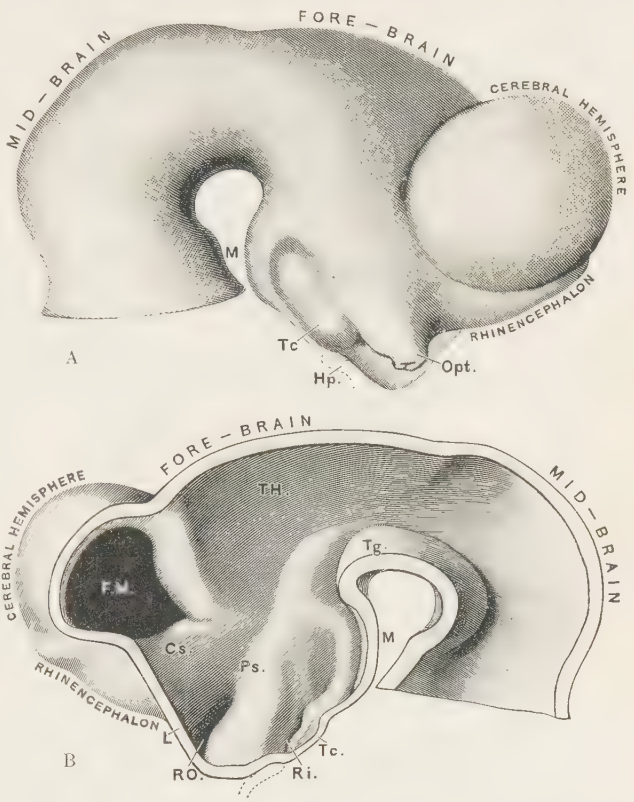

FIG. 475.—TWO DRAWINGS OF THE EMBRYONIC BRAIN (by His).

A, Reconstruction of the fore-brain and mid-brain of His's embryo KO; profile view. B, Same brain as A, divided along the mesial plane and viewed upon its inner aspect.

M, Mammillary eminence; T.c, Tuber cinereum; Hp, Hypophysis (pituitary diverticulum from buccal cavity); Opt, Optic stalk; TH, Optic thalamus; Tg, Tegmental part of mesencephalon; P.s, Par subthalamica; C.s, Corpus striatum; F.M, Foramen of Monro; L, Lamina terminalis; R.O, Recessus opticus; R.i, Recessus infundibuli.

The **roof of the fore-brain** remains thin, and does not proceed to the development of nervous elements, except in its posterior part. Here it forms the pineal body and the posterior commissure. In front of these structures the roof of the fore-brain is epithelial, and remains so during life. It constitutes the epithelial roof of the third ventricle, and it becomes involuted along the middle line into the cavity by the choroid plexuses of the ventricle. The posterior commissure appears as a transverse thickening at the bottom of a transverse groove which appears in the roof of the early brain-tube behind the pineal diverticulum.

**Cerebral Hemisphere.**—The cerebral hemisphere is derived from the alar section of the lateral wall of the telencephalon. From this it grows out and soon assumes very large dimensions. At first it grows forwards and upwards, and a distinct fissure, the

early incisura longitudinalis cerebri, appears between the cerebral hemispheres of opposite sides. The separation of the two cerebral vesicles by the longitudinal fissure begins at the end of the first month. This fissure becomes occupied by mesoblastic tissue, which later on forms the falx cerebri. The cerebral hemisphere, in its further growth, is carried progressively backwards over the hinder parts of the developing brain. At the end of the third month it has covered the optic thalamus. A month later it reaches the corpora quadrigemina, and by the seventh month it has not only covered these, but also the entire upper surface of the cerebellum.

At the end of the first month the olfactory lobe grows out as a hollow protrusion from

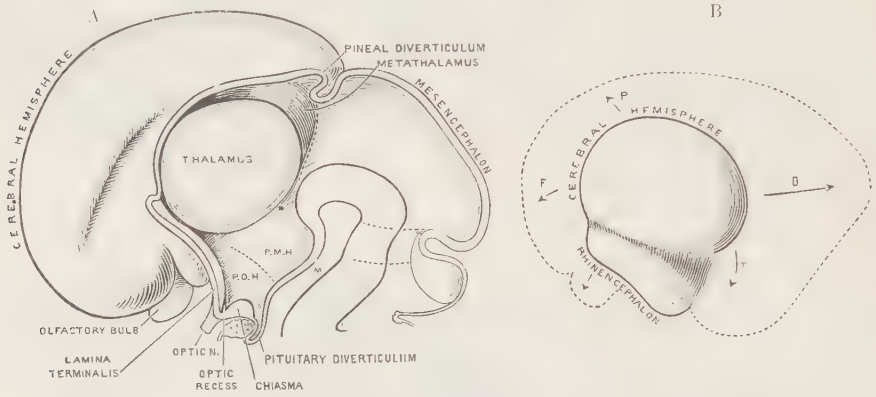

FIG. 476.—TWO DRAWINGS BY HIS, illustrating the development of the human brain.

the lower and fore part of the cerebral vesicle. This in course of time becomes solid and forms the olfactory tract and bulb. In the adult brain the point which corresponds to the original connexion between the early hollow olfactory diverticulum and the cavity of the cerebral vesicle is represented by the extremity of the anterior cornu of the lateral ventricle.

In the floor of the hollow cerebral hemisphere a thickening takes origin, and this ultimately is developed into the corpus striatum. On the outer surface of the vesicle this thickening is seen to correspond to a depression which constitutes the early Sylvian fossa, the further development of which is described on p. 556.

In the earlier stages of its development the cerebral hemisphere is a thin-walled vesicle with a relatively large cavity, which represents the primitive condition of the lateral ventricle. At first the vesicle is bean-shaped and the cavity is curved. At this stage the outline is very similar to that presented by the cerebral hemisphere of a quadruped, and there is little or no trace of an occipital lobe or of a posterior horn of the lateral ventricle. As development goes on, however, the occipital portion of the hemisphere grows backwards over the cerebellum in the shape of a hollow protrusion, and a distinct occipital lobe enclosing the posterior horn of the lateral ventricle is the result. This developmental stage, which is distinctive of man and the apes, begins about the fourth month.

On the mesial aspect of the cerebral hemisphere, in the early stages of its development, an invagination of the wall of the vesicle takes place into the cavity immediately above and behind the large foramen of Monro. This is the choroidal fissure, and the fold of the cerebral wall, which is thus thrust into the cavity, remains thin and entirely epithelial. After a time mesoblastic tissue from the great longitudinal fissure finds its way into the choroidal fissure and occupies the interval between the two thin layers which form the fold. This mesoblastic tissue forms the choroid plexus of the lateral ventricle, and in the early stages of the hemisphere it is so voluminous that it fills up the relatively large cavity of the lateral ventricle.

**Development of the Gyri and Sulci.**—In the early stages of its development, the surface of the cerebral hemisphere is smooth and closely applied to the deep surface of the cranial capsule within which it is enclosed.

After the occipital lobe is fully formed and the fifth month is reached, the cranium grows for a time more rapidly than the brain, with the result that a relatively wide space is

left between the cerebral surface and the surrounding cranial envelope. This is occupied by sodden subarachnoid tissue, and when this stage is reached (in the latter part of the fifth month) the sulci and gyri begin to make their appearance. The incomplete sulci owe their origin to the upheaval of the cerebral cortex on either side of the appearing fissures, and the gyri which bound them are formed as the result of an exuberance of surface growth in localised areas. Owing to the wide interval between the cranial wall and the surface of the cerebral hemisphere, the particular surface areas which grow and foreshadow the future gyri suffer no restriction, and they take the form of rounded eminences which rise from the general surface level of the cerebral hemisphere. As growth goes on, however, the brain gradually assumes a bulk more nearly in accord with the cavity of the cranium, and the space for extension becomes more limited. Finally, about the beginning of the eighth month, the gyral elevations come into close contact with the cranial wall, and a stage of growth-antagonism between the brain and its enclosing capsule is entered upon. As a result of this the gyri are pressed together, the fissures assume more definite shape, and the ordinary convolutionary forms make their appearance. So intimate, indeed, is the contact between the cerebral hemisphere and the skull capsule that the gyri, to some extent, produce an imprint on the deep aspect of the cranial bones.

As already explained, the complete fissures are produced by an infolding of the wall of the cerebral vesicle.

**Cerebral Commissures.**—The development of the cerebral commissures is surrounded with much difficulty. It would seem that the corpus callosum, the anterior commissure, and the fornix all take origin in the lamina terminalis. The triangular interval which is left between these commissures is occupied by the septum lucidum—a structure which has an intimate developmental and morphological connexion with the gyrus subcallosus. The great development of the corpus callosum in man is to be associated with the enormous expansion of the human neo-pallium of which it is the commissure.

### Weight of the Brain.

The average weight of the adult male brain may be said to be about 1360 grammes. The female brain weighs rather less, but this is to be expected from the smaller bulk of the female body. Probably the relative weight of the brain in the two sexes is very much the same. The variations met with in brain-weight are very great, but it is doubtful if normal intellectual functions could be carried on in a brain which weighs less than 960 grammes. In microcephalic idiots brains of extremely small size are met with.

## THE MENINGES OF THE BRAIN AND SPINAL CORD.

The brain and spinal cord are enclosed within three membranes, which are termed the meninges or meningeal membranes. From without inwards these are: (1) the dura mater, (2) the arachnoid mater, and (3) the pia mater. The space between the dura mater and the arachnoid receives the name of subdural space, while the much more roomy interval between the arachnoid and the pia mater is called the subarchnoid space.

### Dura Mater.

The dura mater is a dense and thick fibrous membrane which possesses a very considerable degree of strength. Its arrangement within the cranial cavity is so different from that within the spinal canal that it is customary to speak of it as consisting of two parts, viz. a cranial and a spinal, although in adopting this subdivision it must be clearly understood that both portions are continuous with each other at the foramen magnum.

**Cranial Dura Mater** (dura mater cerebri).—The cranial dura mater is adherent to the inner surface of the cranial wall, and performs a double office. It serves as an internal periosteum for the bones which it lines and constitutes an envelope for the brain. Its inner surface, which bounds the subdural space, is smooth and glistening, and is covered by a layer of endothelial cells. The outer surface, when separated from the cranial wall, is rough, this being due to numerous fine fibrous processes and blood-vessels which pass between it and the bones. Its degree of

adhesion to the cranial wall differs considerably in different regions. To the vault of the cranium, except along the lines of the sutures, the connexion is by no means strong, and in the intervals between the fibrous processes which pass into the bone there are small lymph spaces (epidural spaces) where the outer surface of the membrane is covered by endothelial cells. So long as the sutures are open the dura mater is connected with the periosteum on the exterior of the skull, along the sutural lines, by a thin layer of fibrous tissue which intervenes between the bony margins. Around the foramen magnum, and to the floor of the cranium, the dura mater is very firmly adherent. This is more particularly marked in the case of the projecting parts of the cranial floor, as, for example, the petrous portions of the temporal bones, the clinoid processes, and so on. This firm adhesion in these regions is still further strengthened by the fact that the nerves, as they leave the cranium through the various foramina, are followed by sheaths of the fibrous dura

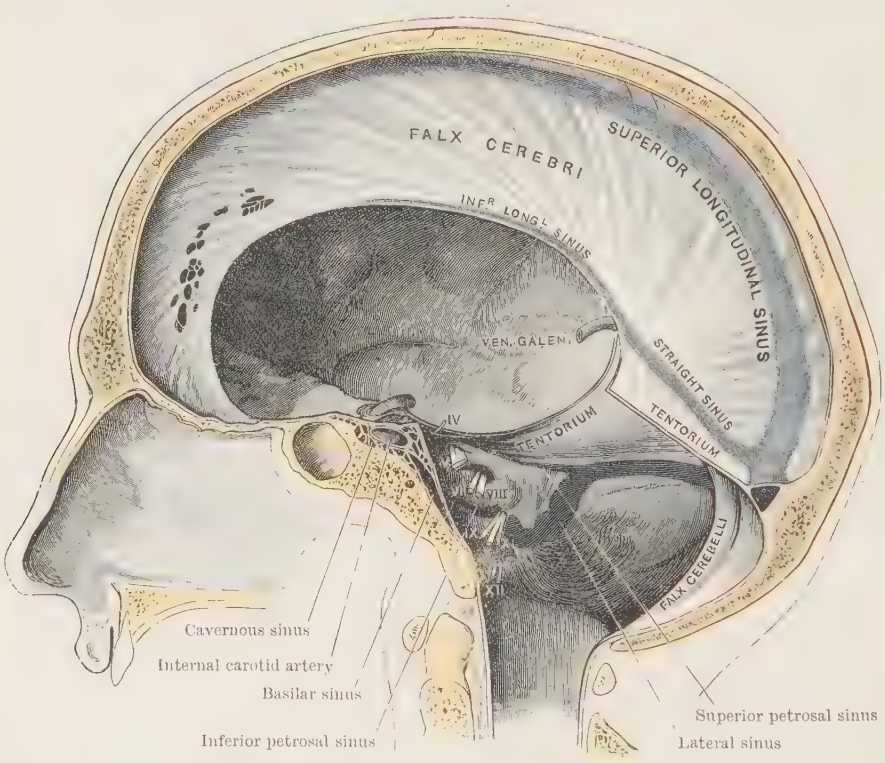

FIG. 477.—SAGITTAL SECTION THROUGH THE SKULL, A LITTLE TO THE LEFT OF THE MESIAL PLANE, to show the arrangement of the dura mater.

The cranial nerves are indicated by numerals.

mater. Outside the cranium these prolongations of the membrane blend with the fibrous sheaths of the nerves, and likewise become connected with the periosteum on the exterior of the skull. In the child, during the growth of the cranial bones, and also in old age, the dura mater is more adherent to the cranial wall than during the intermediate portion of life.

The cranial dura mater is composed of two layers intimately connected with each other, but yet capable of being demonstrated in most regions of the cranium. Along certain lines these two layers separate from each other so as to form channels lined by endothelium. These channels are the **venous blood-sinuses** which receive the blood from veins which come from various parts of the brain. They are described in the section dealing with the Vascular System.

Strong fibrous partitions or septa are given off along certain lines from the deep surface of the dura mater. These project into the cranial cavity, and subdivide it partially into compartments which all freely communicate with each other, and

each of which contains a definite subdivision of the brain. These septa are: (1) the falx cerebri; (2) the tentorium cerebelli; (3) the falx cerebelli; and (4) the diaphragma sellæ.

The **falx cerebri** is a sickle-shaped partition which descends in the great longitudinal fissure between the two hemispheres of the cerebrum. In front it is narrow, and attached to the crista galli of the ethmoid bone. As it is followed backwards it increases in breadth, and behind it is attached along the mesial plane to the upper surface of the tentorium. The anterior narrow part of the falx is frequently cribriform, and is sometimes perforated by apertures to such an extent that it almost resembles lace-work. Along each border it splits into two layers, so as to enclose a blood-sinus. Along its upper convex attached border runs the *great longitudinal sinus*; along its concave free border courses the much smaller *inferior longitudinal sinus*; whilst along its attachment to the tentorium is enclosed the *straight sinus.*

The **tentorium cerebelli** is a large crescentic partition of dura mater, which forms a membranous tent-like roof for the posterior cranial fossa, and thus intervenes between the posterior portions of the cerebral hemispheres and the cerebellum. It is accurately applied to the upper surface of the cerebellum. Thus its highest point is in front and in the mesial plane, and from this it slopes downwards towards its attached border. It is kept at a high degree of tension, and this depends on the integrity of the falx cerebri, which is attached to its upper aspect in the mesial plane.

The *posterior border* of the tentorium is convex, and is attached to the horizontal ridge which marks the deep surface of the occipital bone. Beyond this, on each side, it is fixed to the postero-inferior angle of the parietal bone, and then forwards along the superior border of the petrous portion of the temporal bone. From the internal occipital protuberance to the postero-inferior angle of the parietal bone this border encloses the *lateral blood-sinus*, whilst along the upper border of the petrous bone it encloses the *superior petrosal sinus.* The *anterior border* of the tentorium is sharp, free, and concave, and forms with the dorsum sellæ an oval opening shaped posteriorly like a pointed arch. This opening receives the name of the **incisura tentorii**, and within it is placed the mesencephalon, or the stalk of connexion between the parts which lie in the posterior cranial fossa and the cerebrum. Beyond the apex of the petrous part of the temporal bone the two margins of the tentorium cross each other like the limbs of the letter X; the free margin is continued forwards, to be attached to the anterior clinoid process, whilst the attached border proceeds inwards, to be fixed to the posterior clinoid process.

The **falx cerebelli** is a small, sickle-shaped process of dura mater placed below the tentorium, which projects forwards in the mesial plane from the internal occipital crest. It occupies the notch which separates the two hemispheres of the cerebellum posteriorly. Inferiorly it bifurcates into two small diverging ridges which gradually fade away as they are traced forwards on either side of the foramen magnum.

The **diaphragma sellæ** is a small circular fold of dura mater which forms a roof for the pituitary fossa. A small opening is left in its centre for the transmission of the infundibulum.

**Spinal Dura Mater** (dura mater spinalis).—In the spinal canal the dura mater forms a tube which encloses the spinal cord, and which extends from the foramen magnum above to the level of the second or third piece of the sacrum below. It is very loosely applied to the spinal cord and the nerve-roots which form the cauda equina; in other words, it is very capacious in comparison with the volume of its contents. Moreover, its calibre is not uniform. In the cervical and lumbar regions it is considerably wider than in the dorsal region, whilst in the sacral canal it rapidly contracts, and finally ends by blending with the filum terminale externum, the chief bulk of which it forms. At the upper end of the spinal canal the spinal dura mater is firmly fixed to the third cervical vertebra, to the axis vertebra, and around the margin of the foramen magnum. In the sacral canal the filum terminale externum, with which it blends, extends downwards to the back of the coccyx, to the periosteum of which it is fixed. The lower end of the tube is thus securely anchored and held in its place.

Within the cranial cavity the dura mater is closely adherent to the bones, and forms for them an internal periosteum. As it is followed into the spinal canal its two constituent layers separate. The inner layer is carried downwards as the long cylindrical tube which encloses the spinal cord. The outer layer, which is much thinner, becomes continuous behind and on each side of the foramen magnum with the periosteum on the exterior of the cranium, whilst in front it is prolonged downwards into the vertebral canal in connexion with the periosteum and ligaments on the anterior wall of the canal. The spinal dura mater, therefore, corresponds to the inner layer of the cranial dura mater, and to it alone. It is separated from the walls of the spinal canal by an interval, the **epidural space**, which is occupied by soft fat and a plexus of thin-walled veins. In connexion with the spinal dura mater there are no blood-sinuses such as are present in the cranial cavity, but it should be noted that the veins in the epidural space, placed as they are between the periosteum of the spinal canal and tube of dura mater, occupy the same morphological plane as the cranial blood-sinuses. Another feature which serves to distinguish the spinal dura mater from the cranial dura mater consists in the fact that it gives off from its deep surface no partitions or septa.

The cylindrical tube of spinal dura mater does not lie absolutely free within the vertebral canal. Its attachments, however, are of such a character that they in no way interfere with the free movement of the vertebral column. On either side the spinal nerve-roots, as they pierce the dura mater, carry with them into the intervertebral foramina tubular sheaths of the membrane, whilst in front loose fibrous prolongations—more numerous above and below than in the dorsal region—connect the tube of dura mater to the posterior common ligament of the vertebral column. No connexion of any kind exists between the dura mater and the posterior wall of the spinal canal.

When the interior of the tube of spinal dura mater is inspected, the series of apertures of exit for the roots of the spinal nerves is seen. These are ranged in pairs opposite each intervertebral foramen.

Viewed from the inside of the tube of dura mater, each of the two roots of a spinal nerve is seen to carry with it a special and distinct sheath. When examined on the outside, however, the appearance is such that one might be led to conclude that both roots are enveloped in one sheath of dura mater. This is due to the fact that the two sheaths are firmly held together by intervening connective tissue. The two tubular sheaths remain distinct as far as the ganglion on the posterior root, and then blend with each other.

**Subdural Space.**—The dura mater and the arachnoid mater are closely applied to each other, and the capillary interval between them is termed the subdural space. It contains a minute quantity of fluid, which is just sufficient in amount to moisten the opposed surfaces of the two bounding membranes.

The subdural space in no way communicates with the subarachnoid space. The fluid which it contains is led into the venous blood-sinuses around the Pacchionian bodies, and thus gains exit. The subdural space is carried outwards for a very short distance on the various nerves which are connected with the brain and the spinal cord, and it has a free communication with the lymph-paths present in these nerves. In the case of the optic nerve the sheath of dura mater is carried along its whole length, and with it the subdural space is likewise prolonged to the back of the eyeball.

### The Arachnoidea.

The arachnoid mater is a very thin membrane, remarkable for its delicacy and transparency, which envelopes both the brain and the cord between the dura mater and the pia mater. The cranial part of the arachnoid mater or the **arachnoidea encephali**, except in the case of the great longitudinal and the Sylvian fissures, does not dip into the sulci on the surface of the brain. In this respect it differs from the pia mater. It bridges over the inequalities on the surface of the brain. Consequently, on the basal aspect of the encephalon it is spread out in the form of a very distinct sheet over the medulla, the pons Varolii, and the hollow which lies

in front of the pons, and in certain of these regions it is separated from the brain-surface by wide intervals.

The spinal part of the arachnoid mater or **arachnoidea spinalis**, which is directly continuous with the cranial arachnoidea, forms a loose wide investment for the spinal cord. This arachnoidal sac is most capacious towards its lower part, where it envelopes the lower end of the cord and the collection of long nerve-roots which constitute the cauda equina.

As the nerves, both from the brain and the cord, pass outwards they receive an investment from the arachnoid, which runs for a short distance upon them and then comes to an end.

**Subarachnoid Space** (cavum subarachnoidale).—The interval between the arachnoidea and the pia mater receives the name of the subarachnoid space. It

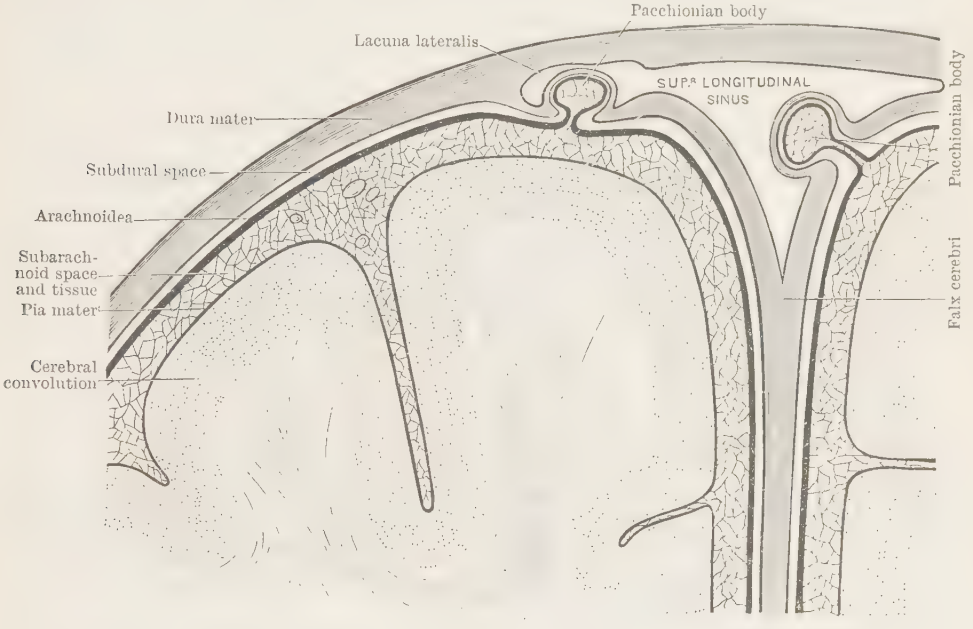

FIG. 478.—DIAGRAM to show the relations of the membranes of the brain to the cranial wall and the cerebral convolutions, and also of the Pacchionian bodies to the superior longitudinal sinus and the lateral lacunæ.

contains the cerebro-spinal fluid, and communicates freely through certain well-defined apertures with the ventricular cavities in the interior of the brain. Three of these (viz. the foramen of Majendie and another at the extremity of each lateral recess) are in connexion with the fourth ventricle; two are slit-like openings into the lateral ventricles, and are placed at the extremity of each descending horn.

Within the cranium the subarachnoid space is broken up by a meshwork of fine filaments and trabeculæ, which connects the two bounding membranes (viz. the arachnoidea and the pia mater) in the most intimate manner, and forms a delicate sponge-like interlacement between them. Where the arachnoidea passes over the summit of a cerebral convolution, and is consequently closely applied to the subjacent pia mater, the meshwork is so dense and the trabeculæ so short that it is hardly possible to discriminate between the two membranes. To all intents and purposes they form in these localities one lamina. In the intervals between the rounded margins of adjoining convolutions, however, distinct angular spaces exist, where the subarachnoid trabecular tissue can be studied to great advantage. These intervals on the surface of the cerebrum constitute numerous communicating channels which serve for the free passage of the subarachnoid fluid from one part of the brain to another. The larger branches of the arteries and veins of the brain traverse the subarachnoid space; their walls are directly connected with the subarachnoid trabeculæ, and are bathed by subarachnoid fluid.

In certain situations within the cranium the arachnoidea is separated from the

pia mater by intervals of considerable width and extent. These expanded portions of the subarachnoid space are termed **cisternæ subarachnoidales**. In these the subarachnoid tissue is much reduced. There is no longer a close meshwork; the trabeculæ connecting the two bounding membranes take the form of long filamentous intersecting threads which traverse the spaces. All the subarachnoid cisterns communicate in the freest manner with each other and also with the narrow channels on the surface of the cerebrum.

Certain of these cisterns require special mention. The largest and most conspicuous is the **cisterna magna**. It is formed by the arachnoid membrane bridging over the wide interval between the back part of the under surface of the cerebellum and the medulla. It is continuous through the foramen magnum with the posterior part of the wide subarachnoid space of the cord.

The **cisterna pontis** is the continuation upwards on the floor of the cranium of the anterior part of the subarachnoid space of the spinal cord. In the region of the medulla it is continuous behind with the cisterna magna, so that this subdivision of the brain, like the spinal cord, is surrounded by a wide subarachnoid space.

In front of the pons Varolii the arachnoidea bridges across between the projecting temporal lobes, and covers in the deep hollow in this region of the brain. This space is called the **cisterna basalis**, and within it are placed the large arteries which take part in the formation of the circle of Willis. Leading out from the cisterna basalis there are certain wide subarachnoid channels. Two of these are prolonged into the Sylvian fissures, and in these are accommodated the middle cerebral arteries. Anteriorly the basal cistern passes into a space in front of the optic chiasma, and from this it is continued into the great longitudinal fissure above the corpus callosum. In this subarachnoid passage the anterior cerebral arteries are lodged.

The spinal part of the subarachnoid space is a very wide interval which is partially subdivided into compartments by three incomplete septa. One of these is a mesial partition called the **septum posticum**, which connects the pia mater covering the posterior aspect of the cord with the arachnoid mater. In the upper part of the cervical region the septum posticum is imperfect, and is merely represented by some strands passing between the two membranes; in the lower part of the cervical region and in the dorsal region it becomes tolerably complete. The other two septa are formed by the **ligamenta denticulata** which spread outwards from either side of the spinal cord. These will be described with the pia mater.

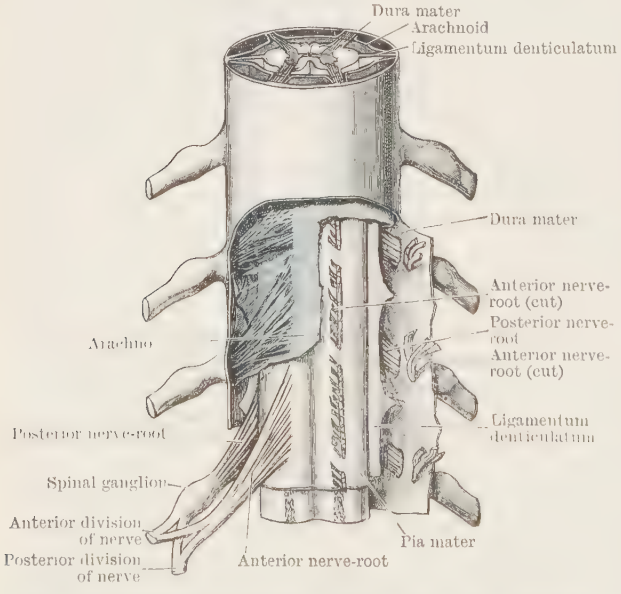

FIG. 479.—MEMBRANES OF THE SPINAL CORD, AND THE MODE OF ORIGIN OF THE SPINAL NERVES.

**Pacchionian Bodies** (granulationes arachnoidales).—When the surface of the dura mater is inspected after the removal of the calvaria, a number of small fleshy-looking excrescences, purplish-red in colour, are seen ranged in clusters on either side of the superior longitudinal sinus, and when this sinus is opened they are also observed protruding in considerable numbers into its interior. These are the Pacchionian bodies, and they are also found in smaller number and distinctly smaller size in connexion with other blood-sinuses, such as the lateral sinus, the

straight sinus, and the cavernous sinus. At first sight they appear to belong to the dura mater, but in reality they are projections from the arachnoidea. In the child they are exceedingly small and rudimentary, and it is only as life advances that they become large and conspicuous.

Each Pacchionian body is a bulbous protrusion of the arachnoid membrane. It is attached to the arachnoidea by a narrow pedicle, and into its interior is prolonged through this a continuation of the subarachnoid space and its characteristic meshwork. The Pacchionian bodies do not pierce the dura mater. As they push their way into a blood-sinus they carry before them a thin covering continuous with the sinus wall. On either side of the superior longitudinal sinus there are a number of irregular spaces in the dura mater which communicate with the sinus either by a small aperture or a narrow channel. These spaces are called the **parasinoidal sinuses** or the **lacunæ laterales**, and certain of the meningeal veins and some of the diploic veins open into them. Pacchionian bodies push themselves into the parasinoidal sinuses from below in such a manner that they receive a

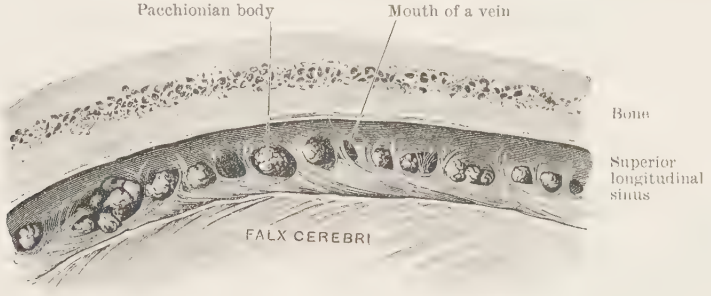

Fig. 480.—Mesial Section through the Cranial Vault in the Frontal Region. Displays a portion of the superior longitudinal sinus and the Pacchionian bodies protruding into it (enlarged).

complete covering from the layer of dura mater which forms the sinus floor. Nor does the bone escape. As the Pacchionian bodies enlarge they cause absorption of the cranial wall, and small pits are hollowed out on its deep surface for their reception. It must be clearly understood, however, that in such cases the Pacchionian body is separated from the bone by the following:—(1) A continuation round the Pacchionian body of the subdural space; (2) the thinned floor of the parasinoidal sinus; (3) the lumen of the sinus; and (4) the greatly thinned upper wall of the sinus.

The Pacchionian bodies have a special function to perform. Through them fluid can pass from the subarachnoid space into the venous sinuses with which they stand in connexion. Whenever the pressure of blood in the sinuses is lower than that of the fluid in the subarachnoid space and the ventricles of the brain, the cerebro-spinal fluid filtrates through the Pacchionian bodies into the blood-sinuses. This is not the only way that subarachnoid fluid may obtain exit. The subarachnoid space is carried outwards for a short distance on the nerves in connexion with their arachnoidal sheaths, and communicates with the lymph channels of the nerves. This connexion is more complete in the case of the olfactory, the optic, and the auditory nerves, than in other nerves. A very free communication between the subarachnoid space and the lymphatics of the nasal mucous membrane is said to exist.

## The Pia Mater.

The pia mater forms the immediate investment of the brain and cord. It is a delicate and very vascular membrane.

**Pia mater encephali.**—The pia mater which covers the brain is finer and more delicate than that which clothes the spinal cord. It follows closely all the inequalities on the surface of the brain, and in the case of the cerebrum it dips into each sulcus in the form of a fold which lines it completely. On the cerebellum the relation is not so intimate; it is only into the larger fissures that it penetrates in the form of folds.

The larger blood-vessels of the brain lie in the subarachnoid space. The finer twigs ramify in the pia mater before they proceed into the substance of the brain. As they enter they carry with them sheaths derived from the pia mater. When a portion of the membrane is raised from the surface of the encephalon, numerous fine processes are withdrawn from the cerebral surface. These are the blood-vessels with their sheaths, and they give the deep surface of the pia mater a rough and flocculent appearance.

As the pia mater is carried over the lower part of the roof or posterior wall of the fourth ventricle of the brain it receives the name of the **tela choroidea inferior**, and it is in connexion with this portion of the pia mater that the choroid plexuses of that cavity are developed. The tela choroidea superior or velum interpositum is a fold of pia mater which is invaginated into the brain, so that it comes to lie over the third ventricle and project in the shape of choroid plexuses into the lateral ventricles. This invagination requires special notice.

The **velum interpositum** (tela choroidea superior) is a double layer or fold of pia mater which intervenes between the body of the fornix which lies above it and the epithelial roof of the third ventricle, and the two optic thalami which lie below it. Between its two layers are blood-vessels, and some subarachnoidal trabecular tissue. In shape the velum interpositum is triangular, and the narrow anterior end or apex reaches forwards as far as the foramina of Monro. The base lies under the splenium of the corpus callosum, and here the two layers of the velum separate and become continuous with the investing pia mater on the surface of the brain by passing out through a cleft called the **transverse fissure.**

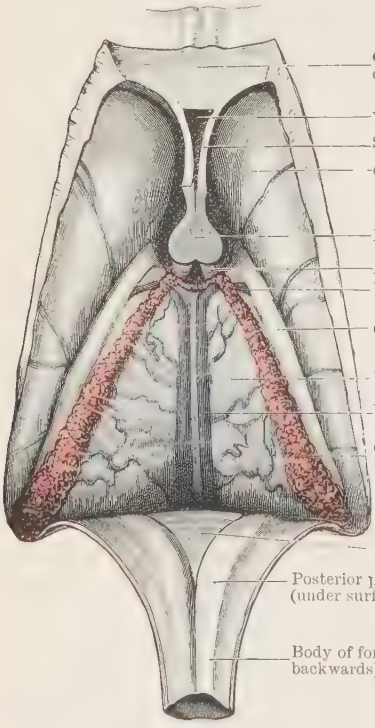

FIG. 481.—DISSECTION TO SHOW THE VELUM INTERPOSITUM, AND THE PARTS IN IMMEDIATE RELATION TO IT.

Along each lateral margin the velum interpositum is bordered by the choroid plexus of the body of the lateral ventricle, which projects into the ventricular cavity from under cover of the free lateral margin of the fornix. It should be borne in mind that the epithelial lining of the ventricle gives a complete covering to the choroid plexus. Posteriorly the choroid plexus is continuous with the similar structure in the descending horn of the ventricle, whilst in front it narrows greatly, and becomes continuous across the mesial plane with the corresponding plexus of the opposite side, behind the epithelial layer which lines the foramen of Monro. From this median junction two much smaller choroid plexuses run backwards on the under surface of the velum interpositum, and project downwards into the third ventricle. These are the choroid plexuses of the third ventricle.

The most conspicuous blood-vessels in the velum interpositum are the two **veins of Galen,** which run backwards, one on either side of the mesial plane. In front, each is formed at the apex of the fold by the union of the vein of the corpus striatum and a large vein issuing from the choroid plexus; behind, they unite to form the **vena magna Galeni,** and this pours its blood into the anterior end of the straight sinus (Fig. 477, p. 598).

The continuous cleft in the brain through which the velum interpositum and the choroid plexuses of the two descending horns of the lateral ventricles are

introduced into the interior of the brain is sometimes called the **transverse fissure**. It consists of an upper intermediate part and two lateral parts. The former passes forwards between the corpus callosum and the fornix above and the roof of the third ventricle and the optic thalami below. It is limited on either side by the epithelial covering of the choroid plexuses, which shuts out these structures from the cavity of the lateral ventricles. The lateral part is the **choroidal fissure**. This is continuous with the intermediate part, and has already been described in connexion with the descending horn of the lateral ventricle (p. 578).

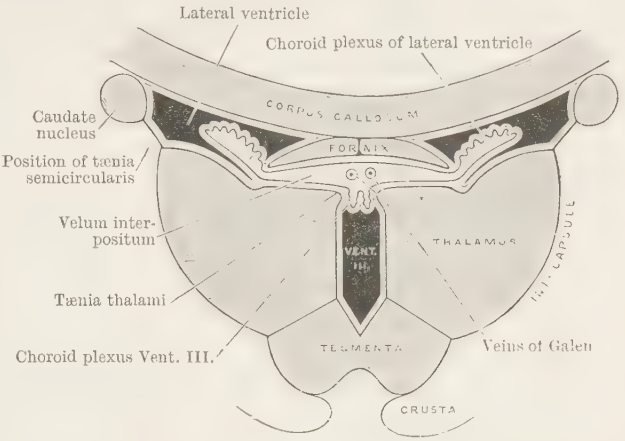

FIG. 482.—DIAGRAMMATIC CORONAL SECTION through the optic thalami, and the parts in immediate relation to them. The intermediate part of the great transverse fissure holding the velum interpositum is seen, and also the manner in which this fissure is shut out from the lateral ventricles by the epithelium which covers the choroid plexus on each side.

**Pia mater spinalis.**—The pia mater of the cord is thicker and denser than that of the brain. This is largely due to the addition of an outside fibrous layer, in which the fibres run chiefly in the longitudinal direction. The pia mater is very firmly adherent to the surface of the cord, and in front it sends a fold into the antero-median fissure of the cord. The septum which occupies the postero-median fissure is likewise firmly attached to its deep surface. In front of the antero-median furrow of the cord the pia mater is thickened in the form of a longitudinal glistening band, termed the **linea splendens**, which runs along the whole length of the cord, and blends with the filum terminale below. The blood-vessels of the spinal cord lie between the two layers of the pia mater.

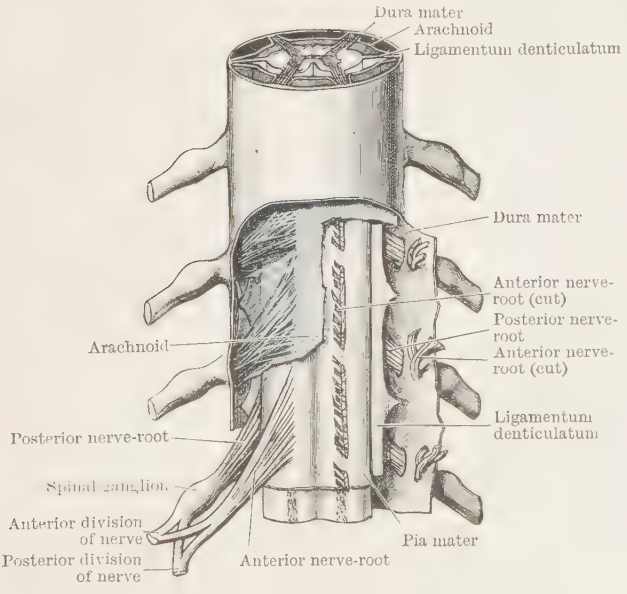

FIG. 483.—MEMBRANES OF THE SPINAL CORD, AND THE MODE OF ORIGIN OF THE SPINAL NERVES.

The nerves which leave both the brain and cord receive closely-applied sheaths from the pia mater. These blend with the connective-tissue sheaths of the nerves.

The **ligamentum denticulatum** is a strong fibrous band which stretches out like a wing from the pia mater on either side of the spinal cord, so as to connect the pia mater with the dura mater. The pial or inner attachment of the ligament extends in a continuous line between the anterior and posterior nerve-roots, from the level of the foramen magnum above to the level of the first lumbar vertebra below. Its outer margin is serrated or denticulated, and for the most part free. From twenty to twenty-two denticulations may be recognised. They occur in the intervals between the spinal nerves, and pushing the arachnoid before them, they

are attached by their pointed ends to the inner surface of the dura mater. The ligamenta denticulata partially subdivide the wide subarachnoid space in the spinal canal into an anterior and a posterior compartment. The anterior nerve-roots traverse the anterior compartment, whilst the posterior nerve-roots traverse the posterior compartment. Further, the posterior compartment is imperfectly subdivided into a right and a left lateral part by the septum posticum.

By means of the ligamenta denticulata the spinal cord is suspended in the middle of the tube of dura mater.

# THE PERIPHERAL NERVES AND THE SYMPATHETIC NERVOUS SYSTEM.

By A. M. Paterson.

Arising from the brain and spinal cord respectively, the cranial and spinal nerves are responsible, collectively, for the central localisation of peripheral stimuli, or for the transmission peripherally of central impulses. The sense organs and the somatic regions of the body are in direct communication by the nerves with the brain and spinal cord. The splanchnic area, and the viscera which it contains, are governed by nerves connected with the central nervous system. By means of the sympathetic nervous system, the nerves from the cerebro-spinal system are directed to their several destinations in the splanchnic area: and connexions are effected with the roots of the nerves on the one hand, and through their peripheral branches, with the somatic region, on the other hand.

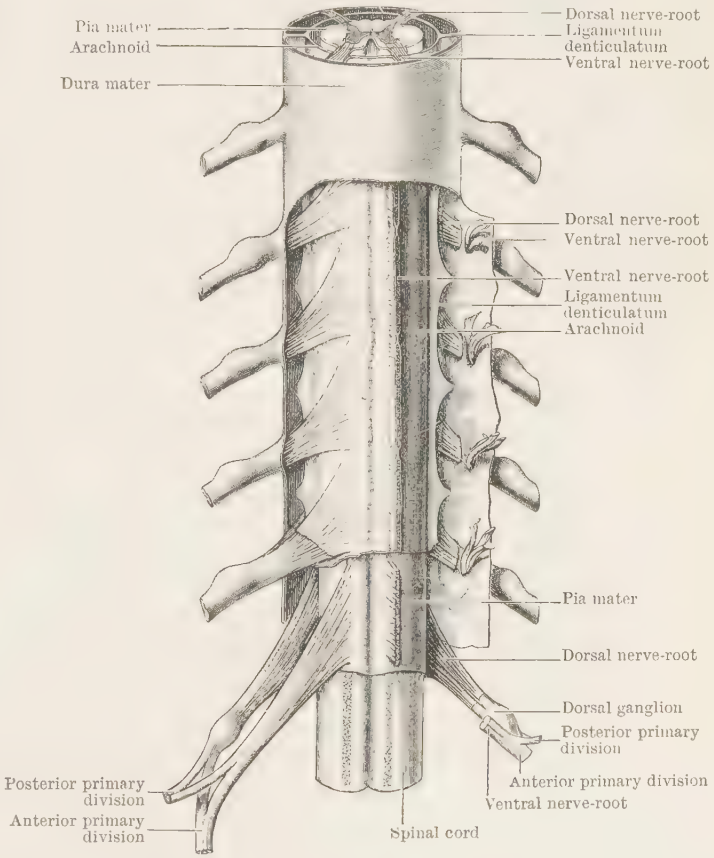

Fig. 484.—Scheme of the Arrangement of the Membranes of the Spinal Cord and the Roots of the Spinal Nerves.

## THE SPINAL NERVES.

The **spinal nerves** are arranged in pairs, of which there are usually thirty-one. Each nerve arises by two roots from the spinal cord, which separately pierce the dura mater. Enclosed in a tubular investment of this membrane, the nerve emerges from the spinal canal through the intervertebral foramen, and is distributed to the trunk and limbs in a manner to be described below.

The nerves are designated **cervical, thoracic, lumbar, sacral,** and **coccygeal,** in relation to the vertebræ between which they emerge from the spinal canal. Each nerve appears below the corresponding vertebra, except the first of the cervical series,

which passes out of the spinal canal between the occipital bone and the atlas. There are thus *eight* cervical nerves (the last appearing between the seventh cervical and first thoracic vertebræ); there are *twelve* thoracic, *five* lumbar, *five* sacral, and *one* coccygeal nerve, all appearing below the corresponding vertebræ.

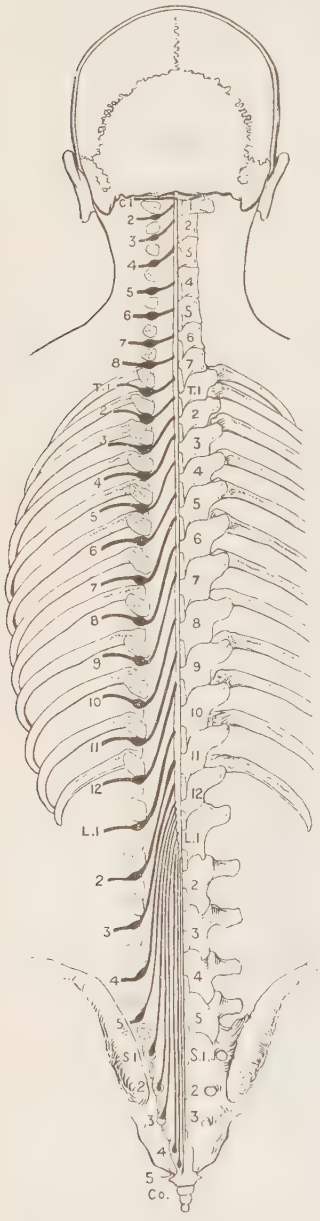

FIG. 485.—DIAGRAMMATIC REPRESENTATION OF THE ORIGIN OF THE SPINAL NERVES, showing the position of their roots and ganglia respectively in relation to the spinal column. The nerves are shown as thick black lines on the left side.

The thirty-first nerve is occasionally absent; and there are sometimes one or two additional pairs of minute filaments below the thirty-first, which, however, do not emerge from the spinal canal. These are rudimentary caudal nerves.

The size of the spinal nerves varies extremely. The largest are those which take part in the formation of the great nerve-trunks for the supply of the limbs (lower cervical and first thoracic, and lower lumbar and upper sacral nerves); and of these the nerves destined for the lower limbs are the larger. The coccygeal nerve is the smallest of the spinal nerves; the thoracic nerves (except the first) are much more slender than the limb nerves; and the cervical nerves diminish in size from below upwards.

**Origin of the Spinal Nerves.**—Each spinal nerve is attached to the spinal cord by **two roots**, called respectively **dorsal** (posterior) and **ventral** (anterior).

The **dorsal root** is larger than the ventral root; it contains a larger number of rootlets, and the individual rootlets are of larger size than in the ventral root. It has a vertical linear attachment to the postero-lateral sulcus of the spinal cord. The rootlets of contiguous dorsal roots are in close relation, and, in some instances, overlap. The dorsal root separates as it passes away from the cord into two bundles, both of which become connected with the inner end of a **spinal ganglion**. From the outer end of this ganglion the dorsal root proceeds to its junction with the ventral root in the intervertebral foramen.

The **spinal ganglia** are found on the dorsal roots of all the spinal nerves. (In the case of the first cervical or sub-occipital nerve, the spinal ganglion may be rudimentary or absent; and the dorsal root itself may be wanting, or derived from the spinal accessory nerve.) They occupy the intervertebral foramina, except in the case of the sacral and coccygeal nerves, the ganglia of which lie *within* the vertebral canal: and the first and second cervical nerves, the ganglia of which lie upon the neural arches of the atlas and axis respectively. With the exception of the coccygeal ganglia they are outside the cavity of the dura mater, but are invested by the membrane. The ganglia are of ovoid form, bifurcated in some cases at their inner ends. They consist of unipolar nerve-cells, whose processes, after a very short course, divide into central (root) and peripheral (trunk) fibres. The central fibres form the portion of the root entering the spinal cord; the peripheral fibres are continued in an outward direction from the ganglion into the spinal nerve.

**Accessory spinal ganglia** (ganglia aberrantia).—Between the spinal ganglion and the spinal cord small collections of cells are occasionally found on the dorsal roots, either as scattered cells or distinct ganglia. They are most frequently met with on the dorsal roots of the lumbar and sacral nerves.

The **ventral root** is smaller than the dorsal root. It arises from the anterior surface of the spinal cord (*anterior root zone*) by means of scattered bundles of nerve-fibres, which occupy a greater horizontal area and are more irregular in their arrangement than the fascicles of the dorsal root. It possesses no ganglion in its course. The rootlets sometimes overlap, and are not unfrequently connected with neighbouring rootlets above and below.

The dorsal and ventral roots, from their attachment to the spinal cord, proceed outwards in the spinal canal towards the intervertebral foramina, where they unite to form the spinal nerve. The direction of the roots of the first two nerves is upwards and outwards; the roots of the remaining nerves course obliquely downwards and outwards, the obliquity gradually increasing until, in the case of the lower lumbar, the sacral and coccygeal nerve-roots, their course is vertically downwards in the spinal canal. The collection of nerve-roots which occupies the lower part of the canal below the first lumbar vertebra, and comprises all the nerve-roots below those of the first lumbar nerve, is designated the **cauda equina**. They arise from the lumbar enlargement and conus medullaris, and surround the filum terminale of the spinal cord.

Within the spinal canal the nerve-roots are in relation with the meninges of the cord, and are separated from one another by the ligamentum denticulatum, and, in the neck, by the spinal part of the spinal accessory nerve. Each receives a covering of pia mater, continuous with the neurilemma; the arachnoid invests each root as far as the point where it meets with the dura mater; and each root pierces the dura mater separately. The two roots are thereafter enclosed in a single tubular sheath of dura mater, in which is included the spinal ganglion of the dorsal root. The spinal nerve thus formed lies in the intervertebral foramen, except in the case of the first two cervical and the sacral and coccygeal nerves.

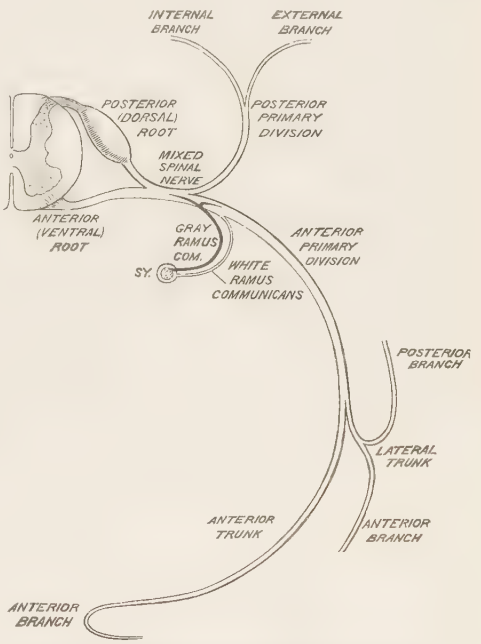

FIG. 486.—SCHEME OF THE DISTRIBUTION OF A TYPICAL SPINAL NERVE.

**Divisions of a Spinal Nerve.**—After emerging from the intervertebral foramen the nerve immediately divides into two primary divisions, named respectively the **posterior** and **anterior primary divisions**. Just before its division each nerve gives off a minute **recurrent branch**, which re-enters the vertebral canal after effecting a junction with a branch from the sympathetic cord, and is distributed to the spinal cord and its membranes.

The **posterior** and **anterior primary divisions** of the spinal nerve are responsible for the innervation of the skeletal muscles and the skin covering the trunk and limbs. They are thus, properly speaking, the somatic branches of the spinal nerve.

In relation to certain of the nerves, a series of much smaller branches exist which are connected with the sympathetic system (Fig. 486, *SY*), in a way to be described later. These constitute the **white rami communicantes**, and may be termed the **visceral divisions** of the spinal nerves. They are derived from the anterior primary divisions of the nerves, and receive their fibres mainly from the ventral roots, though, at least in the case of certain nerves, from the dorsal roots as well. These nerves are directed inwards from the intervertebral foramen over the vertebral column, and, becoming connected with the sympathetic cord, convey spinal fibres to the organs and tissues in the splanchnic area.

The posterior and anterior primary divisions of the nerves contain fibres from

both dorsal and ventral roots. Indeed, each root can be seen, on removal of its sheath, to divide into two portions, of which one portion enters into the formation of the posterior, the other into the formation of the anterior primary division. The posterior primary divisions, with the exception of the first two, are smaller than the anterior primary divisions; and they are, generally speaking, responsible for the innervation of the skin and muscles of the back. They do not supply the muscles of the limbs; although in their cutaneous distribution they are prolonged on to the back of the head, the shoulder, and the buttock. They form two small plexuses —the **posterior cervical** and the **posterior sacral plexuses**. The anterior primary divisions are, with the exception of the first two cervical nerves, much larger than the posterior primary divisions. They supply the sides and fore-parts of the body, the limbs, and the perineum. For the most part they have a complicated arrangement. The thoracic or intercostal nerves alone have a simple mode of distribution; the other nerves give rise to the three great **plexuses—cervical, brachial,** and **lumbo-sacral**.

**Distribution of the Spinal Nerves.**—The distribution, like the origin of the posterior and anterior primary divisions of the spinal nerves, presents primarily and essentially a segmental arrangement, masked and in some cases obliterated by developmental changes which have occurred in the parts supplied. In no region can a single nerve be traced to a complete segment. In the trunk between the limbs the nearest approach to a complete girdle is formed by such a nerve as the sixth thoracic nerve. In its cutaneous distribution it forms a perfect belt, the nerve by its posterior and anterior primary divisions supplying a distinctly segmental area from the middle line of the trunk behind to the sternum in front. Its muscular distribution, also, is almost perfectly segmental. The anterior primary division supplies, unaided, the intercostal muscles of the segment in which it lies. The posterior primary division supplies muscles in the back, not, however, in a strictly segmental manner, on account of the fact that the segmental myotomes have fused together in the back to give rise to complex longitudinal muscles, which are together supplied by the series of muscular branches derived from the posterior primary divisions of contiguous nerves. In other regions greater changes cause more marked deviations from a simple segmental type of distribution and give rise to the various plexuses, by which the trunk, and more particularly the limbs, are innervated.

## POSTERIOR PRIMARY DIVISIONS OF THE SPINAL NERVES.

The posterior primary divisions of the spinal nerves are distributed generally to the skin of the back of the trunk, the back of the head, the shoulder and the buttock, and to the longitudinal muscles of the back, but not to the muscles of the limbs.

Each posterior primary division divides as a rule into two parts, an **internal** and an **external trunk** (Fig. 486, p. 609). In the upper half of the body the internal trunks generally supply the cutaneous branches, while the external trunks are purely muscular nerves. In the lower part of the body the opposite is the case: the external trunks provide the cutaneous nerves and the internal trunks are distributed entirely to muscles. The cutaneous branches have a different course in the two cases. In the upper half of the back they course inwards and backwards beneath and among the muscles to within a short distance of the spinous processes of the vertebræ, close to which they become superficial. They then extend outwards in the superficial fascia. In the lower half of the back the cutaneous nerves are directed downwards and outwards among the muscles, and become superficial at a greater distance from the middle line.

## CERVICAL NERVES.

**First Cervical Nerve** (n. sub-occipitalis).—It has already been pointed out that the dorsal root of this nerve may be rudimentary, or even absent altogether. Its posterior primary division is larger than the anterior primary division; it does not divide into internal or external branches, and it does not directly supply any cutaneous branch.

Passing backwards in the space between the occipital bone and the posterior arch of the atlas, the nerve occupies the sub-occipital triangle, and is placed below and behind the vertebral artery, and under cover of the complexus muscle. It supplies the following branches:—

(*a*) **Muscular branches** to the complexus, recti capitis postici, major and minor, and obliqui, superior and inferior.

(*c*) **A communicating branch** descends to join the second cervical nerve.

The communicating branch may arise in common with the nerve to the obliquus inferior, and reach the second cervical nerve by piercing or passing over or beneath the obliquus inferior. Or it may accompany the nerve to the complexus, and communicate with the great occipital nerve, after piercing that muscle.

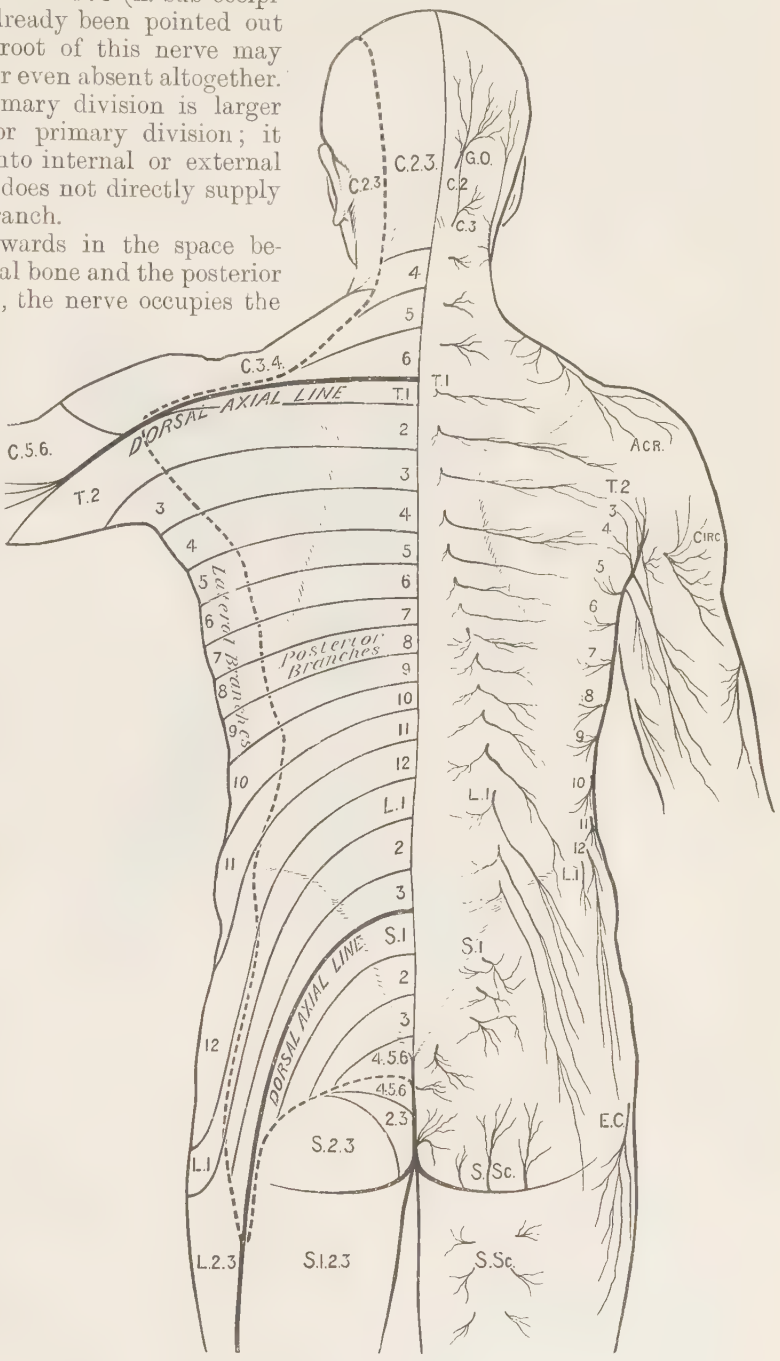

Fig. 487.—The Distribution of Cutaneous Nerves on the Back of the Trunk.

On one side the distribution of the several nerves is represented, the letters indicating their nomenclature.

G.O (C.2), Great occipital; C.3, Least occipital; T.1 *et seq.*, Posterior primary divisions of thoracic nerves: L.1 *et seq.*, Posterior primary divisions of first three lumbar nerves; S.1 *et seq.*, Posterior primary divisions of sacral nerves; Acr, Acromial branches from cervical plexus; T.2-12, Lateral branches of thoracic nerves; Circ, Cutaneous branches of circumflex nerve; L.1, Iliac branch of ilio-hypogastric nerve; E.C, External cutaneous nerve; S.Sc, Small sciatic nerve.

On the other side a schematic representation is given of the areas supplied by the above nerves, the numerals indicating the spinal origin of the branches of distribution to each area.

**Second Cervical Nerve.**—The posterior primary division of this nerve is larger than the corresponding anterior primary division. It passes backwards between the atlas and axis, and in the interval between the obliquus inferior and the semispinalis colli muscles, under cover of the complexus muscle. In this situation the nerve gives off several small muscular and communicating branches. The main trunk, after piercing the complexus and trapezius muscles, accompanies the occipital artery to the scalp as the **great occipital nerve** (n. occipitalis major). This is the chief cutaneous nerve for the back part of the scalp. It enters the superficial fascia at the level of the superior curved line of the occipital bone and about an inch from the external occipital protuberance. Ramifying over the surface, it supplies the skin of the scalp as far as the vertex. It *communicates* on

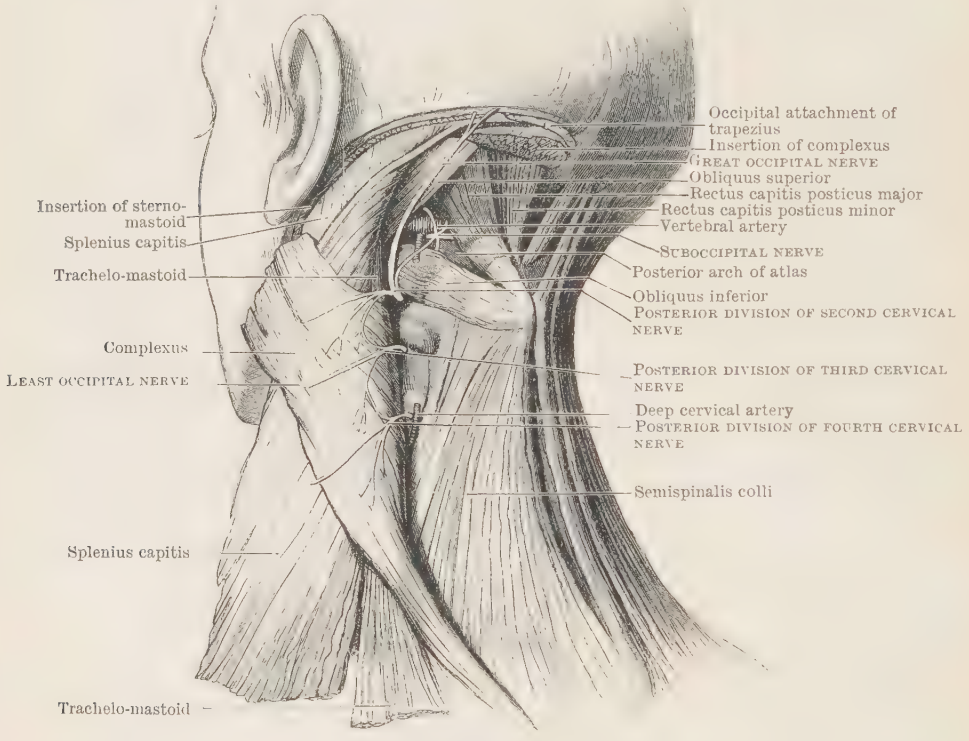

Fig. 488.—Posterior Cervical Plexus.

the scalp with the following nerves: great auricular, small occipital, posterior auricular, and least occipital.

The **muscular branches** of the second cervical nerve are destined for the complexus, obliquus inferior, semispinalis colli, and multifidus spinæ.

Its **communicating branches** form the **posterior cervical plexus**. Descending over the posterior arch of the atlas is a branch from the sub-occipital nerve which forms a loop or network with a corresponding branch of the second nerve. From this loop twigs are supplied to the surrounding muscles. A similar loop is formed by a communication between branches of the second and third nerves, from which muscles are also supplied. Occasionally an additional loop is formed between branches of the third and fourth nerves.

**Third Cervical Nerve.**—This is much smaller than the second nerve. Near its origin it forms a loop of communication with the second, and it may give off a similar communicating branch to the fourth nerve. The main trunk divides into internal cutaneous and external muscular branches. The external muscular branch enters contiguous muscles; the internal cutaneous branch passes backwards and inwards, and becomes superficial as the **third** or **least occipital nerve** (n. occipitalis minimus), close to the middle line of the neck. It supplies fine branches to the neck and scalp, and communicates with the great occipital nerve.

The **fourth, fifth, and sixth cervical nerves** are still smaller. Beneath the complexus each divides into external muscular and internal cutaneous branches. The muscular branches supply neighbouring muscles; the cutaneous branches are small nerves, which, passing backwards, become superficial close to the middle line. They supply the skin of the back of the neck. The sixth is the smallest, and its cutaneous branch is minute, and may be absent altogether. In certain cases the fourth nerve forms, with the third, a loop of communication from which muscles are supplied.

**Seventh and Eighth Cervical Nerves.**—These are the smallest of the posterior primary divisions of the cervical nerves. They give off ordinarily no cutaneous branches, and end in the deep muscles of the back.

## THORACIC NERVES.

The posterior primary division of each thoracic nerve divides into an **internal** and **external branch**. In the case of the upper six thoracic nerves the internal branches are chiefly distributed as cutaneous nerves,—only giving off small muscular branches—while the external branches are wholly muscular in their distribution; in the case of the lower six thoracic nerves the opposite is the case. In all cases the muscular branches serve to innervate the longitudinal muscles of the back. The distribution of the cutaneous branches is different in the upper and lower part of the back. The *upper six* or *seven* thoracic nerves innervate the skin of the scapular region. The **internal cutaneous branches**, after passing backwards from their origin among the dorsal muscles, reach the surface near the spines of the vertebræ and are directed almost horizontally outwards over the vertebral border of the scapula. The first is small; the second is very large and reaches to the acromion process. The rest diminish in size, from above downwards, and become more and more oblique in direction. The **external cutaneous branches** of the *lower five* or *six* thoracic nerves are directed from their origin obliquely downwards and outwards among the parts of the erector spinæ muscle. Becoming cutaneous by piercing the latissimus dorsi at some distance from the middle line, they supply the skin of the back in the lower part of the chest and loin, the lowest nerves (eleventh and twelfth) reaching over the iliac crest on to the buttock. The lower nerves often subdivide into two branches before or after their emergence from the latissimus dorsi muscle.

## LUMBAR NERVES.

**First three Lumbar Nerves.**—The posterior primary divisions of the first three lumbar nerves subdivide into internal and external branches, in the same way as the lower thoracic nerves. The internal branches are muscular and innervate the deep muscles of the back. The external branches are chiefly cutaneous. They are directed obliquely downwards and outwards among the fibres of the erector spinæ and become superficial by piercing the vertebral aponeurosis, just above the iliac crest and a short distance in front of the posterior iliac spine. They are then directed downwards in the superficial fascia of the buttock, and supply a lengthy strip of skin, extending from the middle line above the iliac crest to a point below and behind the great trochanter of the femur.

The **fourth and fifth lumbar nerves** (like the last two cervical nerves) usually supply only muscular branches to the longitudinal muscles of the back. The fifth nerve in many cases sends a minute branch to form a loop of connexion with the posterior primary division of the first sacral nerve (**posterior sacral plexus**).

## SACRAL AND COCCYGEAL NERVES.

The posterior primary divisions of the sacral nerves issue from the posterior sacral foramina. As in the case of the thoracic and lumbar nerves, the upper sacral nerves differ from the lower in their distribution.

The **first three sacral nerves** supply internal muscular branches for the multifidus spinæ, and external cutaneous branches which pierce the fibres of the sacro-sciatic ligament and the gluteus maximus muscle, and supply the skin over

the back of the sacrum and contiguous part of the buttock, giving rise to the posterior sacral plexus.

The **posterior sacral plexus** consists, like the posterior cervical plexus, of loops or plexiform communications over the back of the sacrum between the posterior primary divisions of the first three sacral nerves, to which are frequently joined branches of the last lumbar nerve and fourth sacral nerve. From these loops branches proceed to supply the multifidus spinæ muscle; others, piercing the great sacro-sciatic ligament, form secondary loops beneath the gluteus maximus muscle. From the secondary loops, two or more cutaneous branches arise, which, after traversing the muscle, supply the skin over the sacrum and inner part of the buttock.

**Posterior Sacro-coccygeal Nerve.**—The posterior divisions of the fourth and fifth sacral nerves do not divide into internal and external branches. They unite together to form a cord which, descending behind the coccyx, receives the minute posterior primary division of the coccygeal nerve. The union of the three nerves constitutes the **posterior sacro-coccygeal nerve**, which, after perforating the sacro-sciatic ligament, is distributed to the skin in the neighbourhood of the coccyx. It supplies no muscles. This nerve is the representative of the **superior caudal trunk** of tailed animals.

## Morphology of the Posterior Primary Divisions.

There are several points of morphological interest in relation to the posterior primary divisions of the spinal nerves.

1. **Muscular Distribution.**—In their muscular distribution they are strictly limited to the longitudinal muscles of the back: namely, those associated with the axial skeleton alone.

2. **Cutaneous Distribution.**—Their cutaneous distribution represents two points of interest.

A. In the first place, while the skin of the back is supplied in a regularly segmental manner by the several nerves, certain of them fail to reach the surface at all. The absence of a cutaneous branch from the sub-occipital nerve may be due either to the absence of a perfect dorsal root, or to its communication with the second nerve. The other nerves, which do not usually supply the skin, are the seventh and eighth cervical, and the fourth and fifth lumbar nerves. These nerves are placed in the centre of regions in which the upper and lower limbs are developed. They are minute nerves, while the corresponding anterior primary divisions are among the largest of the spinal nerves. Thus, opposite the centre of each limb, posteriorly, there is a hiatus in the segmental distribution of the posterior primary divisions of the spinal nerves to the skin of the shoulder and buttock, attributable to the formation of the limbs, and the extension into them of the greater part of the nerves of the region. This gap, in the case of the upper limb, commences at the level of the vertebra prominens; in the case of the lower limb it commences opposite the level of the posterior superior iliac spine. It can be continued on to each limb as a hypothetical area (the **dorsal axial line**), which indicates the area of contact (and overlapping) of cutaneous nerves not in strictly numerical sequence. Thus, in the region of the shoulder, the sixth (or fifth) cervical nerve innervates an area of skin adjoining that supplied by the first thoracic nerve; in the region of the buttock the third lumbar nerve supplies an area contiguous with that supplied by the first sacral nerve.

B. The cutaneous branches of the posterior primary divisions of the spinal nerves differ from the muscular branches in respect of their penetration into regions beyond those supplied by their motor roots. The cutaneous branches, in regions where outgrowths or extensions from the trunk have occurred, follow these extensions; and, in consequence, supply skin covering parts which do not belong to segments represented by the nerves in question. Thus the second and third cervical nerves (great and least occipital) are drawn upwards so as to supply the posterior part of the *scalp*; the upper thoracic nerves are drawn outwards over the *scapular region*; the upper lumbar and sacral nerves supply the skin of the *buttock*; and the sacro-coccygeal nerve forms a rudimentary *caudal nerve*.

3. **Plexuses.**—The plexuses formed by the posterior primary divisions of the upper cervical and upper sacral nerves are the simplest met with in the human body. The posterior cervical plexus is one from which muscular branches are supplied; the posterior sacral plexus is mainly concerned in producing cutaneous offsets. In the case of the **posterior cervical plexus** the loops of communication between the first three or four cervical nerves result in the formation of a series of nerves for the supply of the semispinalis, complexus, and other muscles, which bring into contact with these muscles, simultaneously, a considerable area of the spinal cord, and provide a combined and simultaneous innervation for the several parts of each muscle. In the case of the **posterior sacral plexus**, the formation of loops between the nerves results in the innervation of any given spot in the cutaneous area supplied from these loops by more than one spinal nerve. As has been said already, the cutaneous nerves, even without the formation of plexuses, overlap in their cutaneous distribution. The formation of a plexus causes a more intimate union of neighbouring spinal nerves, so that stimulation of the surface affects a wider area in the spinal cord than if the nerves passed separately to it from the surface. While segmentation becomes less obvious, increased co-ordination is effected both of movement and sensation.

# ANTERIOR PRIMARY DIVISIONS OF THE SPINAL NERVES.

The anterior primary divisions of the spinal nerves, are, with the exception of the first two cervical nerves, much larger than the corresponding posterior primary divisions. Composed of elements of both dorsal and ventral roots, each nerve separates from the posterior primary division on emerging from the intervertebral foramen, and, proceeding outwards, is distributed to structures on the lateral and anterior aspects of the body,—including the limbs.

Each nerve is joined near its origin by a **gray ramus communicans** from the sympathetic gangliated cord; and in the case of certain thoracic, lumbar, and sacral nerves, the anterior primary division gives off a delicate bundle of fibres, which forms the **white ramus communicans** of the sympathetic cord. That part of the spinal nerve which is distributed to the body wall and limbs may be termed **somatic**; the small white ramus communicans, innervating the structures in the splanchnic area, may be termed the **visceral** or **splanchnic** part of the spinal nerve.

The anterior primary divisions of the spinal nerves are only,

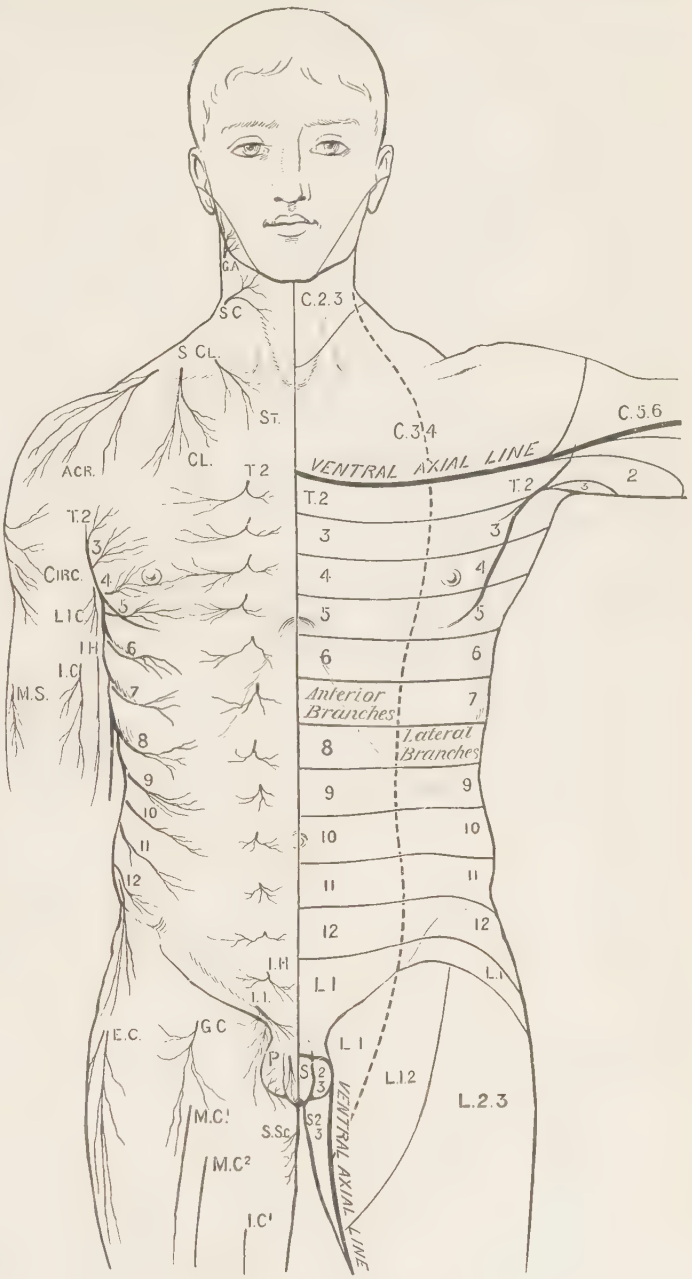

Fig. 489.—The Distribution of Cutaneous Nerves on the Front of the Trunk.

On one side the distribution of the several nerves is represented, the letters indicating their nomenclature.

On the other side a schematic representation is given of the areas supplied by the above nerves, the numerals indicating the spinal origin of the branches of distribution to each area.

in certain cases, distributed in a regular segmental manner. Except in the case of the thoracic nerves, the anterior primary divisions combine to form the three great **plexuses**—cervical, brachial, and lumbo-sacral—and their arrangement and distribution is rendered exceedingly complex.

A **thoracic nerve**, such as the fifth or sixth, may be regarded as a type to illustrate the mode of distribution of the anterior primary divisions of the spinal nerves (Fig. 486, p. 609). It occupies an intercostal space; near its origin it possesses *gray* and *white rami communicantes*; it courses through the interval between the intercostal muscles; it supplies branches to these muscles and gives off, when it reaches the side of the chest, a *lateral branch*, which, after supplying small muscular branches, pierces the external intercostal muscle, and is distributed to an area of skin over the lateral part of the trunk, contiguous dorsally with a similar area, innervated by the cutaneous branches of the posterior primary division of the same nerve. The lateral branch generally subdivides into a smaller *posterior* and a larger *anterior trunk*, as it pierces the muscles clothing the wall of the chest. The anterior primary division of the nerve then pursues its course obliquely forwards to the side of the sternum, where, after piercing the pectoral muscles, it appears superficially as the *anterior terminal cutaneous branch*. This supplies an area of skin continuous with that supplied by the anterior part of the lateral branch of the same nerve. Such a nerve thus supplies, by means of its lateral and anterior

branches, an area of skin which (with the area supplied by the cutaneous branch of its posterior primary division) forms a continuous and uninterrupted belt, extending from the middle line behind to the middle line in front. The lateral and anterior branches of the nerve innervate in their course the intercostal and other muscles, to be afterwards mentioned in detail.

## CERVICAL NERVES.

The anterior primary divisions of the cervical nerves, together with parts of the first and second thoracic nerves, are distributed to the head, neck, and upper extremity. The first four cervical nerves, by means of the **cervical plexus**, innervate the neck; the last four cervical nerves, together with a large part of the first thoracic nerve, through the **brachial plexus**, supply the upper limb. The second thoracic nerve may contribute a trunk to this plexus, and always assists in the innervation of the arm.

## THE CERVICAL PLEXUS.

The anterior primary divisions of the first four cervical nerves are concerned in forming the cervical plexus. Each nerve emerges from the spinal canal behind the vertebral artery. Each is joined on its emergence from the intervertebral foramen, at the side of the vertebral column, by a **gray ramus communicans** from the superior cervical ganglion of the sympathetic. In the neck the cervical nerves are concealed by the sterno-mastoid muscle; in front lies the rectus capitis anticus major, and behind are the scalenus medius, and (behind the first or sub-occipital nerve) the rectus capitis lateralis. The cervical plexus is constituted by the combination of these nerves in an irregular series of loops under cover of the sterno-mastoid muscle.

From these loops the branches of distribution arise, as (*a*) **cutaneous branches** to the head, neck, and shoulder; (*b*) **muscular branches** to the muscles of the neck and the diaphragm; and (*c*) **communicating branches** to the vagus, spinal accessory, hypoglossal, and sympathetic nerves.

For convenience of description, the nerves derived from the plexus may be classified as follows:—

### I. Superficial (cutaneous) Branches—

A. **Ascending Branches** (C. 2, 3).
- Small occipital,
- Great auricular,
- Superficial cervical.

B. **Descending (supra-clavicular) Branches** (C. 3, 4).
- Acromial,
- Clavicular,
- Sternal.

### II. Deep (muscular and communicating) Branches—

A. **External Branches.**

1. Muscular branches to
   - Sterno-mastoid (C. 2),
   - Trapezius (C. 3, 4),
   - Levator anguli scapulæ (C. 3, 4),
   - Scaleni (medius and posticus) (C. 3, 4).
2. Communicating branches to
   - Spinal accessory nerve (C. 2, 3, 4).

B. **Internal Branches.**

1. Muscular to
   - Prevertebral muscles (C. 1, 2, 3, 4),
   - Infra-hyoid muscles (C. 1, 2, 3) (ansa hypoglossi),
   - Diaphragm (C. 3, 4) (phrenic nerve).
2. Communicating branches to
   - Vagus nerve (C. 1, 2),
   - Hypoglossal nerve (C. 1, 2),
   - C. Hypoglossi (C. 2, 3),
   - Sympathetic (C. 1, 2, 3, 4).

The second, third, and fourth cervical nerves are the chief nerves engaged in forming the plexus. The first cervical nerve only enters into the formation of a small part—the internal portion of the deep part of the plexus.

**Superficial Cutaneous Branches.**—These nerves, six in number, are entirely cutaneous. They radiate from the plexus, and appear in the posterior triangle of

the neck at the posterior border of the sterno-mastoid muscle. They are divisible into two series, the one **ascending**: small occipital, great auricular, and superficial cervical; the other **descending** (supra-clavicular): sternal, clavicular, and acromial.

**Ascending Branches.**—The **small occipital nerve** (n. occipitalis minor) is variable in size and is sometimes double. Its origin is from the second and third cervical nerves (more rarely from the second only). It extends backwards beneath the sterno-mastoid, and then upwards along its posterior border. Piercing the deep fascia near the apex of the posterior triangle, it divides into **auricular, mastoid,** and **occipital branches,** and supplies small **cervical branches** to the upper part of the neck. The auricular branch supplies the skin of the deep surface of the pinna; the mastoid and occipital branches supply the scalp. The nerve communicates on the scalp with the great occipital and great auricular nerves, and with the posterior auricular branch of the facial nerve.

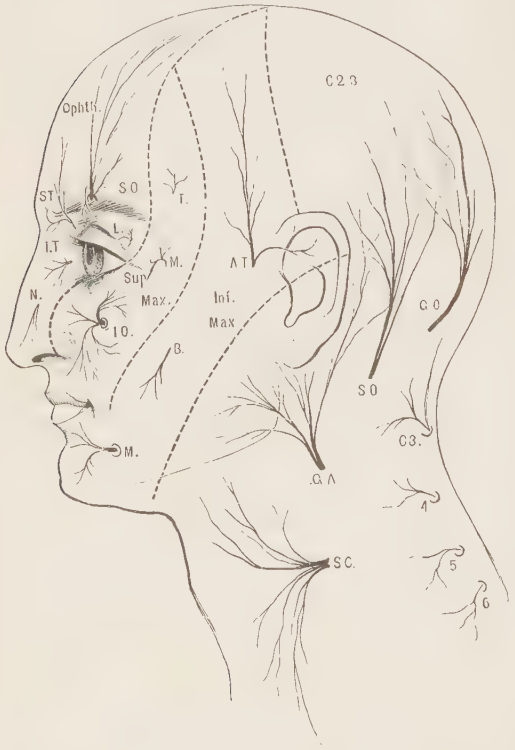

Fig. 491.—Distribution of Cutaneous Nerves to the Head and Neck.

Ophth, Ophthalmic division of the fifth nerve; S.T, Supra-trochlear branch; S.O, Supra-orbital branch; I.T, Infra-trochlear branch; L, Lachrymal branch; N, External nasal branch; Sup. Max, Superior maxillary division; T, Temporal branch; M, Malar branch; I.O, Infra-orbital branch; Inf. Max, Inferior maxillary division; A.T, Auriculo-temporal branch; B, Buccal branch; M, Mental branch; C.2, 3, Branches of the second and third cervical nerves; G.O, Great occipital nerve; S.O, Small occipital nerve; G.A, Great auricular nerve; S.C, Superficial cervical nerve; C.3, Least occipital nerve; 4, 5, 6, Posterior primary divisions of 4th, 5th, and 6th cervical nerves.

The **great auricular nerve** (n. auricularis magnus) is the largest of the cutaneous branches. It arises from the second and third cervical nerves (or, more rarely, from the third alone). Winding round the posterior border of the sterno-mastoid muscle, it courses vertically upwards towards the ear. In this course it crosses the sterno-mastoid muscle obliquely and is covered by the platysma myoides. Before arriving at the ear it subdivides into mastoid, auricular, and facial branches. The **mastoid branches** ascend over the mastoid process and supply the skin of the scalp behind the ear, communicating with the small occipital and posterior auricular nerves. The **auricular branches** ascend to the ear and supply the lower part of the pinna on both aspects; they communicate with the same nerves. The **facial branches,** passing over the angle of the jaw and through the substance of the parotid gland, supply the skin of the cheek over the lower part of the masseter muscle and the parotid gland. They communicate with branches of the facial nerve in the parotid gland.

The **superficial cervical nerve** (n. cutaneus colli) arises from the second and third cervical nerves. It winds round the posterior border of the sterno-mastoid muscle, and crosses the muscle to reach the anterior triangle, under cover of the platysma myoides muscle and the external jugular vein. It divides near the anterior edge of the sterno-mastoid muscle into upper and lower branches, which are distributed through the platysma myoides to the skin covering the anterior triangle of the neck. The upper branches communicate freely beneath the platysma myoides with the infra-mandibular branch of the facial nerve.

Descending (supra-clavicular) Branches.—By the union of two roots derived from the third and fourth cervical nerves a considerable trunk is formed, which

emerges from under cover of the sterno-mastoid muscle and extends obliquely downwards through the lower part of the posterior triangle of the neck. It subdivides into radiating branches—**sternal, clavicular,** and **acromial**—which pierce the deep fascia of the neck above the clavicle, and are distributed to the skin of the lower part of the side of the neck, the front of the chest, and the shoulder. The **sternal branches** (rami supra-sternales) are the smallest. Passing over the inner end of the clavicle, they supply the skin of the neck and chest as far down as the manubrio-sternal joint. The **clavicular branches** (rr. supra-claviculares) pass over the middle third of the clavicle, beneath the platysma, and can be traced

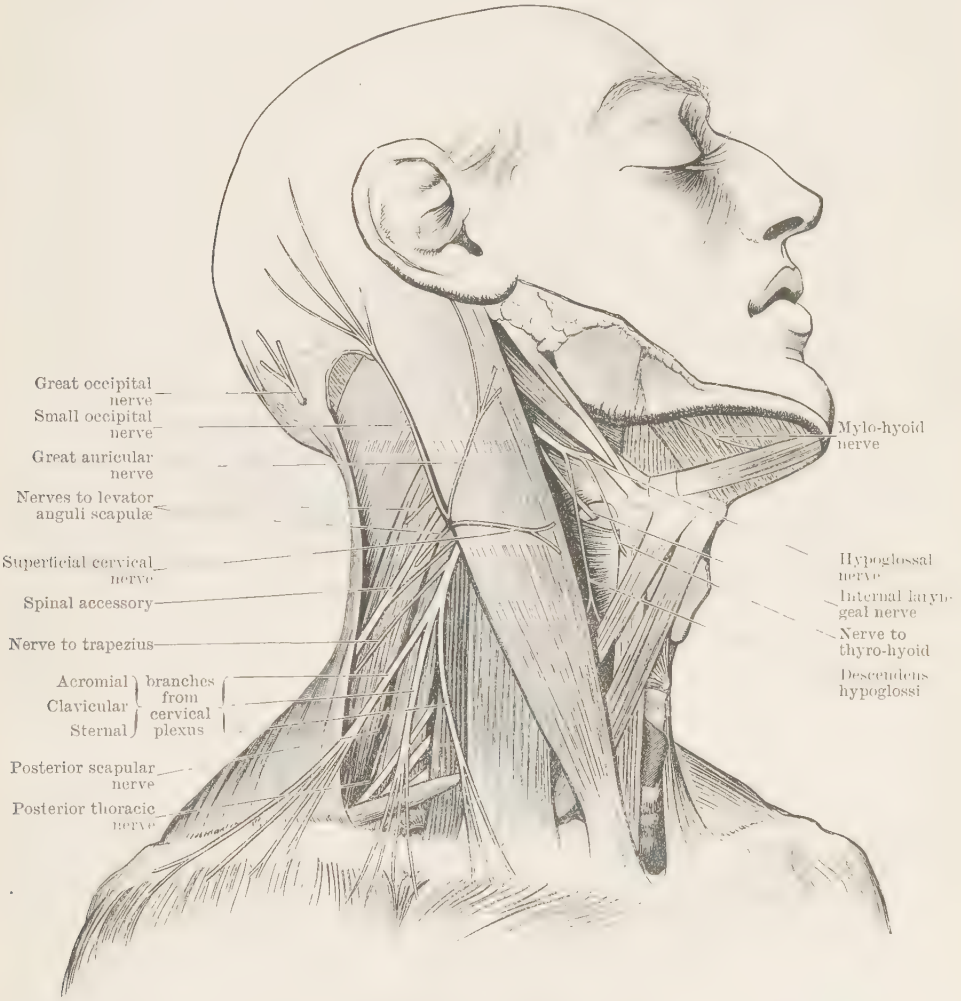

FIG. 492.—THE TRIANGLES OF THE NECK (Nerves).

as low as the nipple. The **acromial branches** (rr. supra-acromiales) pass over or through the insertion of the trapezius muscle, and over the outer third of the clavicle, to the shoulder, where they supply the skin as far down as the lower third of the deltoid muscle.

**Deep Branches.**—The deep branches of the cervical plexus are naturally separated into an **external** and an **internal set** by their relation to the sterno-mastoid muscle. Beneath the muscle, the external branches are directed outwards towards the posterior triangle, the internal branches inwards towards the anterior triangle.

The **external branches** consist of muscular and communicating nerves, which for the most part occupy the posterior triangle.

The **muscular branches** are the following: (1) To the *sterno-mastoid,* from the second cervical nerve. This enters the muscle on its deep surface and communicates

with the spinal accessory nerve. (2) To the *trapezius*, from the third and fourth cervical nerves. These nerves cross the posterior triangle and end in the trapezius, after having communicated with the spinal accessory nerve, in the posterior triangle, and beneath the muscle. (3) To the *levator anguli scapulæ*, from the third and fourth cervical nerves. Two independent branches enter the outer surface of the muscle in the posterior triangle. (4) To the *scaleni* (medius and posticus), from the third and fourth cervical nerves.

The **communicating branches,** already mentioned, are three in number. They

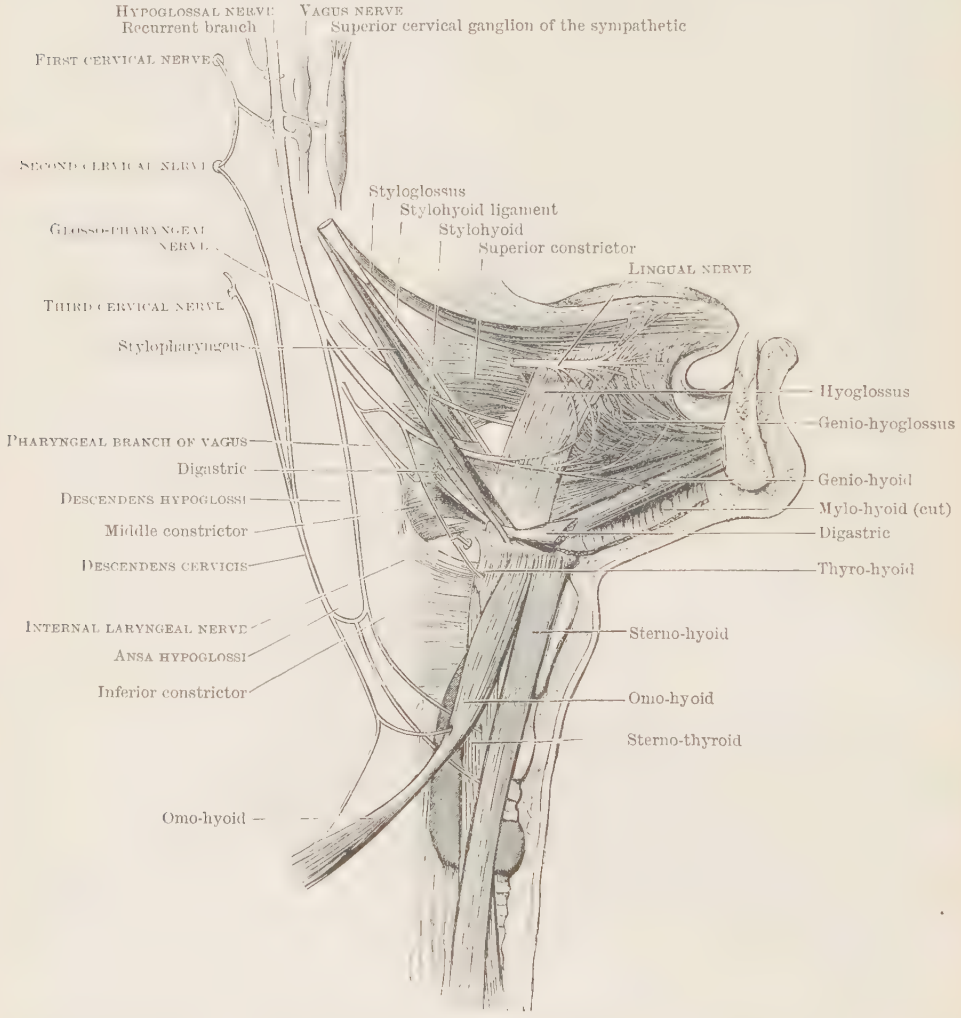

Fig. 493.—The Muscles of the Hyoid Bone and Styloid Process, and the Extrinsic Muscles of the Tongue, with their Nerves.

join the spinal accessory nerve in three situations:—(*a*) A branch from the second cervical nerve to the sterno-mastoid joins the spinal accessory nerve *beneath that muscle.* (*b*) Branches to the trapezius from the third and fourth nerves are connected with the spinal accessory nerve *in the posterior triangle.* (*c*) Branches from the same nerves join the spinal accessory nerve *beneath the trapezius muscle.*

The **internal branches** of the plexus also comprise muscular and communicating branches. The first cervical nerve assists in the formation of this series of nerves, forming a slender loop with part of the second nerve in front of the transverse process of the atlas.

**Communicating Branches.** (*a*) *With the sympathetic.*—Gray rami communicantes pass to each of the first four cervical nerves, near their origins, from the

superior cervical ganglion or from the cord below the ganglion. (*b*) *With the pneumogastric nerve.*—The ganglion of the trunk of the pneumogastric nerve may be connected by a slender nerve with the loop between the first two cervical nerves. This communication is not constant. (*c*) *With the hypoglossal.*—An important communication occurs between the hypoglossal nerve and the loop between the first and second cervical nerves (Fig. 493). A trunk from the last-named nerves joins the hypoglossal just beyond its exit from the skull. One fine branch from this trunk passes upwards along the hypoglossal nerve towards the skull (*meningeal branch*). The main part of the trunk accompanies the hypoglossal and separates from it successively in three nerves—the **descendens hypoglossi**, and the **nerves to the thyro-hyoid** and **genio-hyoid muscles**. The portion of the nerve which remains accompanies the hypoglossal to the muscles of the tongue. It is probable that no part of the hypoglossal nerve itself is concerned in the formation of these three branches. The descending branch of the hypoglossal (r. descendens hypoglossi) descends in front of the common carotid artery, and is joined in the anterior triangle of the neck by the descending cervical nerve, to form the ansa hypoglossi, from which the infra-hyoid muscles are innervated. (The descending branch of the hypoglossal, in some cases, arises from the pneumogastric nerve.)

**Muscular Branches.**—The muscles supplied by the internal branches of the plexus are the prevertebral muscles, the genio-hyoid and infra-hyoid muscles, and the diaphragm.

(*a*) **Prevertebral Muscles.**—1. From the loop between the first and second cervical nerves a small branch arises, for the supply of the rectus capitis lateralis and the recti capitis antici (major and minor). 2. From the second, third, and fourth nerves small branches supply the inter-transversales, longus colli, and rectus capitis anticus major. 3. From the fourth nerve a branch arises for the upper part of the scalenus anticus.

(*b*) **Genio-hyoid and Infra-hyoid Muscles.**—The **descending cervical nerve** (n. cervicalis descendens) is formed in front of the internal jugular vein by the union of two slender trunks from the second and third cervical nerves. It forms a loop of communication in front of the carotid sheath with the descending branch of the hypoglossal nerve (derived ultimately from the first two cervical nerves). This loop of communication is called the **ansa hypoglossi**. It is often plexiform; and from it branches are given to the sterno-hyoid, sterno-thyroid, and omo-hyoid muscles. The nerve to the sterno-hyoid muscle is often continued behind the sternum, to join in the thorax with the phrenic nerve or the cardiac plexus.

The thyro-hyoid muscle and the genio-hyoid muscle are supplied by branches of the hypoglossal nerve, which are also traceable back to the communication between the hypoglossal and the first two cervical nerves.

The anterior muscles in immediate relation to the middle line of the neck, between the chin and the sternum, are thus continuously supplied by the first three cervical nerves. The hypoglossal is the nerve of the muscles of the tongue, and it is not certain that it contributes any fibres to the above-named muscles.

(*c*) **Diaphragm.**—The phrenic nerve supplies the diaphragm.

### Phrenic Nerve.

The **phrenic nerve** (n. phrenicus) is derived mainly from the fourth cervical nerve, reinforced by roots from the third (either directly or through the nerve to the sterno-hyoid) and fifth (either directly or through the nerve to the subclavius muscle). It passes downwards in the neck upon the scalenus anticus muscle; at the root of the neck it enters the thorax between the subclavian artery and vein, and traverses the mediastinum to reach the diaphragm, lying in the middle mediastinum between the pericardium and pleura, and in front of the root of the lung. In its course it presents certain differences on the two sides. In the neck, on the left side, it crosses the first part of the subclavian artery: on the right side it crosses the second part. In the superior mediastinum, *on the left side*, it lies between the left subclavian and carotid arteries, and crosses the pneumogastric nerve and the aortic arch. *On the right side* it accompanies the innominate vein

and superior vena cava, and is entirely separate from the pneumogastric nerve. The left nerve is longer than the right, owing to the position of the heart and the left half of the diaphragm. The right nerve sends fibres along the inferior vena cava through the foramen quadratum. Reaching the diaphragm the nerve separates into numerous branches for the supply of the muscle; some enter its thoracic surface (sub-pleural branches), but most of the fibres supply it after piercing the muscle (sub-peritoneal branches).

The **branches of the phrenic nerve** are—1. Muscular (to the diaphragm); 2. pleural; 3. pericardiac; 4. inferior vena caval; 5. capsular; and 6. hepatic.

The branches to the pleura and pericardium arise as the phrenic nerve traverses the mediastinum. The branches to the inferior vena cava, suprarenal capsule, and liver arise after communication of the phrenic nerve with the diaphragmatic plexus of the sympathetic on the abdominal surface of the diaphragm.

**Communications of the Phrenic Nerve.**—1. The phrenic nerve may communicate with the nerve to the subclavius muscle. 2. It may communicate with the *ansa hypoglossi*, or a branch from it (the nerve to the sterno-hyoid). 3. It frequently communicates with the cervical part of the sympathetic. 4. It communicates with the solar plexus by a junction upon the abdominal surface of the diaphragm with the *diaphragmatic plexus* on the inferior phrenic artery, in which a small *diaphragmatic ganglion* is found on the right side. From this junction branches are given off to the inferior vena cava, suprarenal capsule, and hepatic plexus.

### Morphology of the Cervical Plexus.

The characteristic feature of the cervical plexus is the combination of parts of adjacent nerves into compound nerve-trunks by the formation of series of loops. The result of the formation of these loops is that parts (particularly cutaneous areas) are supplied by branches of more than one spinal nerve.

A. **Cutaneous Distribution.**—By the combinations of the nerves into loops the discrimination of the elements in the upper cervical nerves, corresponding to the lateral and anterior branches of a typical thoracic nerve, is made a matter of some difficulty. The second, third, and fourth nerves, through the cervical plexus, supply an area of skin extending, laterally, from the side of the head to the shoulder; anteriorly, from the face to the level of the nipple. The higher nerves supply the upper region (second and third); the lower nerves supply the lower region (third and fourth). It is not possible to strictly compare the individual nerves with the lateral and anterior branches of a thoracic nerve. A line drawn from the ear to the middle of the clavicle separates, however, a lateral from an anterior cutaneous area; and certain of the cutaneous nerves fall naturally into one of these two categories. The nerves homologous with anterior branches of intercostal nerves are the superficial cervical and the sternal branches of the supra-clavicular series; those homologous with lateral branches are the small occipital and acromial branches. The great auricular and clavicular branches are mixed nerves, comprising elements belonging to both sets.

B. **Muscular Distribution.**—The nerves from the cervical plexus, supplying muscles, are simpler in their arrangement. They are not generally in the form of loops, and they are easily separated into lateral and anterior series. The lateral nerves comprise the branches to the rectus capitis lateralis, sterno-mastoid, trapezius, levator anguli scapulæ. The nerves in the anterior series are those to the recti antici, the hyoid muscles, and the diaphragm.

It is noteworthy that the last-named muscles—genio-hyoid, thyro-hyoid, sterno-hyoid, omo-hyoid, sterno-thyroid, and diaphragm—are continuously supplied by branches from the first five cervical nerves: the higher muscles by the higher nerves; the lower muscles by the lower nerves.

## THE BRACHIAL PLEXUS.

The brachial plexus is formed by the anterior primary divisions of the fifth, sixth, seventh, and eighth cervical nerves, along with the greater part of the first thoracic nerve. In some cases a slender branch of the fourth cervical nerve is also engaged; and the second thoracic nerve, in all cases, also contributes to the innervation of the arm, through the intercosto-humeral nerve. It many cases it contributes also directly to the plexus, by an intra-thoracic communication with the first thoracic nerve.

**Position of the Plexus** —The nerves forming the brachial plexus appear in the posterior triangle of the neck between the scalenus anticus aud scalenus

medius muscles; the plexus is formed in close relation to the subclavian and axillary arteries: the nerves emanating from it accompany the artery to the axilla, where they are distributed to the shoulder and upper limb.

**Communication with the Sympathetic.**—The lower four cervical nerves communicate with the cervical portion of the sympathetic by means of **gray rami communicantes.** Two branches arise from the middle cervical ganglion, and join the anterior primary divisions of the fifth and sixth nerves. Two arising from the inferior cervical ganglion join the seventh and eighth nerves. They reach the nerves either by piercing the prevertebral muscles or by passing round the border of the scalenus anticus muscle.

**Composition of the Brachial Plexus.**—In an analysis of the brachial plexus four stages may be always seen:—

(1) The undivided nerves.

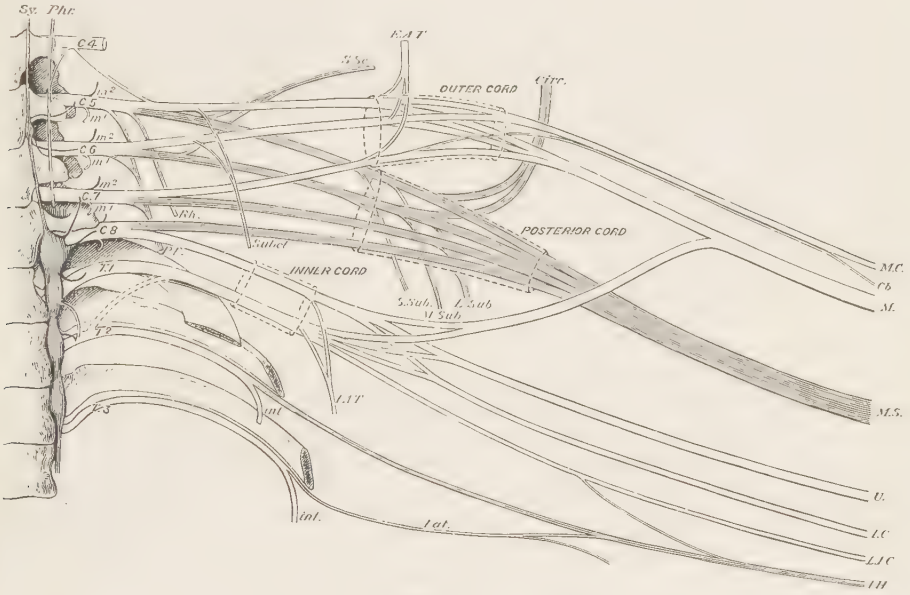

Fig. 494.—The Nerves of the Brachial Plexus.

Sy, Sympathetic gangliated cord; Phr, Phrenic nerve; C.4, 5, 6, 7, 8, T.1, 2, 3, Anterior primary divisions of the lower cervical and upper thoracic nerves; $M^1$, $M^2$, Muscular branches to axial muscles; P.T, Long thoracic nerve; Rh, Nerve to rhomboids (posterior scapular); Subcl, Nerve to subclavius muscle; Int, Intercostal nerves; S.Sc, Supra-scapular nerve. The intercostal part of the first thoracic nerve is omitted.

Outer Cord.—E.A.T, External anterior thoracic nerve; M.C, Musculo-cutaneous nerve; Cb, Nerve to coraco-brachialis; M, Median nerve.

Inner Cord.—I.A.T, Internal anterior thoracic nerve; U, Ulnar nerve; I.C, Internal cutaneous nerve; L.I.C, Lesser internal cutaneous nerve.

Posterior Cord.—Circ, Circumflex nerve; M.S, Musculo-spiral nerve; S.Sub, Short subscapular nerve; M.Sub, Lower subscapular nerve; L.Sub, Long subscapular, nerve; I.H, Intercosto-humeral nerve; Lat, Lateral branch of third intercostal nerve.

(2) The separation of the nerves into ventral (anterior) and dorsal (posterior) trunks; and the formation of three primary cords.

(3) The formation of three secondary cords—outer, inner, and posterior.

(4) The origin of the nerves of distribution.

(1) The undivided nerves have only a very short independent course at the side of the neck, after passing between the scalene muscles.

(2) Almost immediately after entering the posterior triangle there are formed three **primary cords**: the first cord is formed by the union of the fifth and sixth nerves together; the second, by the seventh nerve alone; and the third, by the union of the eighth cervical and first thoracic nerves together. While these cords are being formed, a division occurs in each of the last four cervical nerves, into *ventral* (anterior) and *dorsal* (posterior) *trunks*; the first thoracic nerve usually gives rise to no dorsal trunk. The ventral and dorsal trunks of the fifth, sixth,

and seventh nerves are nearly equal in size. The dorsal trunk of the eighth cervical nerve is much smaller.

(3) The **secondary cords** of the plexus are formed by combinations of these ventral and dorsal trunks in relation to the axillary artery. They are three in number. The **outer cord** (fasciculus lateralis) is formed by a combination of the ventral trunks of the fifth, sixth, and seventh nerves, and lies on the outer side of the axillary artery. The **inner cord** (fasciculus medialis) is formed by a combination of the ventral trunk of the eighth cervical with the part of the first thoracic nerve engaged in the formation of the plexus; it lies on the inner side of the axillary artery. The **posterior cord** (fasciculus posterior) is made up of all the dorsal trunks from the fifth, sixth, seventh, and eighth cervical nerves, and lies behind the axillary artery. The first thoracic nerve does not usually contribute to the posterior cord, and the branch when present is a fine nerve.

(4) The **nerves of distribution** for the shoulder and arm are derived from these secondary cords, and receive in this way various contributions from the constituent spinal nerves. *From the outer cord* arise the external anterior thoracic and musculo-cutaneous nerves, and the outer head of the median nerve. *From the inner cord* arise the inner head of the median, the ulnar, internal cutaneous, lesser internal cutaneous, and the internal anterior thoracic nerves. *From the posterior cord* arise the circumflex, the three subscapular, and the musculo-spiral nerves.

It is to be remembered that, although derived from a secondary cord formed by a certain set of spinal nerves, any given nerve does not necessarily contain fibres from all the constituent nerves; *e.g.* both the musculo-cutaneous and circumflex nerves, from the outer and posterior cords respectively, are ultimately derived only from the fifth and sixth cervical nerves.

### The Branches of the Brachial Plexus.

It is customary to separate artificially the nerves of distribution of the brachial plexus into two sets: (1) supra-clavicular and (2) infra-clavicular. Clinically it is important to realise the position of origin of certain nerves. The nerves to the prevertebral muscles, the communication with the phrenic, the posterior scapular, and long thoracic nerves, arise from the *roots* of the nerves involved in the plexus. The supra-scapular and the nerve to the subclavius arise at the level of formation of the secondary cords; and the anterior thoracic and subscapular nerves arise from the secondary cords, prior to their ultimate subdivision into the nerves of distribution for the upper limb.

**Supra-clavicular Nerves.**—The nerves derived from the plexus above the level of the clavicle are, like the main trunks, divisible into two series; **anterior branches** arising from the front, and **posterior branches** arising from the back of the plexus (Fig. 494, p. 623).

| Anterior Branches. | Posterior Branches. |
|---|---|
| 1. Nerves to scalenus anticus and longus colli. | 1. Nerves to scaleni, medius and posticus. |
| 2. Communicating nerve to join the phrenic nerve. | 2. Posterior scapular nerve. |
| 3. Nerve to the subclavius muscle. | 3. Long thoracic nerve. |
| | 4. Supra-scapular nerve. |

The **muscular twigs** to the scalenus anticus and longus colli arise from the lower four cervical nerves, as they emerge from the intervertebral foramina.

The **communicating nerve to the phrenic** arises usually from the fifth cervical nerve at the outer border of the scalenus anticus. It is sometimes absent, and occasionally an additional root is present from the sixth cervical nerve. In some instances the nerve is replaced by a branch from the nerve to the subclavius, which passes inwards behind the sterno-mastoid muscle to join the phrenic at the inlet of the thorax.

The **nerve to the subclavius** is a slender nerve, which arises from the front of the cord formed by the fifth and sixth cervical nerves. It descends in the posterior triangle of the neck over the third part of the subclavian artery. It often communicates with the phrenic nerve.

The **branches to the scaleni, medius and posticus**, are small trunks which arise from the lower four cervical nerves as they emerge from the intervertebral foramina.

The **posterior scapular nerve** (n. dorsalis scapulæ, nerve to the rhomboids) arises from the back of the fifth cervical nerve, as it emerges from the intervertebral foramen. It appears in the posterior triangle of the neck, after piercing the scalenus medius muscle. It is directed downwards, under cover of the levator anguli scapulæ and rhomboid muscles, and along the vertebral border of the scapula, to be distributed to the levator anguli scapulæ, rhomboideus minor, and rhomboideus major muscles. It occasionally pierces the levator anguli scapulæ.

The **long thoracic nerve** (n. thoracalis longus, external respiratory nerve of Bell) arises by three roots, of which the middle one is usually the largest, from the back of the fifth, sixth, and seventh nerves, as they emerge from the intervertebral foramina. The nerve pierces the scalenus medius as two trunks, of which the lower represents the contribution from the seventh cervical nerve, and, descending along the side of the neck behind the cords of the brachial plexus, it enters the axilla between the upper edge of the serratus magnus and the axillary artery. It continues its downward course over the outer surface of the serratus magnus, to which it is distributed.

There is a more or less definite relation between the roots of this nerve and the parts of the serratus magnus. The first part of the muscle is innervated by the fifth nerve alone; the second part by the fifth and sixth, or the sixth alone; the third part by the sixth and seventh, or the seventh nerve alone.

The **suprascapular nerve** (n. suprascapularis) arises from the back of the cord formed by the fifth and sixth cervical nerves in the posterior triangle of the neck. It occupies a position above the main cords of the brachial plexus, and courses downwards and outwards parallel to them towards the superior border of the scapula. It passes through the suprascapular foramen to reach the dorsum of the scapula. After supplying the supraspinatus muscle it winds round the great scapular notch in company with the suprascapular artery and terminates in the infraspinatus muscle. It also supplies articular branches to the back of the shoulder joint.

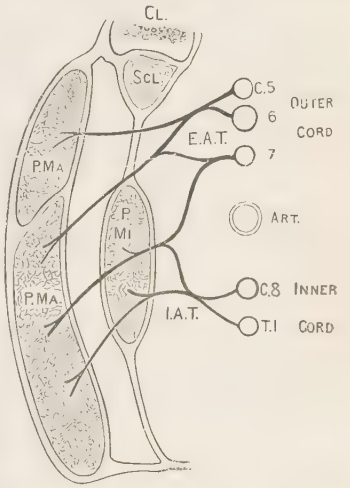

FIG. 495. DIAGRAM OF THE ORIGIN AND DISTRIBUTION OF THE NERVES TO THE PECTORAL MUSCLES.

E.A.T, External anterior thoracic nerve; I.A.T, Internal anterior thoracic nerve; C.5, 6, 7, C.8, T.1, Nerves of the brachial plexus; ART, Axillary artery; CL, Clavicle; SCL, Subclavius muscle; P.MI, Pectoralis minor, joined to subclavius by costo-coracoid membrane; P.MA, Pectoralis major.

**Infra-clavicular Nerves.**—The so-called infra-clavicular branches of the brachial plexus are distributed to the chest, shoulder, and arm. According to their origin they are divisible into two sets—an **anterior set**, derived from the outer and inner cords, and a **posterior set**, derived from the posterior cord. In their distribution the same division is maintained. The anterior nerves of distribution, springing from the outer and inner cords, supply generally the chest and the front of the limb; the posterior nerves, springing from the posterior cord, supply the shoulder and the back of the limb.

### Anterior Branches.

**Nerves from the Outer Cord.**

External anterior thoracic. Outer head of median. Musculo-cutaneous.

**Nerves from the Inner Cord.**

Internal anterior thoracic. Ulnar. Inner head of median.
Internal cutaneous. Lesser internal cutaneous.

### Posterior Branches.

**Nerves from the Posterior Cord.**

Circumflex. Musculo-spiral. Three subscapular nerves.

### Anterior Thoracic Nerves.

The **anterior thoracic nerves** (nn. thoracicales anteriores) are two in number, external and internal. The **external anterior thoracic nerve** arises from the outer cord of the brachial plexus by three roots—from the fifth, sixth, and seventh cervical nerves. The **internal anterior thoracic nerve** arises from the inner cord of the plexus, from the eighth cervical and first thoracic nerves. Each courses downwards and forwards on either side of the axillary artery. A loop of communication is formed between them over the artery. They are finally distributed to the pectoralis major and minor muscles (Fig. 495).

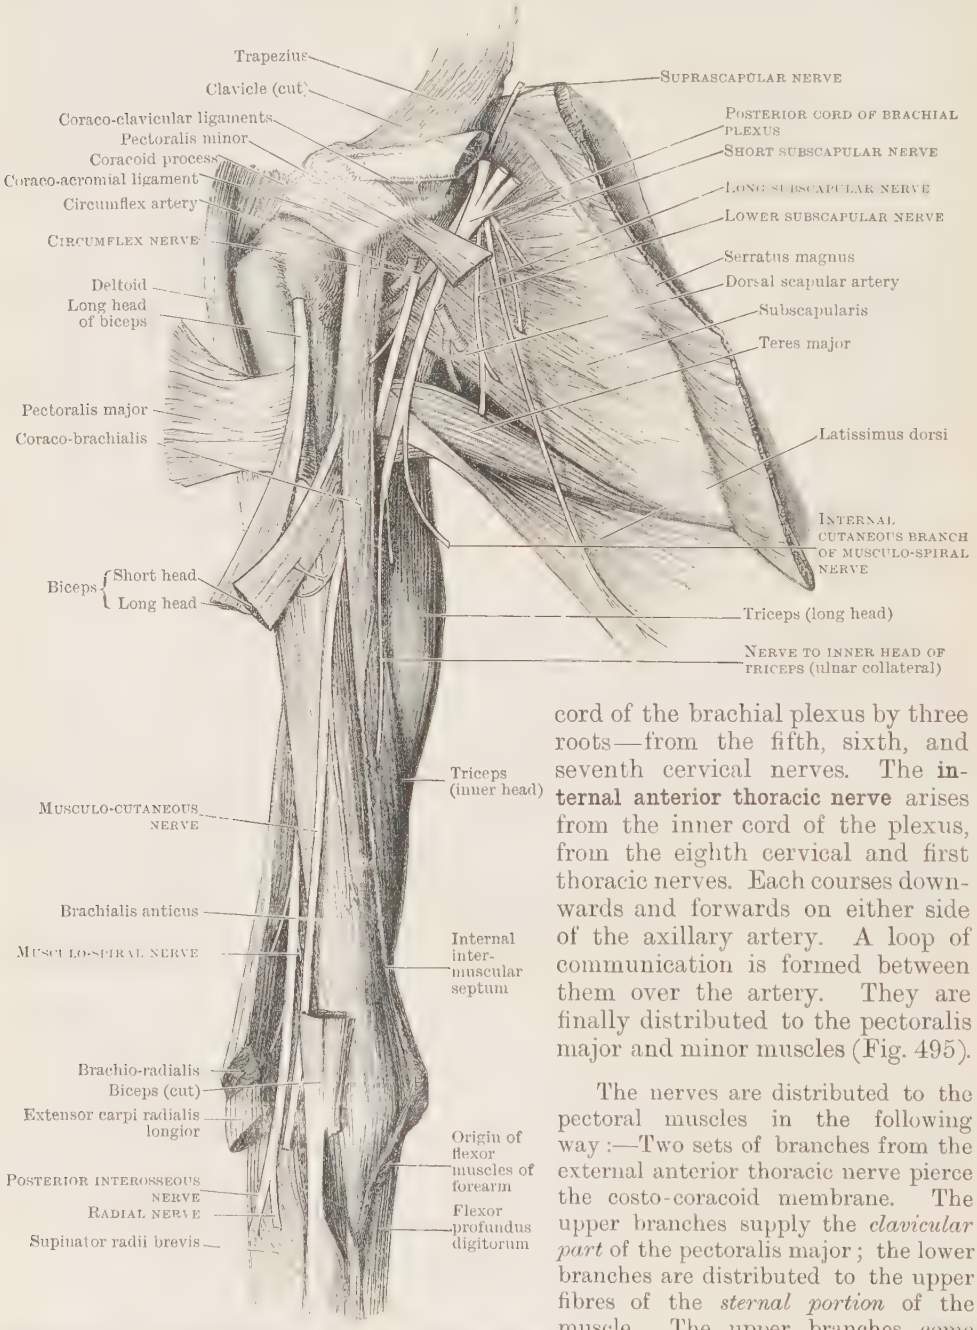

Fig. 196. The Posterior Wall of the Axilla and the Front of the Arm (the biceps being divided).

The nerves are distributed to the pectoral muscles in the following way :—Two sets of branches from the external anterior thoracic nerve pierce the costo-coracoid membrane. The upper branches supply the *clavicular part* of the pectoralis major; the lower branches are distributed to the upper fibres of the *sternal portion* of the muscle. The upper branches come from the fifth and sixth cervical nerves; the lower branches, from the fifth, sixth, and seventh nerves. The *pectoralis minor* is pierced by two sets of nerves—the upper set is derived from the loop of communication between the external and internal anterior thoracic nerves over the axillary artery; the lower set is derived from the internal anterior thoracic nerve alone. These nerves supply the *pectoralis minor* muscle, and, after piercing it, supply the *sternal part* of the pectoralis major. The lower nerve, in

many cases, sends its branches to the pectoralis major round the lower border of the pectoralis minor, and it may supply on its way the *axillary arches*, if present. These two branches are derived—the upper from the seventh, eighth cervical, and first thoracic nerves; the lower from the eighth cervical and first thoracic nerves. The pectoral muscles are thus both supplied by the two anterior thoracic nerves. The clavicular fibres of the pectoralis major are innervated by the fifth and sixth nerves; the sternal fibres, from above downwards, by the fifth, sixth, seventh, and eighth cervical, and first thoracic nerves; and the pectoralis minor is supplied by the seventh and eighth cervical, and first thoracic nerves.

### Musculo-Cutaneous Nerve.

The **musculo-cutaneous nerve** (n. musculo-cutaneus) takes origin from the outer cord of the plexus, from the fifth and sixth cervical nerves (Fig. 496). The **nerve to the coraco-brachialis muscle**, arising from the seventh or sixth and seventh nerves, is usually associated with it. Separating from the outer head of the median nerve, the musculo-cutaneous nerve lies at first between the coraco-brachialis muscle and the axillary artery. It is then directed downwards between the two parts of the coraco-brachialis, and passes between the biceps and brachialis anticus muscles, to the bend of the elbow. In its course it may send a branch under the biceps to join the median nerve. It pierces the deep fascia over the front of the elbow, between the biceps and brachio-radialis, and terminates in cutaneous branches for the supply of the outer side of the forearm.

The branches of the nerve are muscular and cutaneous. The **muscular branches** are supplied to the two heads of the biceps and the brachialis anticus, as the nerve lies between the muscles. The nerve to the coraco-brachialis (usually incorporated with the trunk of the musculo-cutaneous nerve) has an independent origin from the seventh or sixth and seventh nerves. It is usually double, one branch entering each portion of the muscle. The **cutaneous branches** are anterior and posterior (Fig. 497, p. 628). The **anterior branch** descends along the front of the outer side of the forearm to the wrist, and supplies an area extending inwards to the middle line of the forearm anteriorly, and downwards so as to include the ball of the thumb. It communicates above the wrist with the radial nerve, and supplies branches to the radial artery. The **posterior** branch passes backwards and downwards over the extensor muscles and supplies the skin on the outer aspect of the forearm posteriorly in its upper three-fourths, communicating with the cutaneous branches of the musculo-spiral nerve.

In addition to the above branches, the musculo-cutaneous nerve supplies in many cases the following small twigs in the arm: (1) a medullary branch to the humerus; (2) a periosteal branch to the lower end of the humerus on its anterior surface; and (3) a branch to the brachial artery.

### Median Nerve.

The **median nerve** (n. medianus) arises by two roots—one from the outer cord, the other from the inner cord of the brachial plexus. The outer head, from the (fifth), sixth, and seventh nerves, descends along the outer side of the axillary artery; the inner head, from the eighth cervical and first thoracic nerves, crosses the end of the axillary artery or the beginning of the brachial artery, to join the other head in the upper part of the arm. Descending along the outer side of the brachial artery, the nerve crosses over it obliquely in the lower half of the arm. In the hollow of the elbow, it lies internal to the brachial artery, beneath the bicipital fascia and the median basilic vein. It passes into the forearm between the two heads of the pronator radii teres muscle, separated from the ulnar artery by the deep origin of that muscle. Extending down the middle of the forearm, between the superficial and deep muscles to the wrist, it enters the palm of the hand on the outer side of the flexor tendons of the fingers beneath the anterior annular ligament. In the hand it spreads out at the lower border of the annular ligament beneath the palmar fascia and superficial palmar arch, and separates into its six terminal branches. In the forearm a small artery accompanies it,—the comes nervi mediani. Above the wrist it is comparatively superficial, lying on the outer side of the superficial flexor tendons and directly beneath the tendon of the palmaris longus.

**Communications.**—(1) The median, in some cases, receives a communicating branch from the musculo-cutaneous nerve in the arm. (2) It communicates in some cases, in the upper part of the forearm, with the ulnar nerve beneath the flexor muscles. (3) It communicates by means of its cutaneous branches with the ulnar nerve in the palm of the hand.

**Branches.**—The median nerve usually gives off no branches in the upper arm.

Branches in the Forearm.—(1) **Articular Branches.**—Minute articular filaments are distributed to the front of the elbow-joint.

(2) **Muscular Branches.**—Just below the elbow a bundle of nerves arise which is distributed to the following muscles: pronator radii teres, flexor carpi radialis, palmaris longus, flexor sublimis digitorum. Nerves are also generally traceable from this bundle to the upper fibres of the flexor longus pollicis and flexor profundus digitorum. The nerve to the pronator radii teres often arises independently in the hollow of the elbow.

(3) The **anterior interosseous nerve** arises from the back of the median nerve in the forearm, descends in front of the interosseous membrane along with the anterior interosseous artery, passes behind the pronator quadratus muscle, and terminates by supplying articular filaments to the radiocarpal articulation. In its course the nerve supplies muscular branches to the flexor longus pollicis, the outer half of the flexor profundus digitorum, and the pronator quadratus, minute medullary branches to the radius and ulna, and twigs to the periosteum and interosseous membrane.

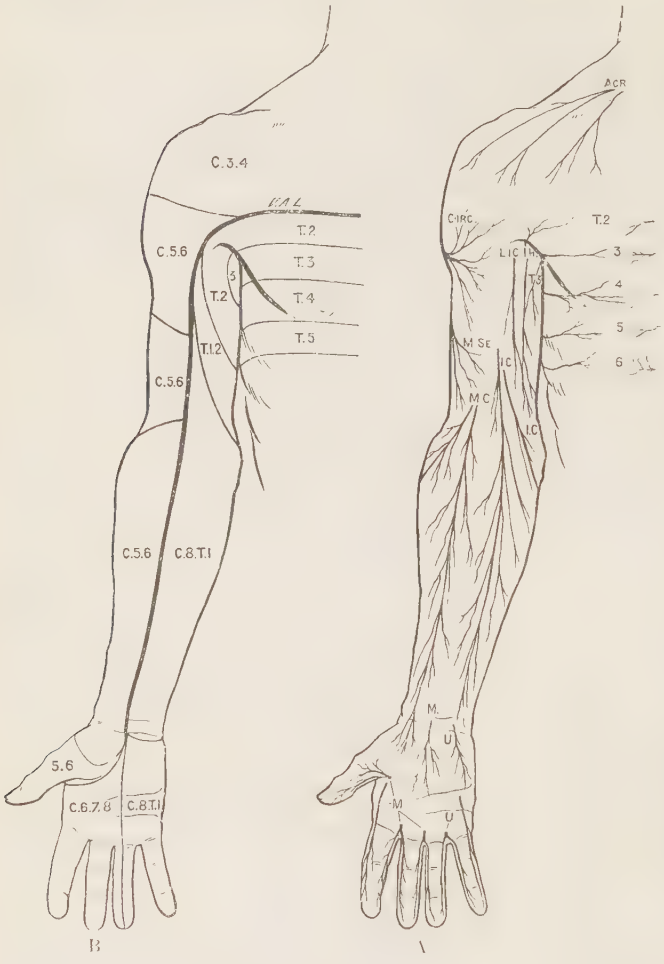

FIG. 497.—THE DISTRIBUTION OF CUTANEOUS NERVES ON THE FRONT OF THE ARM AND HAND.

(A) represents the distribution of the several nerves, the letters indicating their nomenclature. ACR, Acromial branch (cervical plexus); CIRC, Cutaneous branch of circumflex nerve; M.SE, Superior external cutaneous branch of musculo-spiral nerve; M.C, Musculo-cutaneous nerve; M, Median nerve; U, Ulnar nerve; I.C, Internal cutaneous nerve; L.I.C, Lesser internal cutaneous nerve (Wrisberg); I.H, Intercosto-humeral nerve; T.2, 3, 4, 5, 6, Anterior and lateral branches of intercostal nerves.

(B) is a schematic representation of the areas supplied by the above nerves, the lettering indicating the spinal origin of the branches of distribution to each area. V.A.L, Ventral axial line.

(4) **Palmar Cutaneous Branch.**—In the lower third of the forearm a small cutaneous branch arises, which pierces the deep fascia and crosses the anterior annular ligament to reach the palm of the hand. It supplies the skin of the palm and communicates with a similar branch of the ulnar nerve. This branch is not always present.

**Branches in the Hand.**—In the hand the median nerve gives off its terminal branches. These are muscular and cutaneous.

The main **muscular branch** arises just below the anterior annular ligament and passes outwards to the base of the thenar eminence; entering the ball of the thumb superficially on the inner side, it supplies branches to the abductor pollicis, opponens pollicis, and the superficial head of the flexor brevis pollicis.

The **cutaneous branches** are five in number. Three separate branches supply each side of the thumb and the radial side of the index finger. The two remaining branches subdivide at the cleft between the second and third, and the third and fourth fingers respectively, into branches which supply the adjacent sides of the second and third, and the third and fourth fingers. From the nerves which supply respectively the radial side of the index finger, and the contiguous sides of the index and third fingers, fine muscular branches arise for the two outer lumbrical muscles. The cutaneous branches of the median nerve are placed in the palm between the superficial palmar arch and the flexor tendons. They become superficial at the roots of the fingers between the slips of the palmar fascia, or, in the case of the nerves to the thumb and radial side of the index finger, at the outer edge of the central portion of the palmar fascia. In the fingers they are placed superficial to the digital arteries, and are distributed to the sides and front of the fingers. Each nerve supplies one or more dorsal branches, distributed to the skin on the dorsal aspect of the terminal phalanx of the thumb and the two distal phalanges of the first two and a half fingers, thus making up for the deficiency of the radial nerve in these situations.

## Ulnar Nerve.

The **ulnar nerve** (n. ulnaris) arises from the inner cord of the brachial plexus, from the eighth cervical and first thoracic nerves. It also occasionally has a root from the outer cord of the plexus (seventh cervical nerve). In the axilla it lies between the axillary artery and vein, and behind the internal cutaneous nerve; in the upper half of the upper arm it lies on the inner side of the brachial artery in front of the triceps muscle. In the lower half of the arm it is separated from the brachial artery; and passing behind the intermuscular septum, and in front of the inner head of the triceps in company with the inferior profunda artery, it reaches the interval between the internal condyle of the humerus and the olecranon process. It is here protected by an arch of deep fascia stretching between the internal condyle and the olecranon process. It enters the forearm between the humeral and ulnar origins of the flexor carpi ulnaris, and courses downwards between the flexor carpi ulnaris and flexor profundus digitorum. In the lower half of the forearm it becomes comparatively superficial, lying on the inner side of the ulnar artery beneath the tendon of the flexor carpi ulnaris. Just above the anterior annular ligament of the wrist, and external to the pisiform bone, it pierces the deep fascia in company with the artery and passes into the hand over the anterior annular ligament. Reaching the palm it divides beneath the palmaris brevis muscle into its two terminal branches, superficial and deep.

**Communications.**—(1) The ulnar nerve communicates in some cases with the median nerve in the forearm; (2) with the internal cutaneous and sometimes the median nerve by its palmar cutaneous branch; (3) with the cutaneous part of the median nerve in the palm by means of its terminal cutaneous branches; (4) with the radial nerve on the dorsum of the hand by means of its dorsal branch.

**Branches.**—The ulnar nerve gives off no branches till it reaches the forearm.

**In the forearm** it gives off articular, muscular, and cutaneous branches.

The **articular branch** is distributed to the elbow joint and arises as the nerve passes behind the internal condyle.

The **muscular branches** arise as soon as the nerve enters the forearm. They are distributed to the muscles between which the ulnar nerve lies—the flexor carpi ulnaris and the inner half of the flexor profundus digitorum.

The **cutaneous branches** are two in number, palmar and dorsal.

The **palmar cutaneous branch** is variable in size and position. It pierces the deep fascia in the lower third of the forearm and passes to the hypothenar eminence and palm of the hand, to the skin over which it is distributed. It gives branches to the ulnar artery, and communicates often with the internal cutaneous and palmar branch of the median nerve.

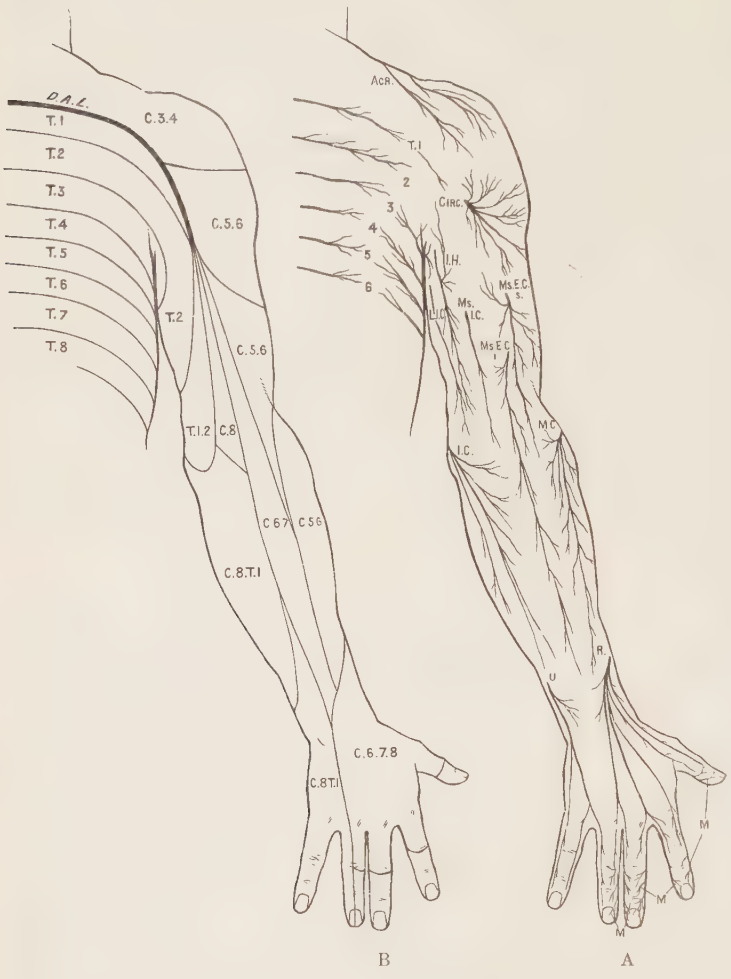

Fig. 498.—The Distribution of Cutaneous Nerves on the Back of the Arm and Hand.

(A) represents the distribution of the several nerves, the letters indicating their nomenclature. Acr, Acromial branches (cervical plexus); Circ, Cutaneous branch of circumflex nerve; Ms.E.C.s, Ms.E.C.i, Superior and inferior external cutaneous branches of musculo-spiral nerve; M.C, Musculo-cutaneous nerve; R, Radial nerve; M, Branches of median nerve to fingers; U, Ulnar nerve; I.C, Internal cutaneous nerve; Ms.I.C, Internal cutaneous branch of musculo-spiral nerve; L.I.C, Lesser internal cutaneous nerve (Wrisberg); I.H, Intercosto-humeral; T.1, 2, 3, 4, 5, 6, Lateral and posterior branches of upper thoracic nerves.

(B) is a schematic representation of the areas supplied by the above nerves, the lettering indicating the spinal origin of the branches of distribution to each area. D.A.L, Dorsal axial line.

The **dorsal cutaneous branch** is much larger (Fig. 498). It arises from the ulnar nerve in the middle third of the forearm; and, directed obliquely downwards and backwards beneath the tendon of the flexor carpi ulnaris, it becomes cutaneous on the inner side of the forearm in its lower fourth. It passes on to the back of the hand, and after giving off branches to the skin of the wrist and hand, which communicate with the radial nerve, it terminates in two branches, to supply the little finger and half the ring-finger in the following way:—the inner branch courses along the inner side of the dorsum of the hand and little finger: the outer branch subdivides at the cleft between the ring and little fingers to supply the adjacent sides of these fingers; this branch communicates with the radial nerve. The nerve may supply two and a half fingers on the dorsum of the hand.

**In the palm** the ulnar nerve supplies a small muscular branch to the palmaris brevis muscle, and then subdivides into its terminal branches, which are named superficial and deep.

The **superficial branch** is purely cutaneous; it passes downwards beneath the palmar fascia, and subdivides into an inner and an outer branch. The inner branch courses along the inner border of the little finger, which it supplies on its

palmar aspect. The outer branch becomes superficial at the cleft between the fourth and fifth fingers, between the slips of the palmar fascia, and subdivides into two branches which supply the adjacent sides of these fingers on their palmar aspect. It communicates with the adjacent digital branch of the median nerve.

The **deep branch** is purely muscular. It separates from the superficial branch,

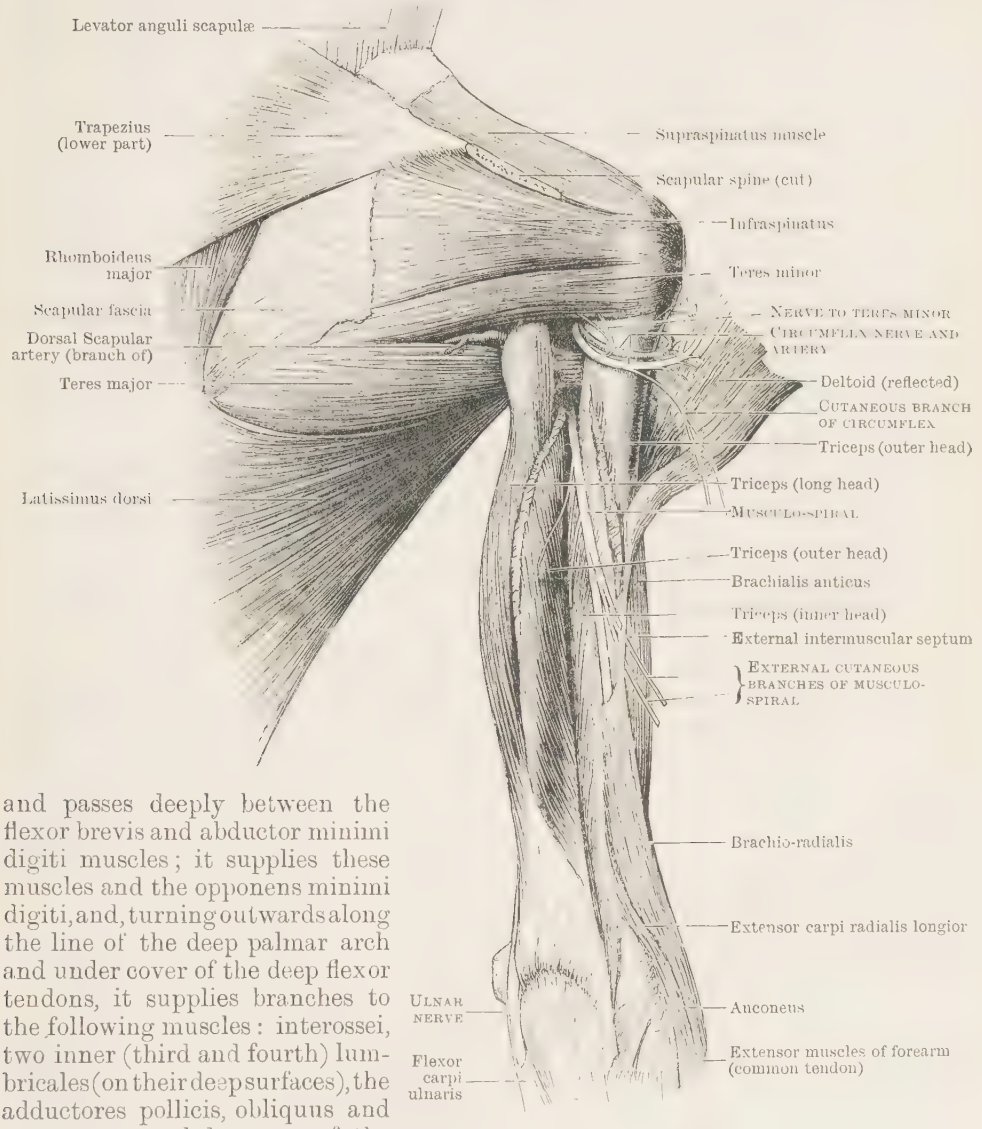

Fig. 499.—Deltoid Region and Back of Arm.

and passes deeply between the flexor brevis and abductor minimi digiti muscles; it supplies these muscles and the opponens minimi digiti, and, turning outwards along the line of the deep palmar arch and under cover of the deep flexor tendons, it supplies branches to the following muscles: interossei, two inner (third and fourth) lumbricales (on their deep surfaces), the adductores pollicis, obliquus and transversus, and deep part of the flexor brevis pollicis.

## Internal Cutaneous Nerve.

The **internal cutaneous nerve** (n. cutaneus brachii medialis) arises from the inner cord of the brachial plexus, from the eighth cervical and first thoracic nerves (Figs. 497 and 498). In the axilla and upper half of the arm it lies superficial to the main artery. It becomes cutaneous by piercing the deep fascia about the middle of the inner side of the upper arm, and accompanying the basilic vein through the lower half of the arm, it divides at the front of the elbow into its two terminal branches.

**Communication.**—The internal cutaneous nerve communicates with the palmar branch of the ulnar nerve in the lower part of the forearm.

**Branches.**—In the arm, as soon as it becomes superficial, the internal cutaneous nerve gives off a branch which supplies the skin of the lower half of the anterior surface of the arm on its inner side. At the elbow it divides into two terminal branches—anterior and internal, which, crossing over or under the median basilic vein, are distributed to the inner side of the forearm.

The **anterior branch** can be followed to the wrist and supplies the whole of the front of the forearm in the inner half; the **internal branch** is not so large, and, passing obliquely backwards and downwards over the origins of the pronator and flexor muscles, it is distributed to the upper two-thirds or three-fourths of the posterior aspect of the forearm on the inner side.

### Lesser Internal Cutaneous Nerve.

The **lesser internal cutaneous nerve** (n. cutaneus brachii medialis minor) arises from the inner cord of the brachial plexus, and ultimately from the first thoracic nerve (Fig. 494, p. 624). It lies at first between the axillary artery and vein; and after descending over, under, or even, in some cases, through the axillary vein, it perforates the deep fascia on the inner side of the arm, and is distributed to the skin of the arm for the upper half or more on its inner side.

The nerve varies considerably in size. It may be absent, its place being taken by branches of the intercosto-humeral or by branches from the internal cutaneous offset of the musculo-spiral nerve. It generally bears a distinct relation in size to the intercosto-humeral, due to the fact that the size of the latter depends upon the size of the part of the second thoracic nerve connected with the first in the thorax. If an intra-thoracic connexion occurs between the first and second thoracic nerves, the intercosto-humeral may be deprived of a certain number of its fibres, which in that case reach the upper limb through the lesser internal cutaneous nerve. When traced up to the plexus the lesser internal cutaneous is found to have an origin from the back of the cord formed by the eighth cervical and first thoracic nerves, and usually receives fibres from the first thoracic nerve only. In cases where "*axillary arches*" are present they may be supplied by this nerve.

### Circumflex Nerve.

The **circumflex nerve** (n. axillaris), at its origin is just below the suprascapular and comes from the same spinal nerves—the fifth and sixth cervical nerves (Fig. 494, p. 623). Extending downwards and outwards behind the axillary artery, it leaves the axilla by passing round the external border of the subscapularis muscle, in company with the posterior circumflex artery, in a quadrilateral space bounded by the humerus, subscapularis, triceps (long head), and teres major. Winding round the surgical neck of the humerus from within outwards, it terminates under the deltoid by supplying that muscle (Fig. 499, p. 631).

**Branches.**—**Muscular branches** are supplied to the teres minor and deltoid muscles. The nerve to the teres minor enters the outer side of the muscle. It possesses a pseudo-ganglion, a thickening of fibrous tissue, on its trunk.

**Articular branches** enter the back part of the capsule of the shoulder-joint.

A **cutaneous branch** (n. cutaneus brachii lateralis) of considerable size passes obliquely downwards and forwards from beneath the deltoid muscle, becoming superficial at its posterior border. Sometimes the branches pierce the muscle. It supplies the skin over the insertion of the deltoid and the upper half of the arm on the outer side (Fig. 498, p. 630).

### Musculo-Spiral Nerve.

The **musculo-spiral** nerve (n. radialis) appears to be the continuation into the upper limb of the posterior cord of the brachial plexus. It usually takes origin from all the nerves which form the posterior cord—the fifth, sixth, seventh, and eighth cervical nerves (Fig. 494, p. 623). In a minority of cases the first thoracic contributes a few fibres, and more frequently the fifth cervical nerve is excluded from it. It extends from the axilla round the back of the humerus to the bend of the elbow, where it ends by dividing into its terminal branches.

*In the axilla* it lies behind the axillary artery, and in front of the subscapularis, teres major, and latissimus dorsi muscles.

*In the arm*, in the upper third, it lies on the inner side of the humerus behind the brachial artery, and upon the long head of the triceps. In the middle third of the arm it courses obliquely outwards and downwards in the spiral groove of the humerus, along with the superior profunda artery, separating the long, external, and internal heads of the triceps muscle (Fig. 499, p. 631). In the lower third of the arm, piercing the upper part of the intermuscular septum at the outer border of the triceps muscle, it descends to the bend of the elbow in front of the external condyle of the humerus, in the interval between the brachio-radialis and brachialis anticus muscles. Under cover of the former muscle, in the hollow of the elbow, it divides into its two terminal branches, the radial and posterior interosseous nerves.

The **collateral branches** are in three sets, arising (*a*) on the inner side, (*b*) on the back, and (*c*) on the outer side of the humerus (Fig. 500).

**Branches arising internal to the humerus.**—1. **Internal cutaneous** (n. cutaneus brachii posterior).—This branch, arising in common with one of the following, or independently, pierces the fascia on the inner side of the arm near the axilla. It supplies the skin of the inner side of the arm in the upper third, above and behind the area supplied by the lesser internal cutaneous nerve (Fig. 498, p. 630). This nerve varies in size, according to the bulk of the lesser internal cutaneous and intercosto-humeral nerves.

2. **Muscular branches** (rr. musculares).—These are in two sets. One series supplies the long head of the triceps muscle near its origin; the other series enters the inner head of the muscle. One of the latter, separating itself from the rest, accompanies the ulnar nerve in the middle third of the arm, and supplies the lower part of the muscle. This is sometimes called the **collateral ulnar nerve**.

FIG. 500.—DIAGRAMMATIC REPRESENTATION OF THE BRANCHES OF THE MUSCULO-SPIRAL NERVE.

M.S, Musculo-spiral nerve; L.H, Nerve to long head of triceps; I.C, Internal cutaneous branch; I.H, Nerve to inner head of triceps; O.H, Nerve to outer head of triceps; I.H, Second nerve to inner head of triceps; Anc. Nerve to anconeus; Art, Articular branch; E.Cs, Superior, external cutaneous branch; E.Ci, Inferior external cutaneous branch; B.A, Nerve to brachialis anticus; Br, Nerve to brachio-radialis; E.C.R.L, Nerve to extensor carpi radialis longior; P.I, Posterior interosseous nerve; R, Radial nerve.

**Branches arising on the back of the humerus.**—**Muscular branches** arise from the nerve in the musculo-spiral groove for the supply of all three heads of the triceps muscle. The branch which enters the inner head of the muscle, besides supplying it, passes through the muscle and behind the external condyle of the humerus, to terminate in the anconeus.

**Branches arising at the outer side of the humerus.**—1. The **cutaneous branches** (n. cutaneus antibrachii dorsalis) are two in number, superior and inferior. Arising from the musculo-spiral nerve before it pierces the external intermuscular septum, these branches pierce the deep fascia close together on the outer side of the arm in its lower half. Descending over the back of the external condyle, the *superior branch* supplies the skin of the outer side and back of the arm in its lower third, and the back of the forearm in its upper half. The *inferior branch* supplies an area of skin on the back of the forearm in the upper two-thirds internal to the area innervated by the musculo-cutaneous nerve (Fig. 498, p. 630).

2. **Muscular branches.**—The musculo-spiral nerve, as it lies in the interval between the brachialis anticus and brachio-radialis, supplies a small branch to the brachialis anticus (which in some cases is not present) and nerves to the brachio-radialis and extensor carpi radialis longior. It may also provide the nerve to the extensor carpi radialis brevior.

### Radial Nerve.

The **radial nerve** (r. superficialis) is entirely cutaneous in its distribution. Arising in the hollow of the elbow beneath the brachio-radialis, it courses downwards under cover of that muscle through the upper two-thirds of the arm, and accompanies the radial artery in the middle third of the forearm. It then passes backwards beneath the tendon of the brachio-radialis and pierces the deep fascia in the outer side of the forearm in the lower third. It is distributed to the skin of the back of the wrist, the outer side and the back of the hand, and the back of the thumb and outer two and a half fingers (Fig. 498, p. 630). Its branches communicate on the ball of the thumb with the musculo-cutaneous nerve, and on the back of the hand with the dorsal branch of the ulnar nerve. The digital branches are small, and are five in number. Two pass to the back of the thumb and reach the inter-phalangeal articulation. One supplies the radial side of the index finger as far as the second phalanx. The remaining two branches divide at the clefts between the second and third, and third and fourth fingers respectively, and innervate the adjacent sides of these fingers as far as the second phalanx. The rest of the skin of these digits to the tips is supplied by digital branches of the median nerve. The nerve may only supply one and a half fingers, being replaced by branches from the ulnar nerve.

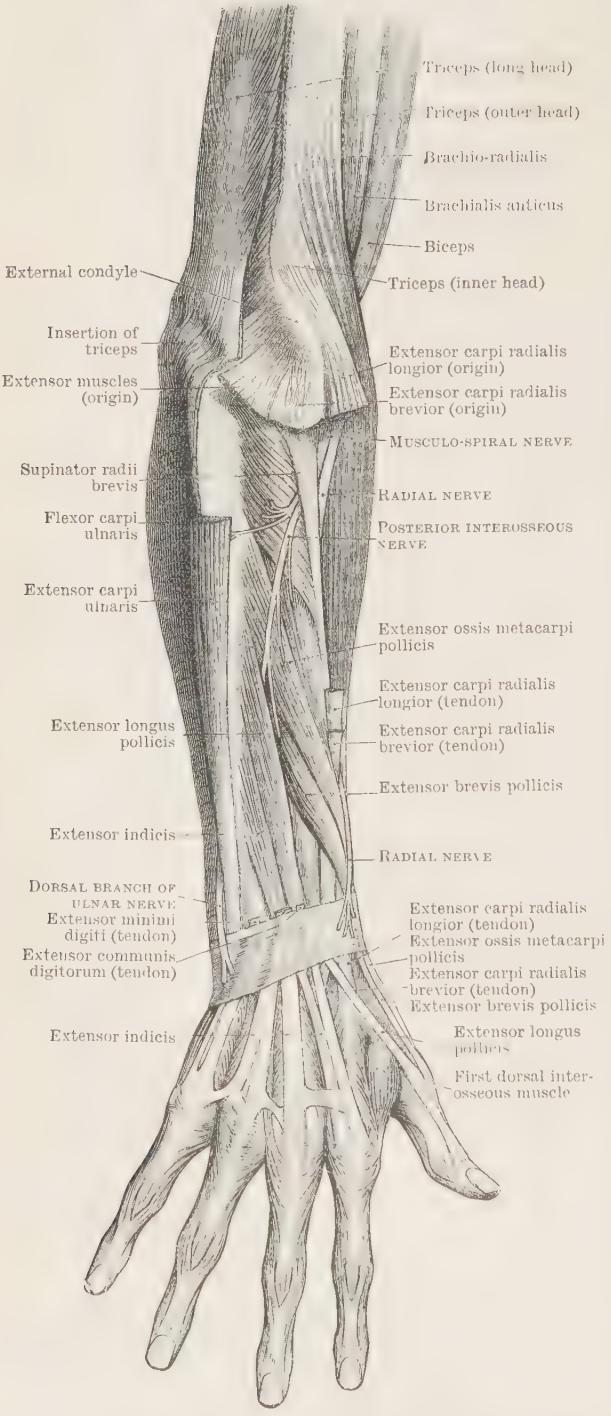

Fig. 501.—The Muscles of the Back of the Forearm (the superficial muscles have been reflected).

### Posterior Interosseous Nerve.

The **posterior interosseous nerve** (r. profundus, n. interosseus antibrachii dorsalis) is entirely muscular and articular in its distribution, and it arises like the radial beneath the brachio-radialis muscle. Directed obliquely downwards and backwards, it

reaches the back of the forearm, after passing round the outer side of the radius, by piercing the fibres of the supinator radii brevis muscle (Fig. 501). On the back of the forearm it is placed in the upper part of its course beneath the superficial extensor muscles, and upon the supinator radii brevis and extensor ossis metacarpi pollicis, along with the posterior interosseous artery. In the lower half of the forearm it passes beneath the extensor longus pollicis, and lies upon the interosseous membrane. At the wrist it passes beneath the extensor tendons on to the back of the carpus, where it terminates in a gangliform enlargement of small size, from which branches pass to the inter-carpal articulations. The posterior interosseous nerve supplies the following branches:—

(1) Terminal **articular branches** to the carpal joints.

(2) **Muscular branches**, in its course through the forearm. Thus on the outer side of the radius it supplies the extensor carpi radialis brevior and the supinator brevis muscle before it enters the fibres of the last-named muscle. After emerging from the supinator brevis it supplies a large bundle of nerves which enter the extensor communis digitorum, extensor minimi digiti, and extensor carpi ulnaris near their origins. Lower down the forearm the nerve gives off branches to the extensor ossis metacarpi pollicis, extensor longus and extensor brevis pollicis, and extensor indicis.

### Subscapular Nerves.

There are three subscapular nerves (nn. subscapulares) (Figs. 494 and 496).

The **first or short subscapular nerve** is generally double, and there may be three trunks present. It arises from the posterior cord of the plexus behind the circumflex nerve, and comes from the fifth and sixth cervical nerves. It passes downwards behind the axillary artery and enters the subscapularis muscle.

The **second or lower subscapular nerve** also arises behind the circumflex from the posterior cord of the plexus, and from the fifth and sixth cervical nerves. Its origin is below and external to that of the first nerve. It courses outwards and downwards behind the axillary artery, and the circumflex and musculo-spiral nerves to the teres major muscle. It supplies branches to the outer part of the subscapularis muscle and ends in the teres major.

The **third or long subscapular nerve** (n. thoraco-dorsalis) arises from the back of the posterior cord of the plexus, behind the musculo-spiral nerve, and from the sixth, seventh, and eighth cervical nerves, or from the seventh and eighth nerves only. It is directed downwards and outwards between the two previous nerves, behind the axillary artery and over the posterior wall of the axilla, in company with the subscapular artery, to the latissimus dorsi muscle, which it supplies on its anterior (inner) surface.

## THORACIC NERVES.

The thoracic nerves are twelve in number, each nerve emerging below the corresponding vertebra and rib. Eleven of the series are intercostal, the twelfth lying below the last rib. The first, second, third, and twelfth nerves present peculiarities in their course and distribution. The other thoracic nerves, as already stated, are simple, and may be regarded as types both in course and distribution.

The **first thoracic nerve** is the largest of the series. It emerges from the spinal canal below the neck of the first rib, and divides in the first intercostal space into two very unequal, upper and lower, parts. The *upper* larger part ascends obliquely over the neck of the first rib, lying external to the superior intercostal artery, and enters the neck behind the subclavian artery and the pleura. It proceeds outwards upon the scalenus medius muscle and enters into the formation of the brachial plexus, as already described.

The *lower, intercostal part* of the nerve is much smaller in size. It courses forwards in the first intercostal space and supplies the intercostal muscles. It usually gives off no anterior branch to the skin of the chest and no lateral cutaneous branch.

In some cases a lateral cutaneous branch emerges from the side of the first intercostal space. This may be derived from the first nerve, or it may be the **intercosto-humeral nerve**, derived from the second thoracic nerve. In many cases an anterior cutaneous branch perforates the first intercostal space and supplies the skin on the front of the chest. This branch, similarly, is sometimes traceable to the second thoracic nerve.

**Communications.**—Besides its junction with the eighth cervical to form the brachial plexus, the first thoracic nerve effects the following communications:—(*a*) The last cervical or first thoracic ganglion of the sympathetic sends a gray ramus communicans to join the nerve on its appearance in the thorax. (*b*) The second thoracic nerve in a majority of cases communicates with the first. This communication varies considerably in size and distribution. It may reinforce the intercostal branch of the nerve, it may send one branch to the intercostal portion and another to the part of the nerve joining the brachial plexus, or it may consist of a nerve proceeding solely to join the brachial plexus by a junction in the first intercostal space with the part of the first thoracic nerve, which is engaged in forming the plexus. (*c*) It is possible that the first *white ramus communicans* in the thoracic region connects the first thoracic nerve with the gangliated cord of the sympathetic, but this is not known with certainty.

The **second thoracic nerve** is of large size, though much smaller than the first. It passes forwards in the second intercostal space, lying at first in the subcostal groove between the external and internal intercostal muscles. At the level of the mid-axillary line it gives off a large lateral branch; continuing its course it pierces the internal intercostal muscle and lies upon the pleura; finally, at the lateral border of the sternum, it passes forwards in front of the internal mammary artery and through the internal intercostal muscle, and the aponeurosis of the external intercostal muscle, and ends by supplying the skin of the front of the chest over the second intercostal space.

The nerve supplies the following branches:—

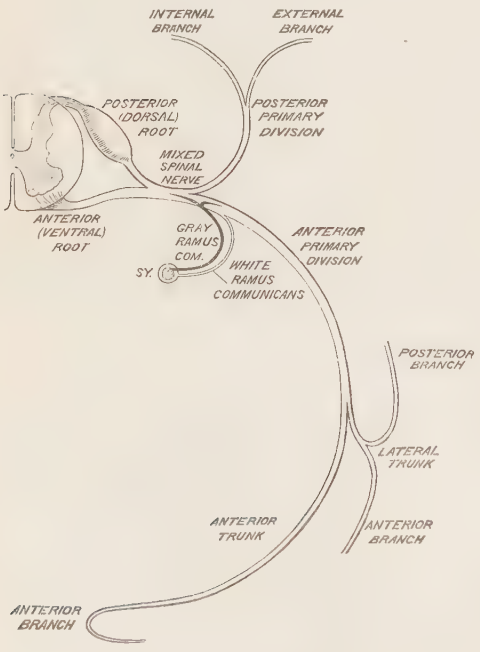

FIG. 502.—SCHEME OF THE DISTRIBUTION OF A TYPICAL SPINAL NERVE.

1. **Muscular branches** to the muscles of the second intercostal space.

2. **Cutaneous branches.** (*a*) **Anterior terminal branches** (rr. cutaneus anterior) to the skin over the second intercostal space (Fig. 503). (*b*) A large lateral cutaneous branch, the **intercosto-humeral nerve** (n. intercosto-brachialis) (Fig. 494, p. 623). This nerve pierces the intercostal muscles and the serratus magnus, and, crossing the axilla, extends to the arm. It pierces the deep fascia just beyond the posterior fold of the axilla, and can be traced down the arm as far as the interval between the internal condyle of the humerus and the olecranon process. It supplies an area of skin stretching across the armpit and along the posterior surface of the arm on the inner side as far as the elbow (Fig. 497, p. 628).

The intercosto-humeral nerve varies in size. It may pierce the first intercostal space, and it is often divisible into anterior and posterior branches, like the lateral branch of an ordinary intercostal nerve.

**Communications.**—(1) The intercosto-humeral nerve communicates with two adjacent nerves. Either before or after piercing the fascia of the axilla it is joined by the lesser internal cutaneous nerve of the brachial plexus. It also communicates with the posterior part of the lateral branch of the third intercostal nerve by means of the branches distributed to the floor and boundaries of the axilla. It may supply the axillary arches, when present. (2) Besides the branches referred to, the second thoracic nerve in many

cases transmits a nerve to the brachial plexus, which becomes incorporated with the first thoracic nerve after passing over the neck of the second rib. This branch is inconstant. As already mentioned, it may join only the intercostal part of the first thoracic nerve, it may join the brachial plexus only, or it may send branches to both parts of the first thoracic nerve. (3) Besides the communications effected by branches of the second thoracic nerve in its course, it also receives a *gray ramus communicans* from the second thoracic ganglion of the sympathetic cord in the thorax. It probably also sends to the sympathetic the first *white ramus communicans*, though this is not known with certainty.

The **third thoracic nerve** only differs from a typical thoracic nerve in one respect. Its **lateral branch** divides in the usual way into anterior and posterior parts, of which the latter is carried to the arm and supplies an area of skin on the posterior half of the inner side near the root of the limb. It effects a junction with the intercosto-humeral nerve (Fig. 494, p. 623).

The **fourth, fifth, and sixth thoracic nerves** have a course and distribution which is simple and typical. Except for the peculiarities above mentioned, the second and third thoracic nerves have a similar distribution.

The nerves appear on the posterior wall of the thorax, in the subcostal groove of the corresponding rib. They extend forwards between the intercostal

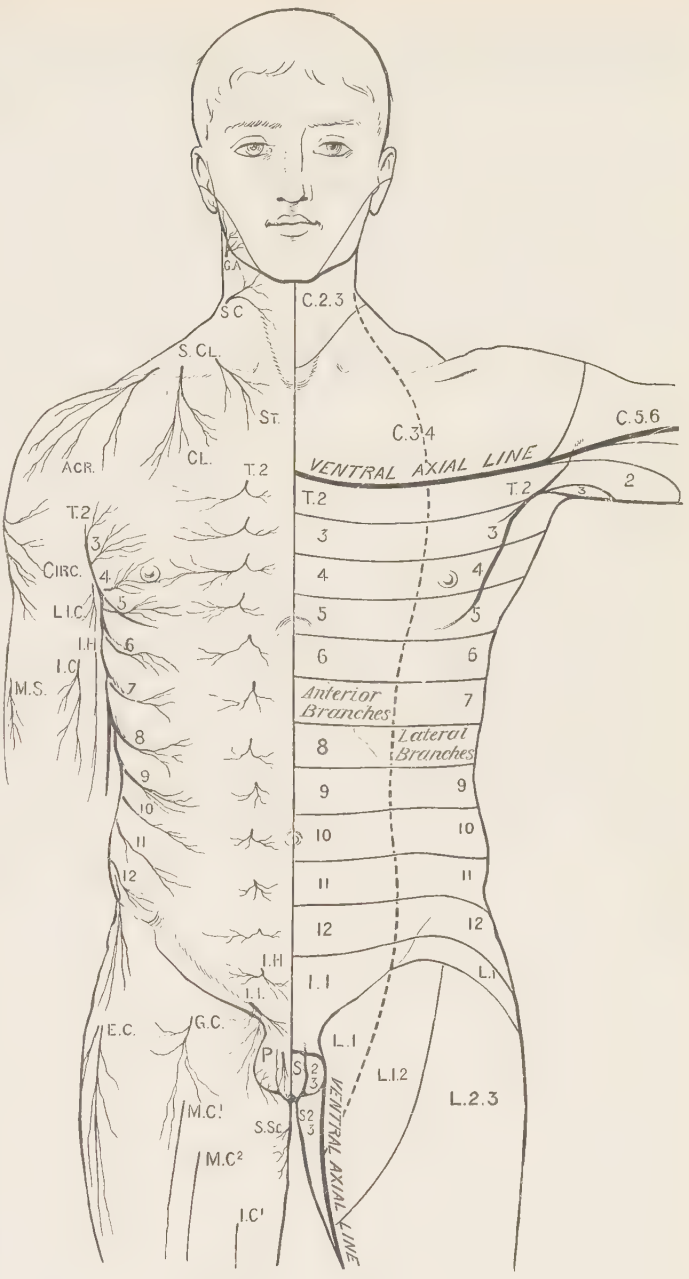

Fig. 503.—The Distribution of Cutaneous Nerves on the Front of the Trunk.

On one side the distribution of the several nerves is represented, the letters indicating their nomenclature.

G.A, Great auricular nerve; S.C, Superficial cervical nerve; S.Cl, Supraclavicular nerves; Acr, Acromial; Cl, Clavicular; St, Sternal; T.2-12, Lateral and anterior branches of thoracic nerves; I.H, Ilio-hypogastric nerve; I.I, Ilio-inguinal nerve; Circ, Cutaneous branch of circumflex nerve; L.I.C, Lesser internal cutaneous nerve; I.H, Intercosto-humeral; I.C, Internal cutaneous; M.S, Cutaneous branch of musculo-spiral nerve, E.C, External cutaneous nerves; G.C, Genito-crural nerve; M.C¹ ², Middle cutaneous nerves; I.C¹, Branch of internal cutaneous nerve; P, Branches of pudic nerve; S.Sc, Branches of small sciatic nerve.

On the other side a schematic representation is given of the areas supplied by the above nerves, the numerals indicating the spinal origin of the branches of distribution to each area.

muscles as far as the middle of the chest wall, lying at a lower level than the intercostal vessels. At the side of the chest each nerve passes obliquely through the internal intercostal muscle, and comes to lie upon the pleura, triangularis sterni muscle, and internal mammary artery. Thereafter, piercing the fibres of the internal intercostal muscle and the aponeurosis of the external intercostal muscle, each nerve ends by supplying the skin of the front of the chest, over an area corresponding to the inner or anterior part of the intercostal space to which it belongs.

**Branches.**—Each intercostal nerve supplies, in addition to the anterior terminal cutaneous branches, *muscular branches* to the intercostal muscles and a **lateral trunk** (r. cutaneus, lateralis), which, piercing the intercostal muscles and the serratus magnus, divides into anterior and posterior branches for the innervation of the skin over the side of the chest. Each area of skin thus innervated is continuous anteriorly with the area innervated by the anterior terminal branches of the same nerves, and posteriorly with the areas supplied by their posterior primary divisions.

The upper six intercostal nerves supply the muscles of the first six intercostal spaces and the triangularis sterni (3, 4, 5, 6). The second, third, fourth, fifth, and sixth nerves supply the skin of the front of the chest: the second, opposite the manubrio-sternal joint; the sixth, opposite the base of the xiphoid cartilage. Their lateral branches supply branches to the intercostal muscles and the skin of the side of the chest, the second (intercosto-humeral) and the third in part being drawn out on to the arm. The fourth supplies the nipple (Fig. 503).

**Communications.**—Each of these intercostal nerves communicates with the sympathetic cord and ganglia by two branches—a *white ramus communicans* to the corresponding sympathetic ganglion or the adjacent part of the sympathetic cord; and a *gray ramus communicans*, which passes to each nerve from the corresponding ganglion.

The **seventh, eighth, ninth, tenth, and eleventh thoracic nerves** only differ from the preceding nerves in regard to a part of their course and distribution. Each has the same course and communications as the preceding nerves in the thoracic wall. In addition, these nerves have a further course and distribution in the abdominal wall. Each nerve traverses its intercostal space in the way described. At the anterior end of the space, the nerve pierces the attachment of the diaphragm and the transveralis abdominis muscles to the costal cartilages, and courses forwards in the abdominal wall between the transversalis and obliquus internus muscles. The nerve then passes between the rectus muscle and the posterior layer of its sheath, and eventually reaches the anterior abdominal wall and becomes cutaneous by piercing the rectus itself and the anterior layer of its sheath.

**Muscular Branches.**—The lower intercostal nerves supply the intercostal muscles of the spaces in which they lie; and in the abdominal wall they innervate the transversalis, obliqui, and rectus abdominis. The branches arise from the main trunk as well as from its lateral and anterior branches. (The ninth, tenth, and eleventh nerves are described as assisting in the innervation of the diaphragm by communications with the phrenic nerve.)

**Cutaneous Branches.**—These are lateral and anterior. The **lateral branches** divide into anterior and posterior parts, and, becoming superficial along the line of inter-digitation of the obliquus externus muscle with the serratus magnus and latissimus dorsi, they are directed more obliquely downwards than the lateral branches of the higher intercostal nerves, and are distributed to the skin of the loin as low down as the buttock. The lateral branch of the eleventh nerve can be traced over the iliac crest (Fig. 503).

The **anterior branches** are small. That of the seventh nerve innervates the skin at the level of the ensiform cartilage. The eighth and ninth appear between the ensiform cartilage and the umbilicus; the tenth nerve supplies the region of the umbilicus; and the eleventh, the area immediately below the umbilicus.

The cutaneous branches of these nerves, including the posterior primary divisions, thus supply continuous belts of skin, which can be mapped out on the body from the vertebral column behind to the middle line in front. These areas are not placed horizontally, but tend to be drawn downwards as the series is followed from the upper to the lower nerves.

The **twelfth thoracic nerve** is peculiar in its course and distribution. It

emerges below the last rib (Fig. 504), and passes outwards and downwards in the posterior abdominal wall under cover of the psoas muscle, and between the external arcuate ligament and the quadratus lumborum muscle; it pierces the transversalis muscle, and courses forwards in the interval between it and the obliquus internus as far as the sheath of the rectus muscle. After piercing the posterior layer of the sheath, the rectus muscle, and the anterior layer of the sheath, it terminates by supplying the skin of the anterior abdominal wall midway between the umbilicus and the pubis. The branches of the nerve are **muscular**, to the transversalis, obliqui, rectus, and pyramidalis muscles of the abdominal wall, and **cutaneous branches**, two in number—an *anterior terminal branch*, which supplies the skin of the anterior abdominal wall midway between the umbilicus and the pubis, and a large *lateral cutaneous* (iliac) *branch*, which, passing obliquely downwards through the lateral muscles of the abdominal wall, becomes superficial above the iliac crest, a couple of inches behind the anterior superior spine. It supplies the skin of the buttock as far down as a point below and in front of the great trochanter of the femur (Fig. 507, p. 645).

The twelfth thoracic nerve, in many cases, receives a **communicating branch** from the eleventh, near its origin, and still more frequently sends a fine branch to join the origin of the first lumbar nerve in the psoas muscle. It may communicate also with the ilio-hypogastric nerve, as they lie together in the abdominal wall.

## THE LUMBO-SACRAL PLEXUS.

The lumbo-sacral plexus is formed by the union of the anterior primary divisions of the remaining spinal nerves — five lumbar, five sacral, and one coccygeal. Frequently, a fine communicating branch of the twelfth thoracic nerve joins the first lumbar nerve near its origin.

Of the nerves in question the first sacral is generally the largest in size, the nerves diminishing gradually above and rapidly below the first sacral. The plexus, for the most part, forms the nerves destined for the supply of the lower limb. In addition, however, nerves arise at its upper limit which are distributed to the trunk above the level of the limb, and at the lower end of the plexus nerves arise for the supply of the perineum.

Partly for convenience of description, and partly on account of the differences in position and course of some of the nerves emanating from it, the plexus is subdivided into three subordinate parts — lumbar, sacral or sciatic, and pudendal plexuses. There is, however, no strict line of demarcation between the three parts.

The **lumbar plexus** is formed by the first four lumbar nerves, and is often joined by a branch from the twelfth thoracic nerve as well. It is limited below by the fourth lumbar nerve (n. furcalis), which also enters into the composition of the sciatic or sacral plexus. The nerves of the lumbar plexus are formed in the loin, and supply that region as well as part of the lower limb. They are separated from the nerves of the sacral portion of the plexus by the articulation of the innominate bone with the sacrum.

The **sacral** or **sciatic plexus** is formed by the fourth and fifth lumbar, and the first two or three sacral nerves. It is generally limited below by the third sacral nerve (n. bigeminus), which also assists in forming the pudendal plexus. The nerves of the sacral plexus are placed on the posterior wall of the pelvis, and are destined almost entirely for the lower limb.

The **pudendal plexus** is formed by the second, third, fourth, and fifth sacral nerves, and the minute coccygeal nerve. It is placed on the back wall of the pelvis and supplies branches mainly to the perineum.

**Communications with the Sympathetic.**—Each of these nerves has communications with the gangliated cord of the sympathetic in the abdomen and pelvis.

**Gray Rami Communicantes.**—From the lumbar and sacral ganglia long slender *gray rami communicantes* are directed backwards and outwards over the bodies of the vertebræ, and (in the lumbar region) beneath the origins of the psoas muscle, to reach the anterior primary divisions of the nerves. These branches are irregular in their arrangement. A given nerve may receive branches from two ganglia, or one ganglion may send branches to two nerves. The rami are longer in the loin than in the pelvis, owing to the projection of the lumbar portion of the vertebral column.

**White Rami Communicantes.**—Certain lumbar and sacral nerves are also connected with the abdominal and pelvic sympathethic by means of *white rami communicantes*. From the first two, and possibly also the third and fourth lumbar nerves, white rami communi-

cantes are directed forwards, either independently or incorporated with the corresponding gray rami, to join the upper part of the lumbar gangliated cord. The fifth lumbar nerve and the first sacral nerves are unprovided with white rami communicantes. From the third, and usually also the second or fourth sacral nerves, white rami (visceral branches) pass inwards, and, crossing over (without joining) the gangliated cord, enter the pelvic plexus of the sympathetic. The fifth sacral and coccygeal nerves possess no white rami communicantes.

## THE LUMBAR PLEXUS.

The lumbar plexus is formed by the anterior primary divisions of the first three

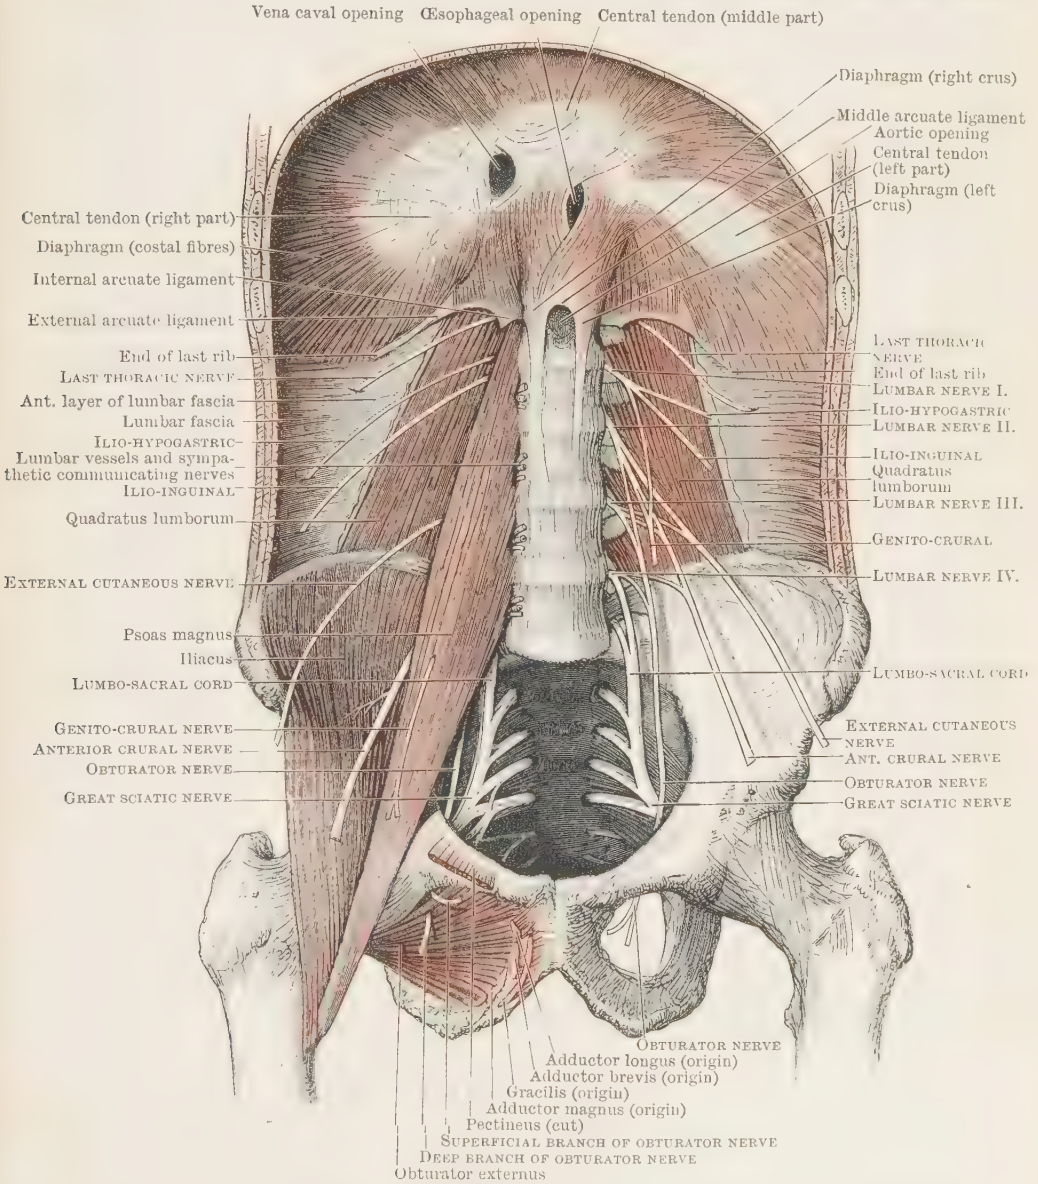

Fig. 505.—View of the Posterior Abdominal Wall, to show the Muscles and the Nerves of the Lumbo-Sacral Plexus.

and a part of the fourth lumbar nerves, with the addition, in some cases, of a small branch from the twelfth thoracic nerve. The nerves increase in size from above downwards (Fig. 505).

**Position and Constitution.**—The plexus is placed deeply in the substance of the psoas muscle, in front of the transverse processes of the lumbar vertebræ. The

nerves, on emerging from the intervertebral foramina, are connected as above described with the sympathetic system, and then divide in the following manner in the substance of the psoas muscle. The first and second nerves divide into upper and lower branches. The upper branch of the first nerve (which may be joined by the branch from the twelfth thoracic nerve) forms two nerves, **ilio-hypogastric** and **ilio-inguinal**. The lower branch of the first joins the upper branch of the second nerve, to produce the **genito-crural nerve**. The lower branch of the second nerve, the whole of the third, and that part of the fourth nerve engaged in the constitution of the plexus divide each into two unequal parts—smaller *anterior* and larger *posterior parts*. The smaller anterior portions combine together to form the **obturator nerve**, which is thus formed by the second, third, and fourth lumbar nerves. The root from the second nerve is not always present. The larger posterior portions of the same nerves combine together to form the **anterior crural nerve**. From the back of the posterior parts of the second and third nerves, the **external cutaneous nerve** arises. The nerves also provide, near their origins, irregular **muscular branches**, for the psoas and quadratus lumborum muscles. The following is a list of the nerves which spring from the lumbar plexus (Figs. 504 and 505):—

(1) Muscular branches to the quadratus lumborum and psoas.
(2) Ilio-hypogastric.
(3) Ilio-inguinal.
(4) Genito-crural.
(5) External cutaneous.
(6) Obturator.
(7) Anterior crural.

**Muscular Branches.**—The nerves to the **quadratus lumborum muscle** arise independently from the first three or four lumbar nerves (and sometimes also from the twelfth thoracic nerve). The nerves to the **psoas muscles** arise from the second and third lumbar nerves, with additions, in some cases, from the first or fourth. They are often associated in their origin with the nerve to the iliacus from the anterior crural. The **psoas minor**, when present, is innervated by the first or second lumbar nerve.

The ilio-hypogastric and ilio-inguinal nerves closely resemble in their course and distribution the lower thoracic nerves, with which they are in series.

The **ilio-hypogastric nerve** (n. ilio-hypogastricus) is the highest branch of the first lumbar nerve. It receives fibres also from the twelfth thoracic, when that nerve communicates with the first lumbar nerve. After traversing the psoas muscle obliquely, it appears at its outer border on the surface of the quadratus lumborum and behind the kidney. It courses through the loin, lying between the transversalis and obliquus internus muscles, above the crest of the ilium. About an inch in front of the anterior superior spine it pierces the obliquus internus, and continues its course in the groin beneath the aponeurosis of the obliquus externus. It finally becomes cutaneous in the anterior abdominal wall, by piercing the aponeurosis of the obliquus externus about an inch and a half above the external abdominal ring (Fig. 507 p. 645).

Its **branches** are—(1) *muscular* to the muscles of the abdominal wall; and (2) *cutaneous branches*, two in number. The **iliac branch** corresponds with the lateral branch of an intercostal nerve, and, after piercing the obliquus internus and obliquus externus, becomes cutaneous just above the iliac crest, below and behind the iliac branch of the last thoracic nerve. It is small, and may be absent. It is distributed to the skin over the upper part of the outer side of the buttock, in continuity with the cutaneous branch of the posterior primary division of the first lumbar nerve. The **hypogastric branch** is the anterior terminal branch of the nerve. It supplies the skin of the anterior abdominal wall below the level of the last thoracic nerve and above the pubis.

The **ilio-inguinal nerve** (n. ilio-inguinalis) is the second branch given off from the first lumbar nerve. It also may receive fibres from the last thoracic nerve. Not unfrequently the ilio-hypogastric and ilio-inguinal nerves are represented for a longer or shorter part of their course by a single trunk. When separate the nerve takes a course similar to that of the ilio-hypogastric nerve, but at a lower level, as far as the anterior abdominal wall. It then pierces the obliquus internus farther forward and lower down than the ilio-hypogastric; and coursing forwards

beneath the aponeurosis of the obliquus externus, just above Poupart's ligament, it becomes superficial after passing through the external abdominal ring and external spermatic fascia (Fig. 507, p. 645).

Its branches are *muscular* to the muscles of the abdominal wall, among which it passes, and *cutaneous branches*, which innervate the skin (1) of the anterior abdominal wall over the symphysis pubis, (2) of the thigh over the upper and inner part of Scarpa's triangle, and (3) of the upper part of the scrotum, and root and dorsum of the penis (of the mons Veneris and labium majus in the female). These last-named branches are contiguous to branches of the pudendal and pudic nerves. No lateral cutaneous branch arises from the ilio-inguinal nerve. It thus corresponds, like the hypogastric part of the ilio-hypogastric nerve, to the anterior trunk of a typical thoracic nerve.

The **genito-crural nerve** (n. genito-femoralis) usually arises by two independent roots from the front of the first and second lumbar nerves, which unite in the substance of the psoas to form a slender trunk. It appears on the posterior abdominal wall, lying on the psoas magnus, internal to the psoas parvus, and, piercing the psoas fascia, it extends downwards on the outer side of the common and external iliac vessels and behind the ureter to Poupart's ligament (Fig. 505, p. 641). At a variable point above that ligament it divides into genital and crural branches. The **genital branch** is a minute nerve. It crosses the terminations of the external iliac vessels, and, along with the vas deferens and spermatic vessels, enters the inguinal canal through the internal abdominal ring. It terminates by supplying small branches to the skin of the scrotum and adjacent part of the thigh. In the female it accompanies the round ligament to the labium majus. This nerve gives off in its course the following small branches: (1) to the external iliac artery; (2) to the cremaster muscle; (3) to communicate with the spermatic plexus of the sympathetic. The **crural branch** continues the course of the parent nerve into the thigh, lying on the outer side of the femoral artery. It becomes cutaneous by passing through the saphenous opening or the iliac portion of the fascia lata, and supplies an area of skin over Scarpa's triangle, external to that supplied by the ilio-inguinal nerve (Fig. 507, p. 645). It communicates in the thigh with the middle cutaneous branch of the anterior crural nerve. Before piercing the deep fascia it gives a minute branch to the femoral artery.

The **external cutaneous nerve** (n. cutaneus femoris lateralis) is only distributed to skin (Fig. 505). It arises from the back of the lumbar plexus, and usually from the second and third lumbar nerves. Emerging from the psoas muscle at its outer border, the nerve crosses the iliacus muscle, beneath the fascia iliaca, to reach the anterior superior iliac spine. It enters the thigh beneath the outer extremity of Poupart's ligament, and either over, under, or through the origin of the sartorius muscle. It extends down the outer side of the front of the thigh for a few inches, lying at first beneath the fascia lata, and afterwards in a tubular investment of the fascia. It gives off small branches in this part of its course, and finally, piercing the fascia about four inches below the anterior superior iliac spine, it separates into anterior and posterior terminal branches. The **anterior branch** is the larger, and is distributed on the outer side of the front of the thigh almost to the knee. The smaller **posterior branch** supplies the skin of the outer side of the buttock below the great trochanter and of the upper two-thirds of the outer side of the thigh (Fig. 507, p. 645).

### Obturator Nerve.

The **obturator nerve** (n. obturatorius) supplies the muscles and skin on the inner side of the thigh. It arises in the substance of the psoas muscle by three roots placed in front of those of the anterior crural nerve, and derived from the second, third, and fourth lumbar nerves (Fig. 505, p. 641). Sometimes the root from the second nerve is absent. Passing vertically downwards, the nerve emerges from the psoas at its inner border, behind the common iliac, and on the outer side of the internal iliac vessels. It passes forwards below the pelvic brim in company with the obturator artery to the obturator groove of the thyroid foramen, through which it reaches the thigh. While in the obturator groove it separates into its two main branches, named superficial and deep (Fig. 506, p. 644).

The **superficial branch** enters the thigh in front of the obturator externus and adductor brevis muscles, and beneath the pectineus and adductor longus. In the middle third of the thigh it is found coursing along the inner border of the adductor longus, anterior to the gracilis; and it finally divides into two slender terminal filaments, of which one enters Hunter's canal and ends on the femoral artery, while the other supplies the skin for a variable distance on the inner side of the thigh and joins in the obturator (sub-sartorial) plexus.

The branches of the superficial part of the nerve are:—

1. An **articular branch** to the hip-joint which arises from the nerve as soon as it enters the thigh, and supplies the joint through the acetabular notch.

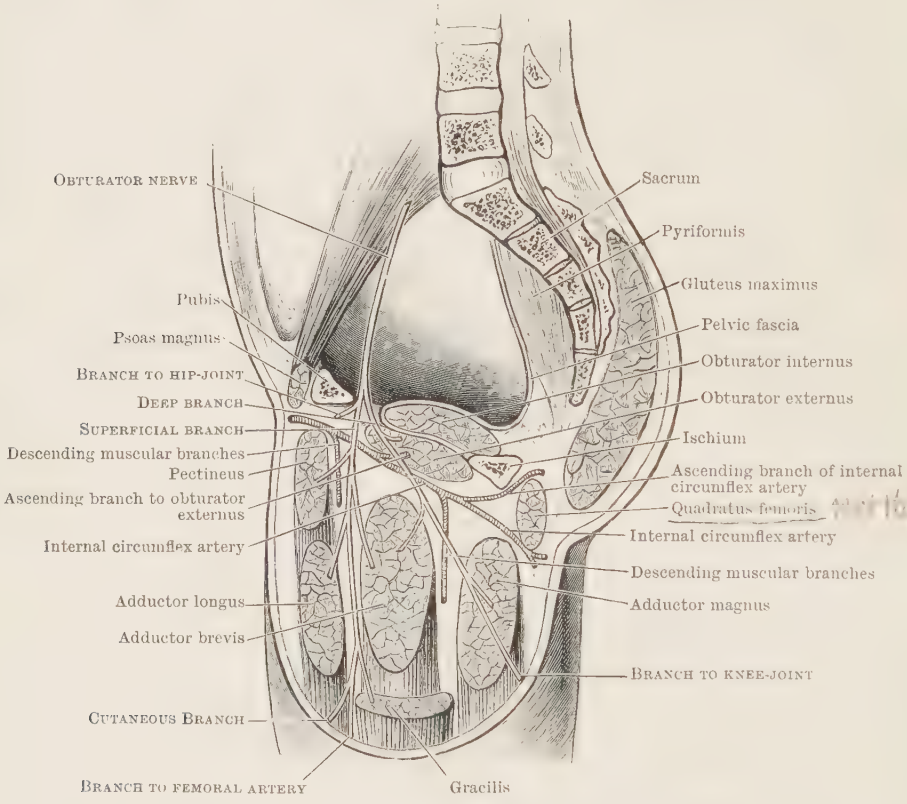

Fig. 506.—Scheme of the Course and Distribution of the Obturator Nerve.

2. **Muscular branches** to the adductor longus, gracilis, adductor brevis (usually), pectineus (occasionally). The last-named muscle is not usually supplied from the obturator nerve.

3. A **cutaneous branch** of very variable size forms one of the terminal branches (Fig. 507). It becomes superficial between the gracilis and adductor longus, in the middle third of the thigh, and may supply the skin of the lower two-thirds of the thigh in its inner side. It is generally of small size, and is connected with branches of the internal cutaneous and internal saphenous nerves behind the sartorius muscle to form the **obturator (sub-sartorial) plexus.** The branch from the internal saphenous nerve to the plexus passes inwards behind the sartorius after piercing the aponeurotic covering of Hunter's canal. The branch from the internal cutaneous nerve is generally superficial at the point of formation of the plexus.

4. The **branch to the femoral artery** is the other terminal branch of the nerve. It enters Hunter's canal along the inner edge of the adductor longus, and ramifies over the lower part of the artery.

5. A fine **communicating branch** sometimes joins the anterior crural nerve in front of the hip-joint.

The deep part of the obturator nerve reaches the thigh by piercing the

obturator externus muscle. It passes downwards between the adductor brevis and adductor magnus muscles. After passing obliquely through the adductor magnus, it appears in the popliteal space on the popliteal vessels, and terminates by piercing the posterior ligament and supplying the knee-joint.

Its branches are:—(1) **muscular branches** to the obturator externus, adductor magnus, and (when the muscle is not supplied by the superficial part of the nerve) the adductor brevis. The branch to the obturator externus arises before the nerve enters the muscle, in the obturator groove. The nerve to the adductor magnus is given off as the obturator nerve passes through the substance of the muscle. (2) An **articular terminal branch** is supplied to the back of the knee-joint.

### Anterior Crural Nerve.

The **anterior crural nerve** (n. femoralis) is the great nerve for the muscles and skin of the front of the thigh. It arises in the substance of the psoas muscle, from the back of the second, third, and fourth lumbar nerves, behind the obturator nerve. Passing obliquely through the psoas muscle, it emerges from its outer border in the false pelvis (Fig. 505, p. 641). Passing downwards in the groove between the psoas and iliacus, it enters the thigh beneath Poupart's ligament, external to the femoral sheath and femoral vessels. In Scarpa's triangle it breaks up into a large number of branches, among which the external circumflex artery passes.

The **branches** of the anterior crural nerve, which are (1) muscular, (2) articular, and (3) cutaneous, arise in the following way:—

*In the abdomen* a muscular branch arises from the outer side of the nerve and enters the iliacus muscle.

*In Scarpa's triangle* the terminal muscular, articular, and cutaneous branches arise in the form of a large bundle of nerves.

1. The **muscular branches** supply the pectineus, sartorius, and quadriceps extensor. The nerve to the *pectineus* arises close to Poupart's ligament, and coursing obliquely downwards and inwards behind the femoral vessels enters the muscle at its outer border. It is not infrequently double. It sometimes gives off a fine communicating branch to the superficial part of the obturator nerve. The nerves to the *sartorius* are in two sets: an outer short set of nerves associated with the outer part of the middle cutaneous nerve, which enter the upper part of the muscle; and an inner longer set which are associated with the inner part of the middle cutaneous nerve, and supply the middle of the muscle. The parts of the *quadriceps extensor* are supplied by several branches. The vastus externus and rectus femoris are supplied on their deep surface by separate nerves which are accompanied by branches of the external circumflex artery. The crureus muscle is supplied superficially by a nerve which passes through the muscle, and innervates also the subcrureus. It also receives fibres from one of

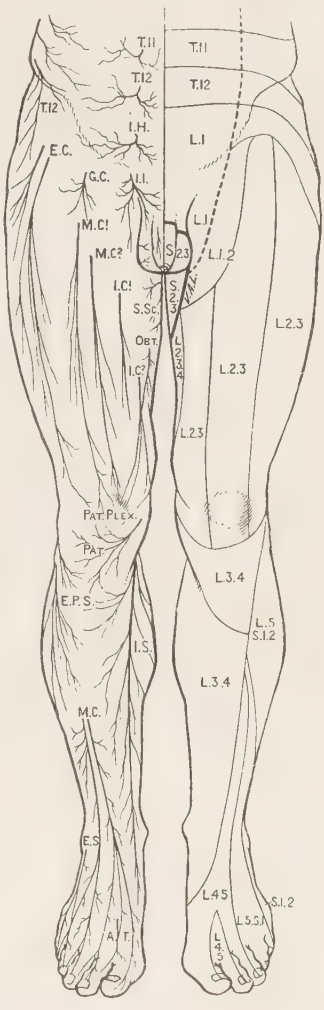

FIG. 507.—DISTRIBUTION OF CUTANEOUS NERVES ON THE FRONT OF THE LOWER LIMB.

On the one side the distribution of the several nerves is represented, the letters indicating their nomenclature.

T.11, Branches of eleventh thoracic nerve; T.12, Branches of twelfth thoracic nerve; I.H, Ilio-hypogastric; I.I, Ilio-inguinal; E.C, External cutaneous; G.C, Genito-crural; M.C¹,², Middle cutaneous; I.C¹,², Internal cutaneous; OBT, Obturator; S.Sc, Small sciatic; PAT. PLEX, Patellar plexus; PAT. Patellar branch of internal saphenous; E.P.S, Sural branches of peroneal nerve; I.S, Internal saphenous; M.C, Musculo-cutaneous; E.S, External saphenous; A.T, Anterior tibial.

On the other side a schematic representation is given of the areas supplied by the above nerves, the figures indicating the spinal origin of the branches of distribution to each area.

the nerves to the vastus internus. The vastus internus muscle is supplied by two nerves: an upper trunk, which supplies the higher part of the muscle, and sends fibres to the crureus as well; and a lower trunk, which descends on the outer side of the femoral artery along with the internal saphenous nerve, and passing beneath the sartorius, over or under the aponeurotic covering of Hunter's canal, enters the inner side of the vastus internus muscle. This nerve gives off a small branch which enters the medullary canal of the femur.

2. The **articular branches** supply the hip and knee-joints. The articular branch to the hip-joint arises from the nerve to the rectus femoris, and is accompanied by branches from the external circumflex artery. The articular branches to the knee-joint are four in number. Three of them arise from the nerves to the vastus externus, crureus, and vastus internus, which, after the muscular nerves are given off, are continued downwards to the knee-joint along the front of the femur. A fourth articular branch arises (sometimes) from the internal saphenous nerve.

3. The **cutaneous branches** are the middle and internal cutaneous, and the internal saphenous nerves (Fig. 507).

The **middle cutaneous nerve** arises in two parts, an *external* and an *internal branch*, in the upper part of Scarpa's triangle. The two branches descend vertically and become cutaneous by piercing the fascia lata over the upper third of the sartorius muscle. They carry muscular branches to the sartorius, and the external branch in many cases pierces the muscle. These two nerves supply the skin of the lower three-fourths of the front of the thigh, between the external cutaneous nerve on the outer side and the internal cutaneous on the inner side. They reach down to the front of the patella, and there assist in the formation of the patellar plexus. The external branch communicates in the upper third of the thigh with twigs from the crural branch of the genito-crural nerve.

The **internal cutaneous nerve** lies at first in Scarpa's triangle on the outer side of the femoral vessels. At the apex of the triangle it crosses over the femoral vessels, and is directed downwards over or through the sartorius muscle, and beneath the fascia lata, to the lower third of the thigh. It is distributed to the skin of the lower two-thirds of the thigh on the inner side by means of three branches—upper, middle, and lower.

The *upper branch* may be represented by two or more twigs. It arises from the main nerve near its origin, and pierces the fascia lata near the apex of Scarpa's triangle. It is distributed to the skin of the upper part of the thigh, along the line of the saphenous vein. The *middle* or *anterior branch* is a larger nerve. It separates from the lower branch at the apex of Scarpa's triangle, and passing over the sartorius muscle becomes cutaneous in the middle third of the thigh on the inner side. It supplies the skin of the lower half of the thigh on the inner side, extending as low as the knee, where it joins in the formation of the patellar plexus.

The *lower* or *internal branch* represents the termination of the nerve. It passes down the inner side of the thigh over the sartorius muscle, and communicates in the middle third of the thigh with the internal saphenous and obturator nerves to form the obturator plexus. Piercing the fascia lata on the inner side of the thigh in the lower third, it ramifies over the inner side of the knee, and assists in the formation of the patellar plexus.

The size of the internal cutaneous nerve varies with the size of the cutaneous part of the obturator, and of the internal saphenous nerve.

The **long** or **internal saphenous nerve** (n. saphenus) may be regarded as the terminal branch of the anterior crural nerve. It is destined for the skin of the leg and foot. From its origin in Scarpa's triangle it descends alongside the femoral vessels to Hunter's canal. In the canal it crosses over the femoral sheath from without inwards. At the lower end of the canal, accompanied by the superficial branch of the anastomotic artery, it passes over the tendon of the adductor magnus, and opposite the inner side of the knee-joint becomes cutaneous by passing between the sartorius and gracilis muscles. The nerve then extends down the leg along with the internal saphenous vein, and coursing over the front of the inner ankle it terminates at the middle of the inner border of the foot.

Branches.— 1. A **communicating branch** arises in Hunter's canal, and passing

inwards beneath the sartorius joins with branches of the obturator nerve in forming the obturator plexus.

2. The **patellar branch** arises at the lower end of Hunter's canal, and piercing the sartorius muscle is directed downwards and forwards below the patella, and over the inner tuberosity of the tibia to the front of the knee and upper part of the leg. It enters into the formation of the patellar plexus.

3. An **articular branch** sometimes arises from the nerve at the inner side of the knee.

4. The **terminal branches** of the internal saphenous nerve are distributed to the skin of the front and inner side of the leg, and the posterior half of the dorsum and inner side of the foot.

**Patellar plexus.**—This plexus consists of fine communications beneath the skin in front of the knee, between the branches of the cutaneous nerves supplying that region. The nerves which enter into its formation are the patellar branch of the internal saphenous, internal and middle cutaneous nerves, and sometimes the external cutaneous nerve.

The **accessory obturator nerve** (n. obturatorius accessorius, n. accessorius anterioris cruralis Winslow) is only occasionally present (29 per cent, Eisler). It arises from the third, or third and fourth lumbar nerves, between the roots of the obturator and anterior crural nerves. Associating itself with the obturator, from which, however, it is quite separable, it appears in the abdomen at the inner side of the psoas muscle, and coursing over the pelvic brim behind the external iliac vessels, it leaves the obturator nerve, and enters the thigh in front of the pubis.

In the thigh, behind the femoral vessels, it usually ends in three branches: a nerve which replaces the branch from the anterior crural to the pectineus, a nerve to the hip-joint, and a nerve which communicates with the superficial part of the obturator nerve. In some cases it only supplies the nerve to the pectineus; more rarely it is of considerable size, and reinforces the obturator nerve in the innervation of the adductor muscles.

The accessory obturator nerve was first described by Winslow as the *n. accessorius anterioris cruralis*. Schmidt later described it in great detail, and gave it the name it now bears. It is more closely associated with the anterior crural than with the obturator. Its origin is behind the roots of the obturator: it is separated, like the anterior crural, from the obturator by the pubic bone, and its chief branch, to the pectineus muscle, replaces the normal branch from the anterior crural nerve. On the other hand, for a part of its course it accompanies the obturator, and in rare cases it may replace branches of that nerve.

## THE SACRAL OR SCIATIC PLEXUS.

The sacral or sciatic portion of the lumbo-sacral plexus is destined almost entirely for the lower limb. It is usually formed by the anterior primary divisions of a part of the fourth lumbar nerve (n. furcalis), the fifth lumbar, the first, and parts of the second, and third sacral nerves (n. bigeminus).

**Communications with the Sympathetic.**—Each of the nerves named is connected to the lumbar or pelvic sympathetic by *gray rami communicantes*, as already described; and *white rami communicantes* pass usually from the third and usually also from the second or fourth sacral nerves to join the pelvic plexus of the sympathetic.

**Position and Constitution.**—The plexus is placed on the back wall of the pelvis between the parietal pelvic fascia and the pyriformis muscle. In front of it are the pelvic colon, the internal iliac vessels, and the ureter.

The plexus is constituted by the convergence of the nerves concerned towards the lower part of the great sacro-sciatic foramen, and their union to form a broad triangular band, the apex of which is continued through the great sacro-sciatic foramen below the pyriformis muscle into the buttock, as the **great sciatic nerve.** From the anterior and posterior surfaces of this triangular band numerous small branches arise, which are distributed to the parts in the neighbourhood of the origin of the nerve.

The great sciatic nerve ends in the thigh by dividing into two large nerves, the **tibial** (internal popliteal), and **peroneal** (external popliteal). In many cases these two nerves are distinct from their origin, and are separated sometimes by fibres of the pyriformis muscle. In all cases on removal of the sheath investing the great sciatic nerve the tibial and peroneal nerves can be traced up to the plexus, from which they invariably take origin by distinct and separate roots.

The descending branch of the fourth lumbar nerve (n. furcalis) after emerging from the inner border of the psoas muscle internal to the obturator nerve, divides

behind the iliac vessels into anterior and posterior (ventral and dorsal) parts, each of which joins a corresponding part of the fifth lumbar nerve. The anterior primary division of the fifth lumbar nerve descends over the ala of the sacrum, and divides into anterior and posterior parts, which are joined by the corresponding parts of the fourth lumbar nerve. The two resulting trunks are sometimes called the **lumbo-sacral cord.** The first and second sacral nerves pass almost horizontally outwards from the anterior sacral foramina, and divide in front of the pyriformis into similar anterior and posterior parts. The third sacral nerve (n. bigeminus) divides into upper and lower parts. The lower part is concerned in forming the pudendal plexus. The upper part is directed outwards, and slightly upwards, towards the preceding nerve, and does not separate into two parts, but remains undivided.

These trunks combine to form the sciatic or sacral plexus, and its main subdivisions, in the following way. Lying in apposition, and converging to the lower part of the great sacro-sciatic foramen, the *posterior* (dorsal) *trunks* of the fourth and fifth lumbar nerves (lumbo-sacral cord), and of the first and second sacral nerves, combine to form the **peroneal nerve** and the subordinate nerves which arise from the posterior aspect of the plexus. The *anterior* (ventral) *trunks* of the fourth and fifth lumbar nerves (lumbo-sacral cord), and of the first and second sacral nerves, together with that part of the third sacral nerve which is contributed to the plexus, unite to form the **tibial nerve** and the subordinate nerves arising from the front of the plexus.

Of these nerves the fifth lumbar and first sacral are the largest; the others diminishing in size as they are traced upwards and downwards. There is no distinct demarcation between the sacral and pudendal plexuses. The second and third sacral nerves (and in some cases the first sacral also) are concerned in the formation of both plexuses.

**Branches.**—The nerves of distribution derived from the sacral plexus are divided according to their origin into an *anterior* (ventral) and a *posterior* (dorsal) *series.* Each set comprises one of the two essential terminal parts—peroneal and tibial nerves—of the great sciatic, and numerous smaller collateral branches.

| Anterior Branches. | Posterior Branches. |
|---|---|
| Tibial (internal popliteal) nerve | Peroneal (external popliteal) nerve |
| *Muscular branches*— | *Muscular branches*— |
| Nerves to hamstring muscles | Nerves to short head of biceps |
| ,, quadratus femoris | ,, pyriformis |
| ,, gemelli | Superior gluteal nerve |
| ,, obturator internus | Inferior gluteal nerve |
| *Articular branches* (to hip-joint) | *Articular branches* (to knee-joint) |

### Great Sciatic Nerve.

The **great sciatic nerve** (n. ischiadicus).—It has already been shown how this nerve is formed. It comprises the two main nerves of the sacral plexus, bound together by an investing sheath, which contains, in addition to the peroneal and tibial nerves, a subordinate branch of each, the nerve to the hamstring muscles, from the tibial, and the nerve to the short head of the biceps flexor cruris, from the peroneal nerve. A thick band about half an inch in breadth is formed, consisting from within outwards of (1) **nerves to the hamstring muscles**, (2) **tibial** (internal popliteal), (3) **peroneal** (external popliteal), (4) **nerve to the short head of the biceps muscle.** The great sciatic nerve extends through the buttock and the back of the thigh. Forming a continuation of the sacral plexus, it enters the buttock by passing through the great sacro-sciatic foramen, in the interval between the pyriformis and superior gemellus. Concealed by the gluteus maximus muscle, it passes downwards to the thigh, accompanied by the sciatic artery, and the arteria comes nervi ischiadici. It lies in the hollow between the great trochanter of the femur and the tuberosity of the ischium, and enters the thigh beneath the fold of the nates at the lower border of the gluteus maximus. At this spot it is comparatively superficial, lying in the angle between the edge of the gluteus maximus above and externally, and the origins of the hamstring muscles internally. In the thigh it is placed upon the adductor magnus beneath the hamstring muscles, and it terminates at a variable point by dividing into the tibial and peroneal nerves. As

already stated, these two nerves may be separate from their origins, and their separation may occur at any point between the great sacro-sciatic foramen and the upper part of the popliteal space.

### The Nerves of Distribution from the Sacral Plexus.

These are divisible into two series—**collateral** and **terminal branches**. Each subdivision consists of a series of *anterior* (ventral) and *posterior* (dorsal) *trunks*.

**Collateral Branches.**—The *anterior branches* are (*a*) muscular branches (to the quadratus femoris, gemelli, obturator internus, and hamstring muscles); and (*b*) articular branches (to the hip-joint). These nerves all arise from the anterior aspect of the sacral plexus.

The **nerve to the quadratus femoris** (and **inferior gemellus**) arises from the front of the fourth and fifth lumbar and first sacral nerves. It passes downwards over the back of the capsule of the hip-joint (to which it sends a fine branch) beneath the sacral plexus, gemelli, and obturator internus muscles. It supplies a nerve to the inferior gemellus, and terminates in the deep surface of the quadratus femoris.

The **nerve to the obturator internus** (and **superior gemellus**) arises from the anterior aspect of the fifth lumbar and first two sacral nerves. In the buttock it lies below the great sciatic nerve on the outer side of the pudic vessels; crossing the ischial spine, it enters the ischio-rectal fossa through the lesser sciatic foramen. The nerve supplies in the buttock a branch to the superior gemellus, and terminates by entering the pelvic surface of the obturator internus.

The **nerve to the hamstring muscles** forms the innermost part of the great sciatic trunk in the lower part of the buttock. It arises from all the roots of the tibial nerve on their anterior aspect, viz., from the fourth and fifth lumbar and the first three sacral nerves. These roots unite to form a cord which is closely associated with the tibial nerve and is placed in front of and afterwards on its inner side. Extending into the thigh, the trunk is distributed to the hamstring muscles by means of two sets of branches. Just below the level of the ischial tuberosity an upper set of nerves passes inwards to enter the upper part of the semi-tendinosus and the ischial head of the biceps. Lower down in the thigh the remaining portion of the nerve separates off from the great sciatic (tibial) trunk and supplies branches to the semi-membranosus, the lower part of the semi-tendinosus, and the adductor magnus.

**Articular branches** for the hip-joint arise from the nerve to the quadratus femoris, and often directly from the front of the great sciatic (tibial) nerve near its origin. They enter the back of the capsule of the joint in the region of the buttock.

The *posterior branches* are: (*a*) muscular branches, viz. a nerve to the pyriformis, the superior gluteal nerve, the inferior gluteal nerve, and a nerve to the short head of the biceps; (*b*) articular branches (to the knee-joint).

These nerves all arise from the posterior aspect of those roots of the sacral plexus, which are associated with the origin of the peroneal nerve.

The **nerve to the pyriformis muscle** may be double. It arises from the back of the second, or first and second sacral nerves, and at once enters the anterior surface of the muscle.

The **superior gluteal nerve** (n. glutæus superior) arises from the back of the fourth and fifth lumbar and first sacral nerves, and is directed backwards and outwards into the buttock, above the pyriformis muscle, along with the gluteal artery. Under cover of the gluteus maximus and gluteus medius, it extends outwards over the gluteus minimus, along with the inferior part of the deep gluteal artery, to the under surface of the tensor vaginæ femoris, in which it ends. On its way it supplies branches to the gluteus medius and gluteus minimus.

The **inferior gluteal nerve** (n. glutæus inferior) arises from the back of the fifth lumbar and first two sacral nerves. It appears in the buttock at the lower border of the pyriformis muscle, superficial to the great sciatic nerve, and at once breaks up into a number of branches for the supply of the gluteus maximus. In its course in the buttock it is closely associated with the small sciatic nerve. Its origin is sometimes combined with that of the following nerve.

The **nerve to the short head of the biceps** springs from the outer side of the

great sciatic (peroneal) trunk in the upper part of the thigh. When traced to its origin, it is found to arise (sometimes in combination with the inferior gluteal nerve) from the fifth lumbar and first two sacral nerves. In its course it is closely applied to the outer side of the peroneal nerve, from which it separates in the middle third of the thigh, usually in combination with the articular branches of that nerve for the knee-joint. In some cases it has an independent course in the thigh, and it may be associated in the buttock with the inferior gluteal nerve.

**An articular branch** for the outer side and front of the knee-joint generally arises from the great sciatic or peroneal nerve in common with the nerve to the short head of the biceps. When traced up to the plexus, it is found to arise from the back of the fourth and fifth lumbar and first sacral nerves. It passes through the upper part of the popliteal space concealed by the biceps muscle, and separates into upper and lower branches, which accompany the upper and lower external articular arteries to the outer side of the knee-joint.

**Terminal Branches.**—The **peroneal** (external popliteal) and **tibial** (internal popliteal) **nerves** are the two main trunks resulting from the combination of the posterior and anterior cords respectively of the sacral plexus. The peroneal nerve is homologous with the musculo-spiral nerve in the upper limb; the tibial nerve represents a medio-ulnar trunk; and, as already stated, the two nerves, constituting the great sciatic nerve, are enveloped in a common sheath for a variable distance before pursuing an independent course in the leg.

### Peroneal Nerve.

The **peroneal** or **external popliteal nerve** (n. peronæus communis) arises from the back of the sacral plexus from the fourth and fifth lumbar and first two sacral nerves. Incorporated with the great sciatic nerve in the buttock and upper half of the thigh, it passes downwards from the bifurcation of that nerve through the popliteal space, to its termination at a point about an inch below the head of the fibula. It is concealed at first by the biceps muscle. Following the tendon of that muscle, it passes obliquely through the upper and outer part of the popliteal space and over the outer head of the gastrocnemius muscle to the back of the head of the fibula. In the lower part of its course and at its termination it is directly beneath the deep fascia.

**Collateral Branches.**—These are divided into two sets: (*a*) Nerves arising from the roots or trunk of the nerve while it is in combination with the tibial nerve in the great sciatic trunk. These have been already described, viz. a **muscular branch** to the short head of the biceps, and an **articular branch** to the knee-joint. (*b*) Nerves arising in the popliteal space. These are **cutaneous branches**, viz. a sural branch and the peroneal communicating.

The **sural branch** (n. cutaneus suræ lateralis) is irregular in size and distribution, and may be represented by two or more branches (Fig. 507, p. 645). Arising from the peroneal nerve in the popliteal space, often in common with the succeeding nerve, it pierces the deep fascia over the outer head of the gastrocnemius, and is distributed to the skin on the outer aspect of the back of the leg in the upper two-thirds. The extent of its distribution varies with that of the small sciatic and external saphenous nerves.

The **peroneal communicating nerve** (r. anastomoticus peronæus, r. communicans fibularis), arising in the popliteal space, passes over the outer head of the gastrocnemius beneath the deep fascia to the middle third of the leg, where it assists in forming the external saphenous nerve by its union with the tibial communicating branch of the tibial nerve. In many cases the two branches do not unite. In such cases the peroneal communicating nerve may be limited in its distribution to the skin of the outer side of the leg, heel, and ankle, or it may be distributed to the area usually supplied by the external saphenous nerve.

**Terminal Branches.**—The terminal branches of the peroneal nerve are recurrent tibial, anterior tibial, and musculo-cutaneous. They arise just below the head of the fibula, and are directed forwards, diverging in their course, beneath the peroneus longus muscle.

The **recurrent tibial nerve** is the smallest branch. Passing forwards beneath

the origin of the peroneus longus and the extensor longus digitorum muscles, it divides below the outer tuberosity of the tibia into branches which supply the upper fibres of the tibialis anticus muscle, the tibio-fibular articulation, and the knee-joint.

### Anterior Tibial Nerve.

The **anterior tibial nerve** (n. peronæus profundus) passes downwards and inwards, beneath the peroneus longus, extensor longus digitorum, and extensor proprius hallucis muscles, to the front of the leg. In its course down the leg it is deeply placed upon the interosseous membrane and the lower part of the tibia, in company with the anterior tibial artery. At the ankle it lies beneath the anterior annular ligament and the tendon of the extensor proprius hallucis, and crossing over the ankle-joint, it divides on the dorsum of the foot into its terminal branches.

1. **Collateral Branches** (in the leg).—These are given off to the muscles between which the anterior tibial nerve passes: tibialis anticus, extensor proprius hallucis, extensor longus digitorum, and peroneus tertius. A fine articular branch supplies the ankle-joint.

2. **Terminal Branches** (on the foot).—The terminal branches are internal and external. The **internal branch** passes along the dorsum of the foot on the outer side of the dorsalis pedis artery to the first interosseous space, where it divides into two dorsal digital branches for the supply of the skin of the outer side of the great toe and the inner side of the second toe. Each of these branches communicates with branches of the musculo-cutaneous nerve. It gives off one or two *dorsal interosseous branches*, which supply the inner tarso-metatarsal and metatarso-phalangeal articulations, and also enter the first dorsal interosseous muscle.

The **external branch** passes outwards over the tarsus beneath the extensor brevis digitorum, and ends in a gangliform enlargement (similar to the gangliform enlargement on the posterior interosseous nerve at the back of the wrist). From this enlargement muscular branches arise for the supply of the extensor brevis digitorum, along with branches for the tarsal, tarso-metatarsal, and metatarso-phalangeal articulations. Its *dorsal interosseous branches* may be as many as four in number. Of these the outer two, extremely small, may only reach the tarso-metatarsal articulations. The inner two are fine branches, which, besides supplying the articulations, may give branches to the second and third dorsal interosseous muscles.

The branches from the anterior tibial nerve to the interosseous muscles are probably sensory, the motor supply of these muscles being certainly derived from the external plantar nerve.

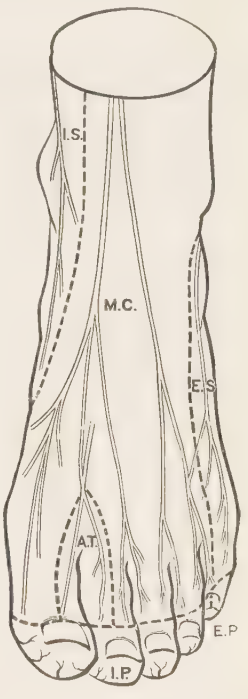

Fig. 508.—Distribution of Cutaneous Nerves on the Dorsum of the Foot.

I.S, Internal saphenous nerve; M.C, Musculo-cutaneous nerve; A.T, Anterior tibial nerve; E.S, External saphenous nerve. The extremities of the toes are supplied by the plantar nerves (I.P, E.P).

### Musculo-Cutaneous Nerve.

The **musculo-cutaneous nerve** (n. peronæus superficialis), the last of the branches of the peroneal nerve, passes below the head of the fibula and beneath the upper fibres of the peroneus longus muscle. Lying in a sheath in the intermuscular septum, between the peronei externally and the extensor longus digitorum internally, it proceeds downwards in front of the fibula to the lower third of the leg, where it pierces the deep fascia in two branches, internal and external.

Its branches are: (1) collateral muscular branches distributed to the peroneus longus and peroneus brevis, as the nerve lies in relation to these muscles; (2) terminal cutaneous branches, internal and external.

The **internal terminal branch** courses downwards over the anterior annular liga-

ment of the ankle, and after supplying offsets to the lower third of the leg and dorsum of the foot, divides into three branches. (1) The internal branch supplies the skin of the dorsum of the foot and the inner side of the great toe, and communicates with the internal saphenous nerve. (2) The intermediate branch passes to the interval between the great toe and the second, and divides into two branches which communicate with the internal branch of the anterior tibial nerve. (3) The external branch passes to the interval between the second and third toes, and divides into two digital branches to supply the adjacent sides of these toes.

The **external terminal branch** of the nerve descends over the anterior annular ligament, and after supplying branches to the lower part of the leg and the dorsum of the foot, divides into two parts, internal and external, which, passing to the intervals between the third and fourth, and fourth and fifth toes respectively, divide into dorsal digital branches for the adjacent sides of these toes. These branches communicate with offsets of the external saphenous nerve.

The arrangement of the cutaneous branches of the musculo-cutaneous is liable to considerable variation. The outer division of the nerve may be increased in size, and may supply the nerve to the adjacent sides of the second and third toes; or in other cases, it may be reduced in size, in which case the external saphenous nerve takes its place on the dorsum of the foot, often supplying as many as two and a half toes on the outer side.

The cutaneous nerves on the dorsum of the toes from the anterior tibial and musculo-cutaneous nerves are much smaller than the corresponding plantar digital nerves. They are reinforced on the dorsum of the terminal phalanges by twigs from the plantar nerves, which supply the tips of the toes and the nails.

### Tibial Nerve.

The **tibial** or **internal popliteal nerve** (n. tibialis) arises from the front of the sacral plexus, usually from the fourth and fifth lumbar and first three sacral nerves (Fig. 511, p. 656). It is incorporated in the great sciatic trunk in the buttock and upper part of the thigh. At the bifurcation of the great sciatic nerve it passes onwards through the popliteal space and the back of the leg. The part of the nerve from its origin from the plexus or the bifurcation of the great sciatic nerve to the lower border of the popliteus muscle, is sometimes called **internal popliteal**; the part of the nerve in the back of the leg being then designated **posterior tibial.** The course of the nerve through the buttock and thigh has already been described (p. 648). In the popliteal space it is concealed at first by the semi-membranosus and other hamstring muscles. It crosses the popliteal vessels from without inwards, and is thereafter found upon the popliteus muscle, under cover of the gastrocnemius and plantaris. In the back of the leg, from the lower border of the popliteus muscle to the ankle, the tibial (or posterior tibial) nerve lies on the tibialis posticus muscle and the tibia, and, along with the posterior tibial vessels, occupies a sheath in the intermuscular septum separating the superficial and deep muscles of the back of the leg. In the upper part of the leg the nerve is internal to the vessels, but, crossing over them, it lies on their outer side in the lower portion of its course. It terminates beneath the internal annular ligament by dividing into the external and internal plantar nerves.

The **collateral branches** may be divided into three series arising respectively in the region of the thigh, the popliteal space, and the back of the leg:—

(a) *Branches arising from the Roots or Trunk of the Nerve while it is incorporated with the Great Sciatic Nerve.*—These have been already described, viz. **muscular branches** to the quadratus femoris, gemelli, obturator internus, and the hamstring muscles, and an **articular branch** to the hip-joint (Fig. 511, p. 656).

(b) *Branches arising in the Popliteal Space above the Knee-Joint.*—These are in three sets—articular, muscular, cutaneous.

1. The **articular branches** are slender nerves, variable in number. There are usually two, an *azygos* branch which pierces the posterior ligament of the knee-joint, and an *internal* branch, a long fine nerve which, crossing the popliteal vessels, descends on the inner side of the space to accompany the lower internal articular artery to the knee-joint. In its course it gives off a branch, often absent, which accompanies the upper internal articular artery.

2. The **muscular branches** are five in number. Nerves for the two heads of the gastrocnemius, and the plantaris enter these muscles at the borders of the popliteal

space. A nerve for the soleus enters the superficial surface of the muscle. A nerve for the popliteus muscle passes over the surface of that muscle, and after winding round its lower border, supplies it on its deep (anterior) surface. As this nerve passes beneath the popliteus it supplies branches to the tibialis posticus muscle, an interosseous branch for the interosseous membrane, which can be traced as far as the lower tibio-fibular articulation, an articular branch for the upper tibio-fibular joint, and a medullary branch for the shaft of the tibia.

3. The **cutaneous branch** is the **tibial communicating nerve** (n. communicans tibialis, n. cutaneus suræ medialis). This nerve passes from the popliteal space in the groove between the two heads of the gastrocnemius muscle, and afterwards lies upon the tendo achillis. It pierces the deep fascia in the middle third of the back of the leg, and is joined immediately afterwards by the peroneal communicating nerve from the peroneal nerve. From their union the **external** or **short saphenous nerve** results, which reaches the foot, winding round the back of the external malleolus along with the external saphenous vein. The external saphenous nerve supplies cutaneous branches to the outer side and back of the lower third of the leg, the ankle and heel, and the outer side of the foot and little toe, as well as articular branches to the ankle and tarsal joints.

The external saphenous nerve communicates on the foot with the musculo-cutaneous nerve, and its size varies with the size of that nerve. It may extend on to the dorsum of the foot for a considerable distance, and may either reinforce or replace the branches of the musculo-cutaneous nerve to the intervals between the fourth and fifth and the third and fourth toes. The mode of formation of the external saphenous nerve is very variable. The usual arrangement is that described. Frequently the peroneal and tibial communicating nerves do not unite, and in such cases the more usual arrangement is for the tibial communicating nerve to form alone the external saphenous nerve, the peroneal communicating nerve extending only to the ankle and heel. It is less usual for the peroneal communicating nerve to form alone the external saphenous nerve, the tibial communicating nerve in these cases ending at the heel.

(c) *Branches arising in the Back of the Leg below the Knee-Joint.*—These branches are mainly muscular and cutaneous.

The **muscular branches** are four in number, comprising nerves to the soleus (entering its deep surface) and tibialis posticus, often arising by a common trunk, and nerves to the flexor longus digitorum and flexor longus hallucis, the latter generally accompanying the peroneal artery for some distance.

The **cutaneous branch** is the **internal calcanean nerve** (rr. calcanei mediales), which pierces the internal annular ligament, and is distributed to the skin of the heel and back part of the sole of the foot.

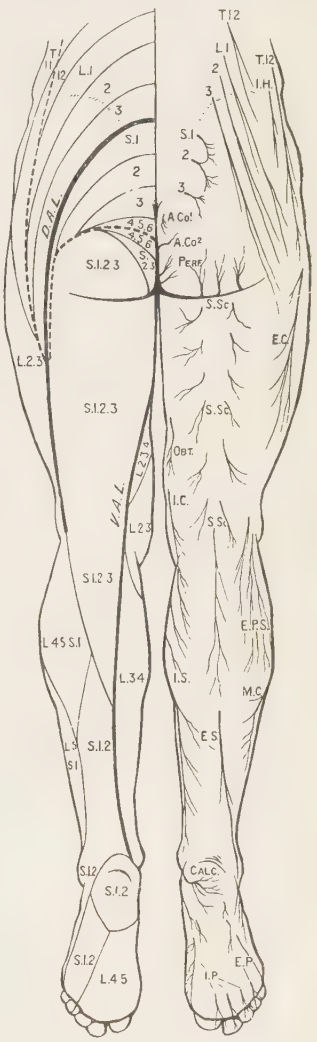

FIG. 509.—DISTRIBUTION OF CUTANEOUS NERVES ON THE BACK OF THE LOWER LIMB.

On the one side the distribution of the several nerves is represented, the letters indicating their nomenclature.

L. 1, 2, 3, S. 1, 2, 3, Posterior primary divisions of lumbar and sacral nerves; I.H, Ilio-hypogastric; T.12, Lateral and posterior branches of last thoracic nerve; A.Co¹, Posterior sacro-coccygeal nerve; A.Co², Anterior sacro-coccygeal nerve; PERF, Perforating cutaneous nerve; S.Sc, Small sciatic; E.C, External cutaneous; OBT, Obturator; I.C, Internal cutaneous; E.P.S, Sural branches of peroneal; I.S, Internal saphenous; E.S, External saphenous; M.C, Musculo-cutaneous; CALC, Calcanean branch of posterior tibial; I.P, Internal plantar; E.P, External plantar nerve.

On the other side a schematic representation is given of the areas supplied by the above nerves, the figures indicating the spinal origin of the branches of distribution to each area.

In addition a medullary nerve to the fibula, and a small articular branch to the ankle-joint, are supplied by the posterior tibial nerve.

The **terminal branches of the tibial nerve** are the internal and external plantar nerves.

### Internal Plantar Nerve.

The **internal plantar nerve** (n. plantaris medialis) is homologous with the median nerve in the hand (Fig. 510, p. 654). It is rather larger than the external plantar. It courses forwards in the sole of the foot beneath the internal annular ligament and abductor hallucis to the interval between that muscle and the flexor brevis digitorum, in company with the internal plantar artery.

The **collateral branches** are muscular, cutaneous, and articular. The *muscular* branches supply the abductor hallucis and the flexor brevis digitorum. The plantar *cutaneous* branches are small twigs which pierce the plantar fascia in the interval between these muscles to supply the inner part of the sole of the foot. The *articular* branches are minute twigs which supply the inner tarsal and tarso-metatarsal articulations.

The **terminal branches** are four in number, and may be designated first, second, third, and fourth, from within outwards.

The **first** (most internal) branch separates from the nerve before the others, and pierces the plantar fascia behind the ball of the great toe. It supplies a muscular branch to the flexor brevis hallucis, and cutaneous branches to the inner side of the foot and ball of the great toe. It terminates as the plantar digital nerve for the inner side of the great toe.

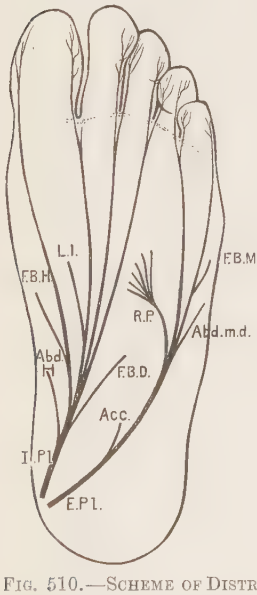

Fig. 510.—Scheme of Distribution of the Plantar Nerves.

I.Pl, Internal plantar nerve, and its cutaneous and muscular branches; F.B.D, Flexor brevis digitorum; Abd.H, Abductor hallucis; F.B.H, Flexor brevis hallucis; L.I, First lumbricalis; E.Pl, External plantar nerve, and its cutaneous and muscular branches; Acc, Accessorius; Abd.m.d, Abductor minimi digiti; F.B.M.D, Flexor brevis minimi digiti; R.P, Ramus profundus.

The **second branch** arises along with the third and fourth; after supplying a branch to the first lumbrical muscle, it becomes superficial in the interval between the first and second toes, and terminates by dividing into two collateral digital nerves for the supply of the adjacent sides of these toes.

The **third** and **fourth branches** are entirely cutaneous in their distribution. They become superficial in the intervals between the second and third and the third and fourth toes respectively, and there divide into collateral digital branches for the supply of the adjacent sides of these toes.

The **plantar digital nerves** supply the whole length of the toes on the plantar aspect, and, in relation to the terminal phalanges, furnish minute dorsal offsets for the supply of the nails and tips of the toes on their dorsal surface. The internal plantar nerve thus supplies the skin of the three and a half inner toes in the sole of the foot; and four muscles:—the abductor hallucis and flexor brevis digitorum, the flexor brevis hallucis, and the first lumbrical muscle.

### External Plantar Nerve.

The **external plantar nerve** (n. plantaris lateralis) is homologous with the ulnar nerve in the hand. From its origin beneath the internal annular ligament it extends forwards and outwards in the sole, in company with the external plantar artery, between the flexor brevis digitorum and accessorius muscles, towards the head of the fifth metatarsal bone. Here it terminates by dividing into superficial and deep branches.

**Collateral Branches.**—*Muscular branches* are given off from the undivided nerve to the accessorius and abductor minimi digiti muscles. *Cutaneous branches* pierce the plantar fascia at intervals along the line of the intermuscular septum, between the flexor brevis digitorum and abductor minimi digiti.

Terminal Branches.—The **superficial branch** (r. superficialis) is mainly cutaneous.

Passing forwards between the flexor brevis digitorum and abductor minimi digiti, it divides into external and internal parts.

The *external branch*, after supplying the flexor brevis minimi digiti muscle, and sometimes one or both interossei of the fourth space, becomes superficial behind the ball of the little toe, and supplies cutaneous twigs to the sole of the foot and ball of the toe. It terminates as the digital branch for the outer side of the little toe.

The *internal branch* passes forwards to the interval between the fourth and fifth toes, where it becomes cutaneous, and divides into two collateral digital branches for the supply of the adjacent sides of these toes. It communicates with the fourth terminal branch of the internal plantar nerve.

The **deep branch** (r. profundus) of the external plantar nerve, passing deeply along with the external plantar artery, extends inwards towards the great toe, beneath the accessorius and adductor obliquus hallucis. It gives off *articular branches* to the tarsal and tarso-metatarsal articulations, and *muscular branches* to the interossei of each space (except in some cases the muscles of the fourth space): to the adductor obliquus and adductor transversus hallucis, and the outer three lumbrical muscles. These nerves enter the deep surface of the muscles, that to the second lumbrical reaching its muscle after passing forwards beneath the adductor transversus hallucis.

## THE PUDENDAL PLEXUS.

The pudendal plexus constitutes the third and last subdivision of the lumbo-sacral plexus. It is composed for the most part of the spinal nerves below those which form the sacral plexus; but, as already stated, there is no distinct point of separation between the two plexuses. On the contrary, there is considerable overlapping, so that two and sometimes three of the principal nerves derived from the pudendal plexus have their origin in common with nerves of the sacral plexus.

The plexus is formed by fibres from the anterior primary divisions of the first three sacral nerves, and by the whole of the anterior primary divisions of the fourth and fifth sacral and coccygeal nerves. The size of the nerves diminishes rapidly from the first sacral to the coccygeal, which is extremely slender.

**Position and Constitution.**—The plexus is formed on the back wall of the pelvis. Of the nerves forming it, the upper ones emerge from the anterior sacral foramina; the fifth sacral nerve appears between the last sacral and first coccygeal vertebra; and the coccygeal nerve appears below the transverse process of that vertebra. The nerves of distribution derived from the plexus are the following:—

1. Visceral branches.
2. Small sciatic nerve.
3. Perforating cutaneous nerve.
4. Pudic nerve.
5. Muscular branches.
6. Sacro-coccygeal nerve.

Omitting the visceral branches, all the nerves are distributed to the perineum. Only two, the small sciatic and perforating cutaneous nerves, send branches to the lower limb.

**Visceral Branches.**—Like the other spinal nerves, the fourth and fifth sacral and coccygeal nerves are provided with fine *gray rami communicantes* from the sacral gangliated cord, which joins them after a short course on the front of the sacrum. The third (along with the second or fourth) sacral nerve in addition sends a considerable *white ramus communicans* or **visceral branch** inwards to the pelvic plexus and viscera.

**Small Sciatic Nerve** (n. cutaneus femoris posterior).—This nerve is complex both in origin and distribution (Fig. 511, p. 656). Springing from the junction of the sacral and pudendal plexuses, it is derived from the first three or second and third sacral nerves. It is distributed to the lower limb and perineum, and is associated with other nerves belonging to both regions. It arises from the back of the roots of the sacral plexus in the pelvis. Its higher roots from the first and second sacral nerves are intimately associated with the origin of the inferior gluteal nerve; its lowest root from the third sacral nerve is associated with the origins of the perforating cutaneous or pudic nerve. It enters the buttock through the great sciatic notch below the pyriformis, along with the sciatic artery and inferior gluteal

nerve. Proceeding downwards behind the great sciatic nerve, it enters the thigh at the lower border of the gluteus maximus muscle, where it gives off considerable branches. Becoming gradually smaller as it courses downwards over the hamstring

muscles to the popliteal space, it finally pierces the popliteal fascia in one or more cutaneous branches, which supply the skin over the calf of the leg for a variable distance (Fig. 509, p. 653).

**Branches.**—The small sciatic is a purely cutaneous nerve. It supplies branches to the perineum, buttock, thigh, and leg.

The **perineal branch** (rr. perinæales; inferior pudendal nerve; long scrotal nerve) arises from the small sciatic nerve at the lower border of the gluteus maximus muscle (Fig. 512, p. 658). It sweeps inwards towards the perineum, lying on the origin of the hamstring muscles below the ischial tuberosity, and becomes subcutaneous after passing over the pubic arch. Its terminal branches supply the skin of the scrotum and root of the penis, or in the female the labium majus and clitoris, some of them being directed backwards towards the anus and central point of the perineum. They communicate with the inferior hæmorrhoidal and perineal branches of the pudic nerve, and with the ilio-inguinal nerve. In its course to the perineum the nerve gives off *collateral branches* to the skin of the upper and inner part of the thigh.

The **gluteal branches** (rr. clunium inferiores) are large and numerous (Fig. 509, p. 653). They arise from the small sciatic nerve beneath the gluteus maximus, and become subcutaneous by piercing the fascia lata at different points along its lower border. They supply the skin of the lower half of the buttock. The outermost branches, reaching to the back of the great trochanter, overlap the terminal filaments of the gluteal branches of the external cutaneous nerve, and the posterior primary divisions of the first three lumbar nerves. The innermost branches, which may pierce the great sacro-sciatic ligament, reach nearly to the coccyx, and are co-terminous in their distribution with the branches of the perforating cutaneous nerve, which they reinforce and not infrequently replace.

The **femoral branches** are divisible into two sets—*internal* and *external*. They pierce the fascia lata of the thigh at intervals, and supply the skin of the back of the thigh on its inner and outer sides respectively.

The **sural branches** are two or more slender nerves which pierce the fascia over the popliteal space, and are distributed for a variable extent to the skin of the back of the leg. They may stop short over the popliteal space, or may extend as far as the ankle. Usually they innervate the skin as far as the middle of the calf. They communicate with the external saphenous nerve.

In cases where the great sciatic nerve is naturally divided at its origin into tibial (internal popliteal) and peroneal (external popliteal) nerves (*e.g.* by the pyriformis muscle), the small sciatic nerve is also separated into two parts: a **dorsal part**, associated with the peroneal nerve and arising in common with the lower roots of the inferior gluteal nerve (usually from the first and second sacral nerves), and comprising the gluteal and external femoral branches; and a **ventral part**, associated with the tibial nerve and arising usually from the second and third sacral nerves, along with the perforating cutaneous and pudic nerves, and comprising the perineal and internal femoral branches.

**Perforating Cutaneous Nerve** (n. perforans ligamenti tuberoso-sacri (Schwalbe), n. cutaneus clunium inferior medialis (Eisler)).—This nerve arises from the back of the second and third sacral nerves (Fig. 512, p. 658). At its origin it is associated with the lower roots of the small sciatic nerve. Passing downwards it pierces the great sacro-sciatic ligament, along with the coccygeal branch of the sciatic artery; and after winding round the lower border of the gluteus maximus muscle, or in some cases piercing its lower fibres, it becomes subcutaneous a little distance from the coccyx, and supplies the skin over the lower part of the buttock and the inner part of the fold of the nates.

The perforating cutaneous nerve is not always present. In a minority of cases it is associated at its origin with the pudic nerve. When absent as a separate nerve, its place is taken by (1) gluteal branches of the small sciatic nerve, or (2) a branch from the pudic nerve, or (3) a small nerve (n. perforans coccygeus major, Eisler), arising separately from the back of the third and fourth sacral nerves.

**Muscular Branches.**—Between the third and fourth sacral nerves (occasionally reinforced by the second, Eisler) a plexiform loop is formed, from which muscular nerves are given off to the levator ani (supplying the muscle on its pelvic surface), coccygeus, and external sphincter. The nerve to the external sphincter

(*perineal branch of fourth sacral*) pierces the great sacro-sciatic ligament and the coccygeus muscle, to which it gives offsets, and appears in the ischio-rectal fossa between the gluteus maximus and the external sphincter. Besides supplying the posterior fibres of the external sphincter, it distributes cutaneous offsets to the skin of the ischio-rectal fossa and the fold of the nates behind the anus. This nerve replaces in some instances the perforating cutaneous nerve.

**Anterior Sacro-coccygeal Nerves** (nn. ano-coccygei).—By the union of the remaining part of the fourth with the fifth sacral and coccygeal nerves, the so-called **coccygeal plexus** is formed. A fine descending branch of the fourth sacral nerve passes over or through the great sacro-sciatic ligament, to join the fifth sacral nerve. This fifth sacral nerve, joined by the descending branch of the fourth, descends alongside the coccyx and is again joined by the coccygeal nerve, so that a plexiform cord results, homologous with the inferior caudal trunk of tailed animals. Fine twigs arise from it, which pierce the sacro-sciatic ligament and supply the skin in the neighbourhood of the coccyx, internal to the perforating cutaneous nerves and behind the anus.

### The Pudic Nerve.

The **pudic nerve** (n. pudendus) is the principal nerve for the supply of the perineum. It arises in the pelvis usually by three roots from the second, third, and

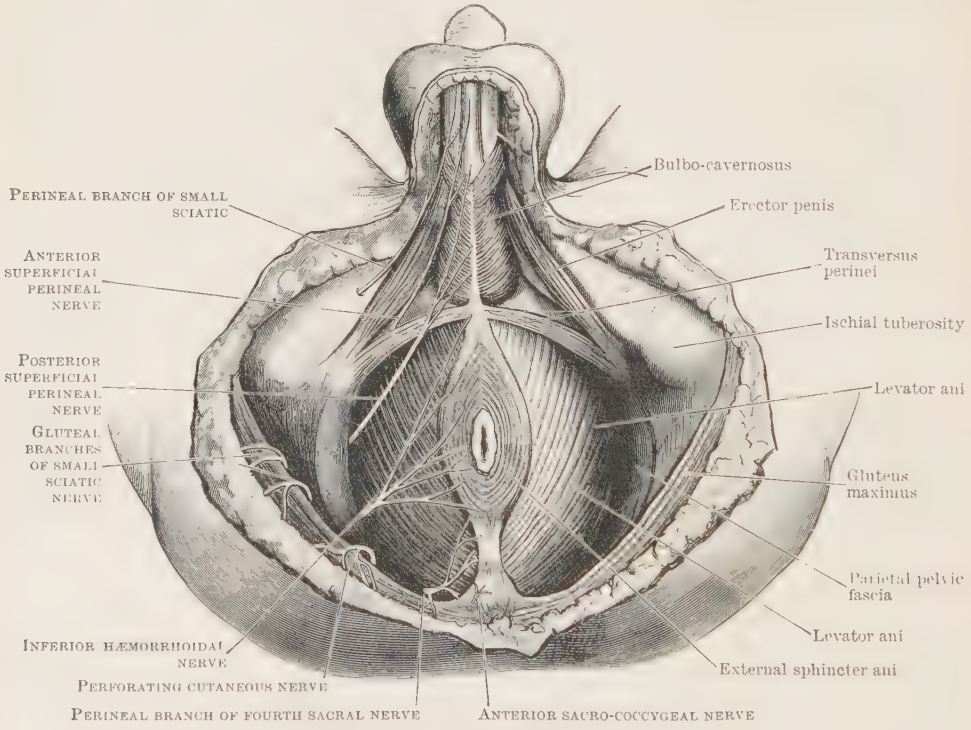

Fig. 512.—The Muscles and Nerves of the Male Perineum.

fourth sacral nerves (Fig. 511, p. 656). (Frequently one of its branches, the inferior hæmorrhoidal nerve, arises independently from the third and fourth sacral nerves). The nerve passes to the buttock through the great sacro-sciatic foramen below the great sciatic nerve, and lies on the lesser sacro-sciatic ligament, or the spine of the ischium, internal to the internal pudic artery. It enters the perineum along with the pudic artery through the small sacro-sciatic foramen. In the perineum it is deeply placed in the outer wall of the ischio-rectal fossa, enclosed in a special sheath derived from the parietal pelvic fascia covering the inner surface of the obturator internus muscle. At the anterior limit of the ischio-rectal fossa, the nerve approaches the surface and divides at the base of the triangular ligament into its terminal branches, the perineal nerve and the dorsal nerve of the penis.

The branches of the pudic nerve are essentially the same in the two sexes. As a rule no branches are given off till the nerve enters the perineum, but sometimes the inferior hæmorrhoidal nerve has an independent origin from the plexus, merely accompanying the pudic nerve in the first part of its course; and in exceptional cases the perforating cutaneous nerve of the buttock is a branch of the pudic nerve.

The **inferior hæmorrhoidal nerve** (n. hæmorrhoidalis inferior) arises from the pudic nerve under cover of the gluteus maximus, at the posterior part of the ischio-rectal fossa. In cases in which it has an independent origin from the plexus, it arises from the third and fourth sacral nerves. It crosses the ischio-rectal fossa in company with the inferior hæmorrhoidal vessels, and separates into numerous branches—muscular, cutaneous, and communicating.

The **muscular branches** end in the external sphincter ani muscle. The **cutaneous branches** supply the skin around the anus. The **communicating branches** connect the inferior hæmorrhoidal with three other nerves—the perineal branches of the small sciatic, pudic, and fourth sacral nerves.

The **perineal nerve** (n. perineus), one of the two terminal branches of the pudic nerve, arises near the base of the triangular ligament. It almost immediately divides into two parts, superficial and deep.

The **superficial part** is purely cutaneous and consists of two nerves, the posterior

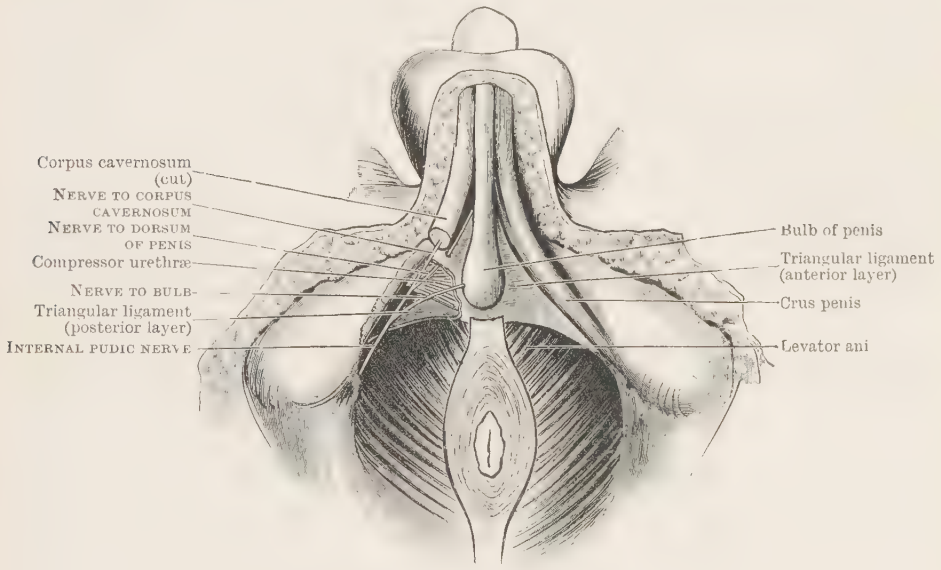

Fig. 513.—The Triangular Ligament of the Perineum.

or external and the anterior or internal superficial perineal nerves, which pass, along with the superficial perineal vessels, to the anterior part of the perineum. The **posterior or external superficial perineal nerve**, at the anterior limit of the ischio-rectal fossa, usually passes over the base of the triangular ligament and over the transversus perinei muscle. The **anterior or internal superficial perineal nerve**, lying more deeply, pierces the base of the triangular ligament and goes underneath or through the transversus perinei muscle. Becoming superficial in the anterior (urethral) triangle of the perineum, they are distributed to the skin of the scrotum (or labium majus), and communicate with the perineal branch of the small sciatic nerve and with the inferior hæmorrhoidal nerve.

The **deep part** of the perineal nerve is mainly but not entirely muscular. Coursing forwards through the anterior part of the ischio-rectal fossa, it passes between the two layers of the triangular ligament towards the urethra. It supplies muscular branches to the anterior parts of the levator ani and external sphincter, to the transversus perinei, erector penis (or clitoridis), bulbo-cavernosus (ejaculator urinæ or sphincter vaginæ), and compressor urethræ. It terminates as the nerve to the bulb, which, piercing the triangular ligament, enters the bulb of the urethra

and supplies the erectile tissue of the bulb and corpus spongiosum, as well as the mucous membrane of the urethra as far as the glans penis (or clitoridis).

The **dorsal nerve of the penis**, the other terminal branch of the pudic nerve, accompanies the internal pudic artery beneath the superficial layer of the triangular ligament. It passes forward close to the pubic arch, lying beneath the crus and erector penis (or clitoridis), and triangular ligament, and upon the compressor urethræ muscle; piercing the triangular ligament near its apex, at the outer side of the dorsal artery of the penis (or clitoris), it passes on to the dorsum of the penis or clitoris, to which it is distributed in its distal two-thirds, sending branches round the sides of the organ to reach its under surface. In the female the nerve is much smaller than in the male. The dorsal nerve of the penis supplies one branch, the **nerve to the corpus cavernosum**, as it lies beneath the triangular ligament. This is a slender nerve, which, piercing the triangular ligament, supplies the erectile tissue of the crus and corpus cavernosum.

**Morphology of the Pudendal Plexus.**—The structures occupying the perineum are placed in the ventral axis of the body, and comprise from before backwards, the penis and scrotum, or mons Veneris and vulva, the central point of the perineum, the anus and ischio-rectal fossa, and the coccyx. They are placed on the mesial side of the attachment of the lower limbs—the penis or mons Veneris in relation to the preaxial border; the coccyx in relation to the postaxial border of the limb.

The nerves of the perineum, thus reaching the ventral axis of the trunk, are homologous with the anterior (ventral) terminations of other nerves. They are separated into two series. Mainly supplied through the pudendal plexus by the last four sacral and the coccygeal nerves, the perineum is also innervated to a minor extent by the first lumbar nerve through the ilio-inguinal nerve, which reaches the root of the penis and the scrotum. The region is thus supplied by two series of widely separated nerves, which have their meeting-place on the dorsum and side of the penis and scrotum. This junction of the ilio-inguinal and pudendal nerves constitutes the beginning of the **ventral axial area or line**, which extends peripherally along the inner side of the lower limb. Apart from this break in their distribution, a definite numerical order may be followed in the arrangement of the perineal nerves. The higher parts of the perineum are innervated by the higher spinal nerves; the lower parts, by the lower nerves. This is best exemplified in the distribution of the cutaneous nerves. The base of the penis and scrotum (or mons Veneris) is supplied by the first lumbar nerve (ilio-inguinal). The dorsal nerve of the penis (or clitoris), when traced back to the pudendal plexus, is found to come from the second, and to a less extent from the third sacral nerves; the scrotal nerves (perineal branches of the pudic and small sciatic) similarly arise from the third, and to a less extent from the second sacral nerves; the skin of the ischio-rectal fossa and anus is innervated by the inferior hæmorrhoidal (third and fourth sacral nerves), and the perineal branch of the fourth sacral nerve. The coccygeal plexus, lastly, supplies the skin round the coccyx (fourth and fifth sacral and coccygeal nerves). Judged from its nerve supply the perineum is to be regarded as occupying, for the most part, a position behind or more caudal than that of the lower limb in relation to the trunk. There is here a remarkable gap in the numerical sequence of the nerves supplying the ventral axis of the body. All the nerves between the first lumbar and the second sacral fail to reach the mid ventral line of the trunk and are wholly concerned in the innervation of the lower limb.

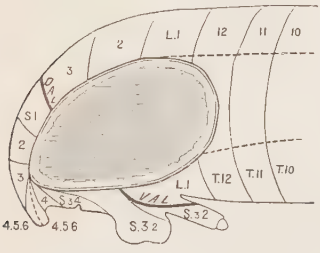

FIG. 514.—SCHEME of the innervation of the hinder portion of the trunk and of the perineum, and the interruption of the segmental arrangement of the nerves associated with the formation of the limb.

T.10, 11, 12, The areas of distribution of the lower thoracic nerves; L.1, 2, 3, The posterior primary divisions of the first three lumbar nerves; L.1, The ilio-inguinal nerve; S.1, 2, 3, 4, 5, 6, The posterior primary divisions of the sacral and coccygeal nerves (6); S.3, 2, S.3, 2, Branches of pudic nerve to penis and scrotum; S.3, 4, Inferior hæmorrhoidal nerve; 4, Perineal branch of the fourth sacral nerve; 4, 5, 6, Anterior sacro-coccygeal nerve; D.A.L, Dorsal axial line; V.A.L, Ventral axial line.

At the preaxial border of the limb (groin) the first lumbar nerve, the highest nerve supplying the perineum, is concerned also in innervating the skin of the limb. At the postaxial border of the limb (fold of the nates and back of the thigh), the nerves which are the highest of those constituting the pudendal plexus (the second and third sacral nerves) are also implicated in innervating that border of the limb. The fourth sacral nerve is only concerned to a very slight extent in the innervation of the limb by means of the perineal branch, which reaches the beginning of its postaxial border; the last two spinal nerves are wholly unrepresented in the limb proper and end entirely in the trunk behind the limb.

## DEVELOPMENT OF THE SPINAL NERVES.

1. **Origin of the Spinal Nerve Roots.**—The process of development of the spinal

nerves commences by means of the outgrowth of the **dorsal** and **ventral roots** from the medullary tube. The two roots take origin in quite different ways.

The **dorsal root** is the first to appear,—before, during, or after the union of the medullary plates and the formation of the neural tube. It takes origin as a **cellular bud** from the dorsal surface of the medullary tube in one of three ways:—(1) It may arise from the junction of the medullary plate and surface epiblast before the closure of the medullary groove. (2) It may spring from the *neural crest*, a ridge on the dorsal aspect of the medullary tube, after its closure is complete. (3) It may be simply a direct outgrowth from the dorsal surface of the medullary tube. Pyriform in shape, the bud enlarges and becomes separated from the medullary tube, and projects ventrally in the space between the myotome and the medullary tube. Each bud is separated by only a slight interval from its neighbour.

The cells (**neuroblasts**) composing the bud become rapidly spindle-shaped, and by the middle of the fourth week give rise to *two sets of processes*; (1) a **central series**, which

grow backwards and are secondarily connected with the dorso-lateral aspect of the medullary tube as the fibres of the dorsal root; and (2) a **peripheral series**, which constitute the dorsal root fibres of the spinal nerve and join the ventral root, to form the spinal nerve proper. The intermediate cellular mass remains as the **spinal ganglion**.

The **ventral root** of a spinal nerve arises in quite a different way, from cells (**neuroblasts**) in the substance of the medullary tube. In the account of the development of the spinal cord it has been shown how the cellular constituents of the medullary tube are converted into two classes of cells: (1) **spongioblasts**, which produce the matrix (neuroglia) of the spinal cord; and (2) **germ-cells** or **neuroblasts**, which produce the nerve-cells of the gray matter of the cord. The neuroblasts give rise to the axis-cylinder processes or

**axons**, which, penetrating the spongy tissue of the medullary tube and the outer limiting membrane, find their way into the mesoblastic tissue on the ventro-lateral surface of the tube. Fibrous from their earliest origin and derived from nerve-cells which remain within the medullary tube, the axons of which the ventral root is composed become surrounded by mesoblastic cells immediately on their emergence, which give rise to the sheaths of the nerve. The ventral root is a little later in its date of appearance than the dorsal root. It begins to be evident at the twenty-fourth day and is completely formed by the twenty-eighth day.

II. **Formation of the Spinal Nerve.**—The fibres of the dorsal root ganglion and the ventral root grow by extension from the cells with which they are respectively connected, and meet in the space between the myotome and the side of the medullary tube to form the **spinal nerve**. It has been already shown that in the adult there is a fundamental division of the spinal nerve into posterior and anterior primary divisions. In the process of development this separation is even more obvious. As the fibres of the dorsal and ventral roots approximate, they separate at the same time each into two unequal portions: the smaller parts of the two roots unite together to form the **posterior**, and the larger parts unite to form the **anterior primary division** of the spinal nerve.

The **posterior primary division**, curving outwards and dorsally, passes through the myotome and is connected with it. In the substance of the myotome it separates into branches as it proceeds towards the dorsal wall of the embryo. At a later stage, the branches are definitely arranged into an outer and an inner set.

The **anterior primary division** grows gradually in a ventral direction to reach the somato-splanchnopleuric angle, under cover of the growing myotome. It spreads out at its distal end and eventually separates into two portions: a smaller, splanchnic, or visceral; and a larger, somatic, or parietal portion. (1) The smaller, **splanchnic**, or **visceral portion** grows inwards, dorsal to the Wolffian ridge, to be connected with the sympathetic cord and the innervation of organs in the splanchnic area. This branch of the spinal nerve becomes the **white ramus communicans** of the sympathetic. It is not present in the case of all the spinal nerves (cervical, lower lumbar, and upper sacral). It will be referred to again in connexion with the sympathetic system. (2) The larger, **somatic**, or **parietal portion** becomes the main part of the anterior primary division of the nerve. It continues the original ventral course of the nerve, and, reaching the body wall, subdivides into two terminal branches—a lateral branch, which grows outwards and downwards and reaches the lateral aspect of the trunk, after piercing the myotome; and a ventral or anterior branch, which grows onwards in the body wall to reach the ventral axis. This arrangement is met with in the trunk between the limbs and in the neck.

III. **Formation of Limb-plexuses.**—The method of growth of the spinal nerves, just described, is modified in the regions where the limbs are developed. In relation to the limbs, which exist in the form of buds of cellular undifferentiated mesoblast before the spinal nerves have any connexion with them, the development of the nerve proceeds exactly in the way described up to the point of formation of somatic and splanchnic branches. The **somatic branches** then stream out into the limb bud, passing into it below the ends of the myotomes and spreading out into a bundle of fibres at the basal attachment of the limb. Later on, the nerves separate each into a pair of definite trunks, which are named **dorsal** and **ventral**, and which, dividing round a central core of mesoblast, proceed to the dorsal and ventral surfaces respectively of the limb bud. While this process is going on, a *secondary union* takes place between (parts of) adjacent dorsal and ventral trunks. Dorsal trunks unite with dorsal trunks, ventral trunks unite with ventral trunks, to form the nerves distributed ultimately to the surfaces and periphery of the limb. These **dorsal and ventral trunks** are homologous with the **lateral and ventral branches** of the somatic nerves in other regions.

## Morphology of the Limb-plexuses.

The arrangement of the limb nerves is rendered complex and the significance of the plexuses is obscured by the changes through which, coincidently, the nerves on the one hand and the parts supplied by them on the other hand have passed in the course of development.

**Nature of the Limbs.**—As already described, the mammalian limbs arise as flattened buds from the extremities of the **Wolffian ridge**. Each bud possesses a *preaxial* and a *postaxial border*, and a *dorsal* and a *ventral surface*, continuous with the dorsal and ventral aspects of the trunk and homologous with its lateral and ventral surfaces. Each bud consists at first of a mass of undifferentiated, unsegmented mesoblast, covered by epithelium. Around the central core of mesoblast which produces the skeletal axis, the vessels and muscles of the limb are formed *in situ*, the muscles as double dorsal and ventral strata, beneath the corresponding surfaces of the bud.

Each limb bud is connected to the lateral and ventral aspects of the trunk, and is associated with a number of body segments, varying in the two extremities and in different animals.

Although the mesoblastic material of which the limb bud is composed exhibits in itself no segmental divisions at any period of its development, a clear indication of the segmental relations of the limbs is obtained from the arrangement of the limb nerves. Taking the nerves which supply the limbs as a guide, the segments engaged in the formation of the upper extremity are the last five cervical and first two thoracic. The lower extremity is related by its nerves to all the lumbar and the first three sacral segments. In each limb, the segments at the preaxial and postaxial borders are only partially concerned in limb formation.

It has been already shown that the somatic branches of the nerves enter the substance of the embryonic limb and divide in their course into dorsal and ventral trunks, which supply the dorsal and ventral surfaces of the limb bud. The higher nerves supply the preaxial border, the lower nerves supply the postaxial border, while the nerves most centrally situated extend furthest towards the periphery of the limb.

In order to understand properly the constitution of the limb-plexuses, it is necessary further to make a comparison of the surfaces and borders of the embryonic and adult limbs.

**Upper Limb.**—(*A*) **Borders.**—The **preaxial border** of the upper extremity extends from the middle of the clavicle, in the line of the cephalic vein, down the front of the shoulder, the outer side of the arm, forearm and hand, to the outer border of the thumb. The **postaxial border** extends from the middle of the axilla along the inner side of the arm (in the line of the basilic vein), the inner side of the forearm and hand, to the inner border of the little finger.

(*B*) **Surfaces.**—The areas of the limb between these lines, anteriorly and posteriorly, correspond to the ventral and dorsal surfaces of the embryonic limb bud. The **ventral surface** is represented by the front of the chest, arm, and forearm, and the palm of the hand. The **dorsal surface** is represented by the scapular and deltoid regions, the back of the arm, forearm, and hand.

**Lower Limb.**—(*A*) **Borders.**—The **preaxial border** of the lower limb extends from the middle of Poupart's ligament down the inner side of the thigh and leg in the line of the internal saphenous vein, to the inner side of the great toe. The **postaxial border**, beginning at the coccyx, extends along the fold of the nates and the outer side and back of the thigh and leg (in the line of the external saphenous vein) to the outer border of the foot and little toe.

(*B*) **Surfaces.**—The areas between these lines correspond to the primitive dorsal and ventral surfaces of the embryonic limb bud. The unequal amount of rotation in the parts of the lower limb obscures the relation of fœtal and adult surfaces, which are most easily made out in the infantile position of the limbs, with the thighs and knees flexed and the soles of the feet inverted. The **ventral surface** of the embryonic limb is represented by the inner side and back of the thigh, the back of the leg, and the sole of the foot. The **dorsal surface** is represented by the front of the thigh and buttock, the front of the leg, and the dorsum of the foot.

**Composition of the Limb-plexuses.**—In all mammals the same definite plan underlies the constitution of the limb-plexuses. The nerves concerned are the anterior primary divisions of certain segmental spinal nerves, which (with certain exceptions at the preaxial and postaxial borders) are destined wholly and solely for the innervation of the limb. Each of the anterior primary divisions engaged divides into a pair of **secondary trunks**, named **dorsal** or posterior, **ventral** or anterior. The dorsal and ventral trunks again subdivide into **tertiary trunks**, which combine with the corresponding subdivisions of neighbouring dorsal and ventral trunks to form the **nerves of distribution**. The combinations of *dorsal trunks* provide a series of nerves for the supply of that part of the limb which is derived from the *dorsal surface* of the embryonic limb bud; the combinations of *ventral trunks* give rise to nerves of distribution to the regions corresponding to its *ventral surface*. The relation of the nerves derived from the limb-plexuses to the areas of the limbs is given in the accompanying tables :—

## I. Upper Limb.

| Origin. | | Nerves. | Distribution. | |
|---|---|---|---|---|
| Brachial Plexus | Dorsal trunks (*Posterior cord*) | Posterior scapular | Scapular region and shoulder | Dorsal surface |
| | | Posterior thoracic | | |
| | | Suprascapular | | |
| | | Subscapular (3) | | |
| | | Circumflex | | |
| | | (Lesser internal cutaneous (?)) | Arm, inner side | |
| | | (Intercosto-humeral (?)) | | |
| | | Musculo-spiral | Back of arm, forearm, and hand | |
| | Ventral trunks (*Outer and inner cords*) | Nerve to subclavius | Front of chest | Ventral surface |
| | | Anterior thoracic (2) | | |
| | | Musculo-cutaneous | Front of arm and forearm | |
| | | Lesser internal cutaneous | Inner side of arm | |
| | | Internal cutaneous | Front of arm and forearm | |
| | | Median | Front of forearm and hand | |
| | | Ulnar | | |

## II. Lower Limb.

| Origin. | | Nerves. | Distribution. | |
|---|---|---|---|---|
| Lumbo-sacral Plexus | Dorsal trunks | Ilio-hypogastric (iliac branch) | Buttock | Dorsal surface |
| | | Superior gluteal | | |
| | | Inferior gluteal | | |
| | | Nerve to pyriformis | | |
| | | Small sciatic | Buttock and thigh, outer side and front | |
| | | External cutaneous | Front of thigh | |
| | | Genito-crural (crural branch) | Front and inner side of thigh, leg, and foot | |
| | | Anterior crural | Front of leg and foot | |
| | | Peroneal | | |
| | Ventral trunks | Ilio-hypogastric (hypogastric branch) | Abdominal wall (ventral surface) | Ventral surface |
| | | Ilio-inguinal | Abdominal wall, thigh, and perineum | |
| | | Genito-crural (genital branch) | Groin | |
| | | Obturator | Thigh (inner side) and knee (back) | |
| | | Nerve to obturator internus and superior gemellus | Buttock and back of thigh | |
| | | Nerve to quadratus femoris and inferior gemellus | | |
| | | Nerve to hamstrings | Back of thigh and perineum | |
| | | Small sciatic | Back of knee, leg, and sole of foot | |
| | | Tibial | | |

In the regions of the limbs no anterior cutaneous branches, derived from the limb nerves, supply the trunk. The whole of the nerve is carried into the limb and is absorbed in its innervation, and the dorsal and ventral trunks forming the limb-plexuses are to be looked upon as homologous with the lateral and anterior trunks of an intercostal nerve. Two series of anomalies in relation to the formation and distribution of the nerves to the limbs must, however, be considered, because it has been suggested (Goodsir) that the nerves of the limbs are serially homologous with not the whole, but with only the lateral branches of the anterior primary divisions of the intercostal nerves.

(1) **Nerves in connexion with the primitive borders of the Limbs.**—**At the preaxial border of the upper limb,** at its root, the fourth cervical nerve, which supplies the anterior and lateral surfaces of the neck, is also distributed through the supraclavicular nerves to the skin of both ventral and dorsal surfaces of the limb. The nerves and surfaces are here not merely homologous, but in actual continuity.

**At the preaxial border of the lower limb,** similarly, the first lumbar nerve, by means of the ilio-hypogastric and ilio-inguinal branches, supplies on the one hand the buttock, in series with the lateral branches of the lower thoracic nerves, and, on the other hand, the lower part of the abdominal wall and the adjacent inner side of the thigh, in series with the anterior terminal branches of the lower thoracic nerves.

**At the postaxial border of the upper limb** the first and second thoracic nerves are concerned in supplying trunk segments as well as parts of the limb. The first thoracic nerve, besides supplying the limb through the inner cord of the plexus, also innervates at least the muscles of the first intercostal space; the second thoracic nerve is concerned in the innervation of the limb, principally by means of its lateral branch only, which, as the intercosto-humeral nerve, supplies the skin along the postaxial border of the limb and on its *dorsal side.* **At the postaxial border of the lower limb,** in the same way, the third and fourth sacral nerves, partially implicated in the innervation of the limb (through the tibial, small sciatic, perforating cutaneous nerve, and perineal branch of the fourth sacral nerve), are also engaged in supplying the trunk (perineum) through the pudic nerve. These peculiarities of arrangement of the nerves at the borders of the limbs may be explained on the supposition that the segment corresponding to the nerve named is only partially concerned in limb formation, and is, at the same time, implicated to a greater or less extent in the formation of structures belonging to the trunk.

(2) **The origin and distribution of the nerves at the postaxial border of the limbs** present a special difficulty. In the composition respectively of the brachial and lumbo-sacral plexuses, the first thoracic and third sacral nerves do not as a rule divide into ventral and dorsal trunks, but contribute only to the formation of the ventral series of nerves. A solution of this difficulty may be found in the examination of the areas of distribution of the nerves derived from the first thoracic and third sacral nerves. In the case of the brachial plexus (the inner cord of which

receives normally the whole contribution of the first thoracic nerve) the lesser internal cutaneous, the inner branch of the internal cutaneous, and the dorsal branch of the ulnar nerve supply the dorsal aspect of the limb on its postaxial border. These nerves are in serial homology with the intercosto-humeral and lateral trunks of intercostal nerves. In the case of the lumbo-sacral plexus similarly, in which the third sacral nerve does not divide into ventral and dorsal trunks, the small sciatic and tibial nerves containing the contribution from the third sacral nerves innervate, by means of the gluteal and external femoral branches of the former and the tibial communicating branch of the latter, the dorsal surface of the limb along the postaxial border, in series with the perforating cutaneous nerve and the perineal branch of the fourth sacral.

These apparent anomalies appear to indicate that, instead of dividing into its proper dorsal and ventral trunks, the entire contribution of the spinal nerve concerned is in these instances carried undivided along the postaxial border of the limb in association with the ventral trunks, and that the dorsal subdivisions are thrown off successively as the plexus cords approach the periphery. Indeed, in the case of the small sciatic nerve, Eisler has shown that, when the peroneal and tibial nerves are separated at their origin, its gluteal and external femoral branches arise from and are connected with the dorsal, and the perineal and internal femoral branches with the ventral trunk.

## The Distribution of the Spinal Nerves to the Muscles and Skin of the Limbs.

By dissection, experiment, and clinical observation, it is conclusively proved that as a rule each nerve of distribution in the limb, whether to muscle or skin, is made up of fibres derived from more than one spinal nerve; and, further, that in cutaneous distribution a considerable overlapping occurs in the course of the several peripheral nerves. Moreover, the arrangement of the distribution of the nerves to skin and to muscles is not identical. In the case of the skin of the limbs, by the covering of the limb being drawn on to it from adjacent parts in the process of growth, cutaneous nerves are engaged, which are derived from sources not represented in the muscular innervation of the limbs. Again, among the muscles, some have undergone fusion, others have become rudimentary, and others again have altered their position in the limb. Bearing these qualifications in mind, it is possible to formulate a definite plan for the innervation of the skin and muscles of the upper and lower limb. The accompanying tables give an analysis of the distribution of the spinal nerves to the skin and muscles of the upper and lower limb respectively:—

### I. Upper Limb.

A. **Innervation of the Muscles of the Limbs.**—The following laws appear to be applicable to the upper and lower limbs alike :—

1. *No limb-muscle receives its nerve-supply from posterior primary divisions.*

2. *The dorsal and ventral strata of muscles are always supplied by the corresponding dorsal and ventral branches of the nerves concerned. The ventral muscular stratum is more extensive than the dorsal; the ventral nerves are the more numerous, and the additional nerves are postaxially placed.* The spinal nerves supplying muscles of the upper limb are C. 5, 6, 7, 8 (dorsal), and C. 5, 6, 7, 8, T. 1 (ventral); the nerves for the muscles of the lower limb are L. 2, 3, 4, 5, S. 1, 2 (dorsal), and L. 2, 3, 4, 5, S. 1, 2, 3 (ventral).

3. *The dorsal and ventral trunks of the nerves are distributed in the limb in a continuous, segmental manner*; so that, "of two muscles, that nearer the head end of the body tends to be supplied by the higher nerve, and that nearer the tail end by the lower nerve" (Herringham).

4. *The nerves placed most centrally in the plexus extend furthest into the limb, and the more preaxial nerves terminate sooner in the limb than the more postaxial nerves.*

**Upper Limb.**

| Dorsal Surface. | | Ventral Surface. | |
|---|---|---|---|
| Muscles of shoulder . | C. 3, 4, 5, 6, 7, 8. | Muscles of chest . | C. 5, 6, 7, 8, T. 1. |
| „ arm . . | C. 6, 7, 8. | „ arm . | C. 5, 6, 7. |
| „ forearm . | C. 6, 7. | „ forearm . | C. 6, 7, 8, T. 1. |
| | | „ hand . | C. 6, 7, 8 (T. 1). |

**Lower Limb.**

| | | | |
|---|---|---|---|
| Muscles of thigh and buttock . . . | L. 2, 3, 4, 5, S. 1, 2. | Muscles of thigh . | L. 2, 3, 4, 5, S. 1, 2, 3. |
| Muscles of leg and foot | L. 4, 5, S. 1. | „ leg . | L. 4, 5, S. 1, 2. |
| | | „ foot . | L. 5, S. 1, 2. |

The only exception to this rule is on the ventral (anterior) surface of the upper arm, where a suppression of the muscle elements leads to an absence of the regular series of segmental nerves (C. 8, T. 1) on its postaxial border. These nerves reappear in the forearm, and the occasional

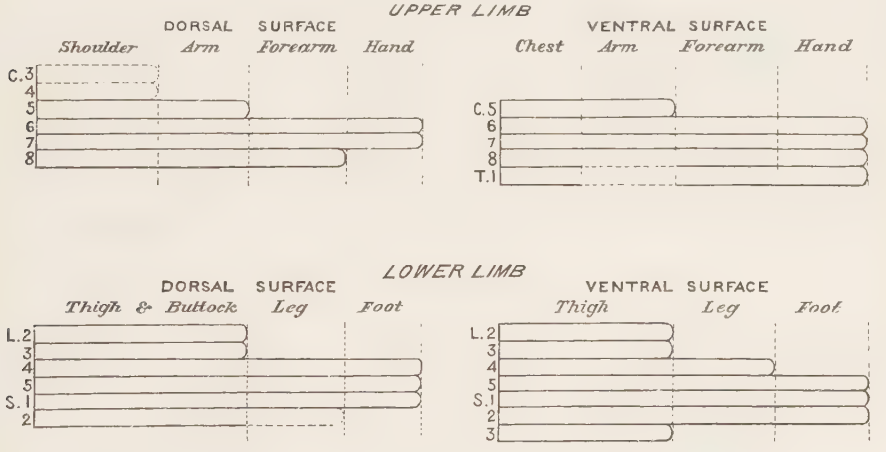

FIG. 516.—SCHEME of the segmental distribution of the muscular nerves of the upper and lower limbs.

"axillary arches" may be regarded as the muscular elements usually suppressed, and, when present, supplied by these nerves.

**Muscles with a Double Nerve-supply.**—The existence of more than one nerve to a muscle indicates usually that the muscle is composite and is the representative of originally separate elements, belonging to more than one segment or to both surfaces of the limb. In the case of the pectoralis major, subscapularis and flexor profundus digitorum, adductor magnus, and soleus, parts of the same (ventral or dorsal) stratum have fused, to form muscles innervated from the corresponding ventral or dorsal nerves. The other muscles having a double nerve-supply—brachialis anticus, biceps flexor cruris, and (sometimes) pectineus—are examples of fusion at the preaxial or postaxial border of muscular elements derived from the dorsal and ventral surfaces of the limb, which are correspondingly innervated by branches from both dorsal and ventral series: *e.g.* the brachialis anticus is innervated by the musculo-cutaneous and musculo-spiral nerves; the biceps flexor cruris, by the peroneal (short head) and tibial (long head) nerves; and the pectineus, by the anterior crural and (sometimes) obturator nerves.

B. **Innervation of the Skin of the Limbs.**—While the scheme of cutaneous innervation of the limbs is fundamentally segmental, yet the arrangement is confused and complicated by various causes. The growth of the limb from the trunk has caused the skin to be drawn out over it like a stretched sheet of india-rubber (Herringham), and at the same time the extent of the dorsal area of the limb is increased at the expense of the ventral area. The central nerves of the plexus remain buried deeply in the substance of the limb, only coming to the surface towards the periphery. The proximal parts of both surfaces of the limb thus become innervated by

cutaneous nerves otherwise not necessarily concerned in the innervation of the limbs. Herringham has shown that—(A) *Of two spots on the skin, that nearer the preaxial border tends to be supplied by the higher nerve.* (B) *Of two spots in the preaxial area, the lower tends to be supplied by the lower nerve; and of two spots in the postaxial area, the lower tends to be supplied by the higher nerve.* In other words, from the root of the limb down the preaxial border to its distal extremity, and up the postaxial border to the root of the limb again, there is a definite numerical sequence of spinal nerves supplying skin areas through nerves of the limb-plexuses. A similar numerical sequence in the arrangement of the nerves is also found extending over the dorsal and ventral surfaces of the limbs from preaxial to postaxial border, except in certain situations.

On the dorsal and ventral surfaces of both upper and lower limbs there is a hiatus, for a certain distance, in the numerical sequence of the spinal nerves in their cutaneous distribution, explicable on the ground that the central nerves of the plexus, which fail to reach the surface in these situations, are replaced by cutaneous branches from neighbouring nerves. This hiatus has been named the *axial area or line.*

**In the upper limb,** *the dorsal axial area or line* extends from the middle line of the back, opposite the vertebra prominens, to the insertion of the deltoid.

*The ventral axial area or line* extends anteriorly from the middle line of the trunk, at the manubrio-sternal joint, across the chest, down the front of the arm and forearm to the wrist.

**In the lower limb,** *the dorsal axial area or line* may be traced from the middle line of the back over the posterior superior iliac spine, across the buttock and thigh, to the head of the fibula.

*A ventral axial area or line* can also be traced from the root of the penis along the inner side of the thigh and knee, and down the back of the leg to the heel.

These areas or lines represent the meeting-place and overlapping of nerves, which are not in numerical sequence; and it is only at the peripheral parts of the limbs, on the dorsal and ventral surfaces, that the nerves appear in numerical sequence from the preaxial to the postaxial border. In the case of the upper limb the hiatus is caused, in both surfaces of the limb, by the absence of cutaneous branches of the seventh cervical nerve; in the case of the lower limb the hiatus is due to the absence of branches from the fifth lumbar nerve on both surfaces of the limb, and the absence of branches from the fourth lumbar nerve, in addition, on the dorsal surface.

Understanding the significance of these dorsal and ventral axial areas or lines, and at the same time bearing in mind the overlapping which occurs in the cutaneous distribution of each spinal nerve, the areas of skin supplied through the limb-plexuses can be mapped out with considerable precision, as indicated in the following tables:—

## *A.* Upper Limb.

### Cutaneous Distribution.

| | Nerves. | Spinal Origin. | Distribution. |
|---|---|---|---|
| **Preaxial border** from neck to hand ↓ | Supraclavicular nerves | C. 3. 4. | Chest, shoulder, deltoid, and scapular regions. |

### Variations in the Position of the Limb-plexuses.

Two different kinds of variations occur in relation to the limb-nerves.

(1) **Individual variations**, in both the extent of origin and in the area of distribution of a given nerve, are not uncommon; these variations are usually concomitant with compensatory variations in adjacent nerves, and are due to the fibres of a given spinal nerve taking an abnormal course in the trunk of another nerve of distribution and effecting a communication with the proper nerve peripherally. In this way the variations in the origin and distribution of the intercosto-humeral nerve may be explained; and, similarly, the ulnar nerve may have some of its fibres carried as far as the forearm incorporated with the median and transferred to it by a communication between the two nerves in that region.

(2) **Variations in the limb-plexus**, in relation to the vertebral column, are the chief cause of variations in the constitution of the limb-nerves. These variations affect more or less the whole series of nerves in the plexus.

The **brachial plexus** is subject only to very slight variation in position and arrangement. It may be reinforced at the upper end by a slender trunk from the fourth cervical nerve, and, more frequently, by an intra-thoracic communication between the second and first thoracic nerves. The presence of one or other of these nerves is an indication of a slight tendency towards a cephalic or caudal shifting of the whole plexus in relation to the spinal cord. It is, however, never sufficient to cause the exclusion to any extent of the nerves normally implicated. The presence of a cervical rib may coincide with little or no change in the relation of the nerves. Indeed, the inclusion of the second thoracic nerve in the plexus may be, as already stated, merely an individual variation, a change in the path to the limb of the intercosto-humeral nerve. Concomitant variations occur among groups of nerves, however, which indicate a certain tendency to variation in the position of the whole plexus. At one end, the suprascapular and musculo-cutaneous nerves may arise from the fourth and fifth, fifth alone, or fifth and sixth cervical nerves. At the other end of the plexus, the musculo-spiral may or may not receive a root from the first thoracic nerve, and this addition is rather more likely to occur when the second thoracic nerve is implicated in the plexus.

The **lumbo-sacral plexus** shows a very considerable variability in position and constitution. Eisler records concomitant variations in the plexus in 18 per cent of the cases examined by him.

The variations occur within wide limits. The plexus may begin at the eleventh or twelfth thoracic or first lumbar nerve. The last nerve in the great sciatic cord may be the second, third, or fourth sacral nerve. The position of the n. furcalis is a guide to the arrangement of the plexus. It may be formed by the third, third and fourth, fourth, fourth and fifth, or fifth lumbar nerves. The resulting variations are illustrated by the following extreme cases:—

| | (1) *Prefixed Variety.* | (2) *Postfixed Variety.* |
|---|---|---|
| Nervus furcalis . . . | L. 3 and 4 (double). | L. 5. |
| Obturator . . . . | L. 1, 2, 3. | L. 2, 3, 4, 5. |
| Anterior crural . . . | T. 12, L. 1, 2, 3, 4. | L. 2, 3, 4, 5. |
| Tibial . . . . . | L. 3, 4, 5, S. 1, 2. | L. 5, S. 1, 2, 3, 4. |
| Peroneal . . . . . | L. 3, 4, 5, S. 1. | L. 5, S. 1, 2, 3. |

Those variations in the constitution of the lumbo-sacral plexus are most numerous which are due to the inclusion of nerves more caudally placed. Thus, out of twenty-two variations in the position of the *n. furcalis*, in nineteen Eisler found it formed by the fifth lumbar nerve; in two cases only, by the third lumbar nerve. There is further evidence that variations in the position of the plexus are accompanied by variations in the vertebral column itself. Out of the twenty-two abnormal plexuses examined by Eisler, sixteen were coincident with abnormal arrangement of the associated vertebræ.

### Significance of the Limb-plexuses.

From the above considerations, it is obvious that something more than convenience of transit for the spinal nerves to skin and muscles is secured by the formation of the limb-plexuses. It has been shown that by their combinations in the plexuses, every spot or area of skin in the limbs is innervated by more than one spinal nerve; and generally, also, each limb-muscle is supplied by more than one spinal nerve. Each cutaneous area and each limb-muscle is thus brought into relationship with a wider area of the spinal cord than would occur if the plexuses were non-existent. A simultaneous record of sensation is thus transmitted from any given point on the surface of the limb through more than one dorsal root; and a more ready co-ordination of muscular movement is brought about by the transmission of motor impulses from the ventral root of a given spinal nerve to more than one muscle at the same time. In a word, a plexus exists to supply the whole limb and the limb as a whole, as an organ which has its different active parts connected with the central nervous system by means of the limb-plexus.

## THE CRANIAL NERVES.

The series of cranial nerves is arranged in twelve pairs, which present striking differences in origin, in distribution, and in functions.

| Number. | Name. | Function. | Superficial Attachment to Brain. |
|---|---|---|---|
| I. | **Olfactory** . . | Smell . . . . . | Olfactory bulb. |
| II. | **Optic** . . . | Sight . . . . . | Optic thalamus. |
| III. | **Oculo-motor** . | Motor to the muscles of eyeball and orbit | Crus cerebri. |
| IV. | **Trochlear** . . | Motor to superior oblique muscle of eyeball | Superior medullary velum. |
| V. | **Trigeminal** . . | Sensory to face, tongue, and teeth; motor to muscles of mastication | Pons Varolii. |
| VI. | **Abducent** . . | Motor to external rectus muscle of eyeball | Junction of pons and medulla. |
| VII. | **Facial** . . . | Motor to muscles of scalp and face, sensory to tongue | Posterior border of pons Varolii. |
| VIII. | **Auditory** . . | Hearing and equilibrium . . | Posterior border of pons Varolii |
| IX. | **Glosso-pharyngeal** | Sensory to tongue and pharynx . | Medulla oblongata. |
| X. | **Pneumogastric** . | Sensory to pharynx, œsophagus and stomach, and respiratory organs | Medulla oblongata. |
| XI. | **Spinal accessory** | (*a*) **Accessory to vagus.**—Motor to muscles of palate, pharynx, œsophagus, stomach and intestines, and respiratory organs; inhibitory for heart | Medulla oblongata. |
| | | (*b*) **Spinal part**: motor to trapezius and sterno-mastoid muscles | Spinal cord. |
| XII. | **Hypoglossal** . | Motor to muscles of the tongue | Medulla oblongata. |

The deep cerebral connexions of the cranial nerves are dealt with in the section which treats of the Brain (pp. 514 and 540). Certain general points in connexion with these nerves are also touched upon in the chapter introductory to the Nervous System (p. 443).

## The First or Olfactory Nerve.

The olfactory nerve (n. olfactorius) consists of several parts: (1) a series of fine **nerves**, which arise from (2) the **olfactory bulb**. This again is connected by (3)

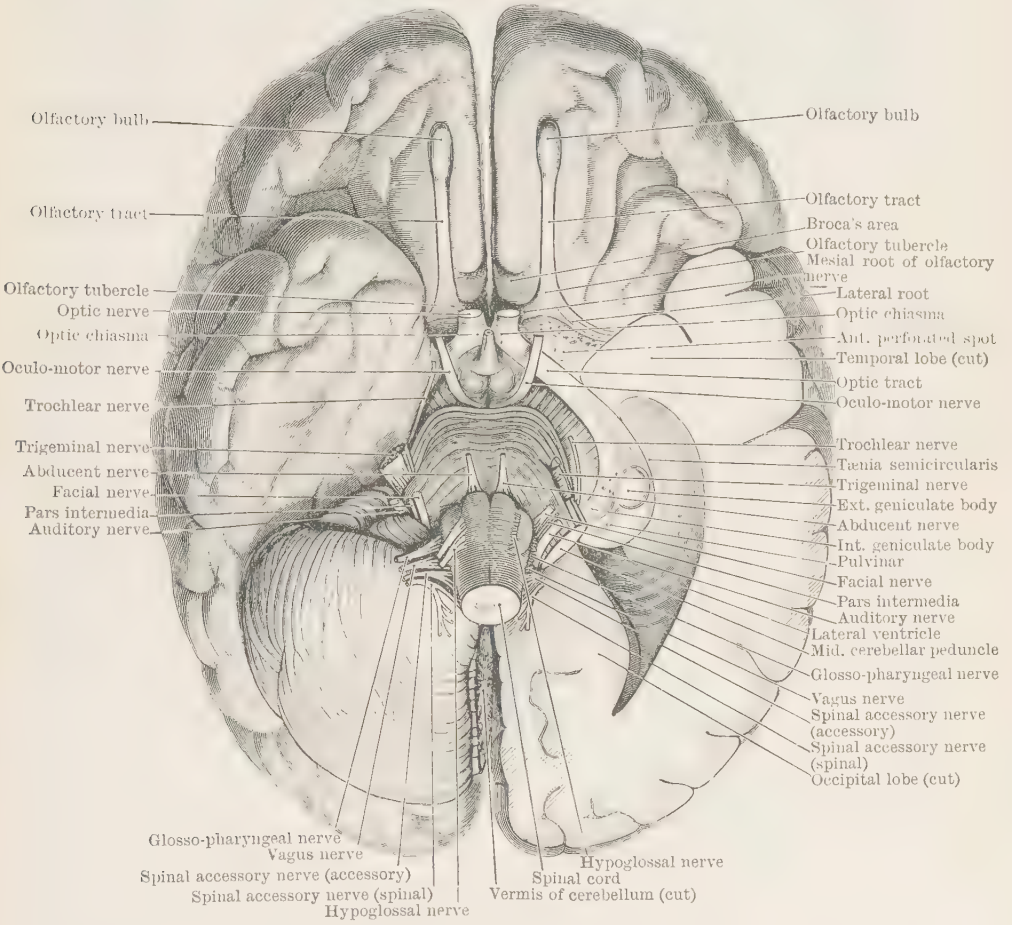

Fig. 517.—View of the Under Surface of the Brain, with the lower portion of the temporal and occipital lobes, and the cerebellum on the left side removed, to show the origins of the cranial nerves.

the **olfactory tract** with the brain, to which it is attached by (4) two **roots** (Fig. 517).

The anatomy of the roots, tract, and bulb of the olfactory nerve are described elsewhere (pp. 569 and 587).

The **olfactory nerves**, about twenty in number, arise from the under surface of the olfactory bulb. The fibres are non-medullated. Piercing the cribriform plate of the ethmoid bone, enveloped in sheaths of dura mater, they are distributed in the nasal cavity as the nerves of smell. The fibres form fine plexuses over a limited area on the upper portion of the nasal septum, and to even a less extent over the outer wall of the nose.

## The Second or Optic Nerve.

The optic nerve (n. opticus) arises from the brain by means of the **optic tract** (Fig. 551). This takes origin from the external and internal geniculate bodies,

situated on the under surface of the optic thalamus at its posterior end, and also from the brachium of the upper of the two corpora quadrigemina (*vide* pp. 532 and 551). The optic tract reaches the base of the brain after sweeping round

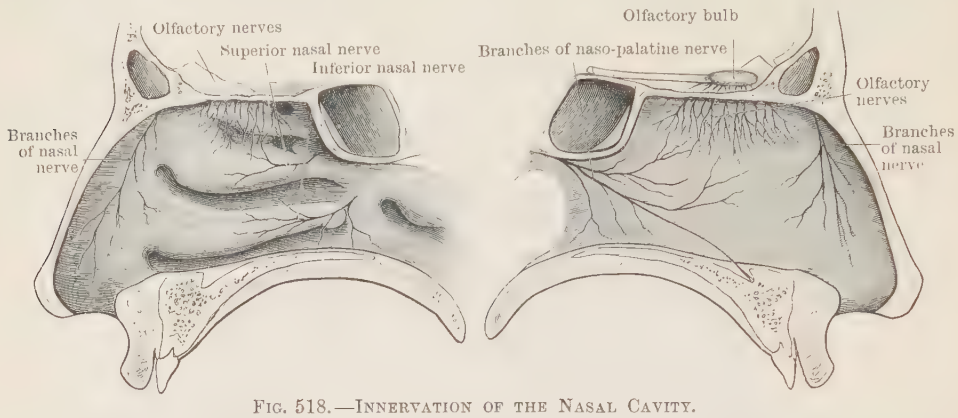

FIG. 518.—INNERVATION OF THE NASAL CAVITY.

between the crus cerebri and the hippocampal convolution of the temporal lobe. The two optic tracts converge in front of the inter-peduncular space, internal to the anterior perforated spot and the termination of the internal carotid artery, and unite to form the **optic chiasma** or **commissure**. This adheres to the under surface of the floor of the third ventricle in front of the tuber cinereum, and gives rise at each end to the **optic nerve**. The optic nerve, directed outwards and forward, pierces the dura mater, and passes from the cranial cavity into the orbit through the optic foramen in company with the ophthalmic artery. In the orbit the nerve is imbedded in the fat behind the eyeball, and is surrounded by the ocular muscles. It is connected with the globe of the eye at a point one-eighth of an inch on the inner side of the axis of the eyeball. After piercing the fibrous and vascular coats, the nerve spreads out at the **optic disc** to form the innermost layer of the **retina**. In the orbit the nerve is crossed by the ophthalmic artery and the nasal nerve, and nearer to its termination it is surrounded by the ciliary vessels and nerves, and by the capsule of Tenon. It is pierced obliquely on its under surface by the central artery of the retina.

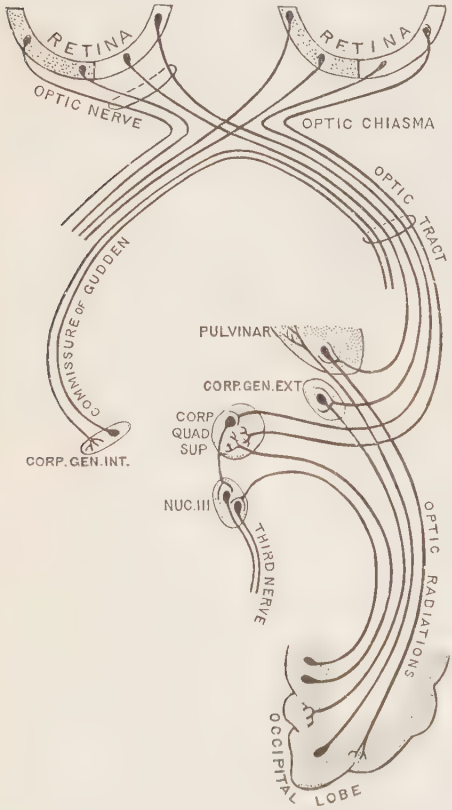

FIG. 519.—DIAGRAM OF THE CENTRAL CONNEXIONS OF THE OPTIC NERVE AND OPTIC TRACT.

**Decussation in the Optic Commissure.**—In the optic commissure the fibres of the two optic tracts separate, the inner half of each tract decussating to form the mesial half of the opposite optic nerve. The other, outer half of each tract, continues its course to form the outer half of the optic nerve on the same side. At the back of the commissure another bundle of fibres is found passing from tract to tract behind the decussating fibres, and known as **Gudden's commissure** (see p. 552).

### THE THIRD OR OCULO-MOTOR NERVE.

The oculo-motor nerve (n. oculo-motorius) arises from the brain, in the region of the posterior perforated spot, by several radicles emerging from the **oculo-motor**

**sulcus**, on the inner side of the crus cerebri, just in front of the pons Varolii (Fig. 517). Passing forwards between the posterior cerebral and superior cerebellar arteries, the nerve pierces the dura mater on the outer side of the posterior clinoid process, in a small triangular space between the free and attached borders of the tentorium cerebelli. Beneath the dura mater the nerve courses through the outer wall of the cavernous sinus, and enters the orbit through the sphenoidal fissure

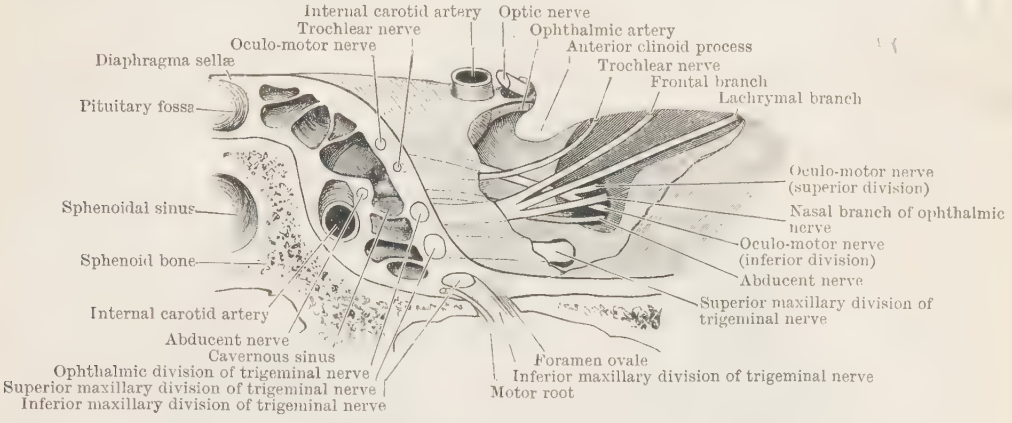

Fig. 520.—Relations of Structures in the Cavernous Sinus and Sphenoidal Fissure.

and between the two heads of the external rectus muscle. As it enters the orbit it divides into upper and lower branches, separated by the nasal nerve.

**Branches.**—The **superior branch** of the nerve supplies two muscles of the orbit —the superior rectus and the levator palpebræ superioris.

The **inferior branch** passes forwards, and after giving branches to the internal and inferior recti, ends in the inferior oblique muscle. The short root of the ciliary ganglion arises from the terminal branch which goes to the last-named muscle.

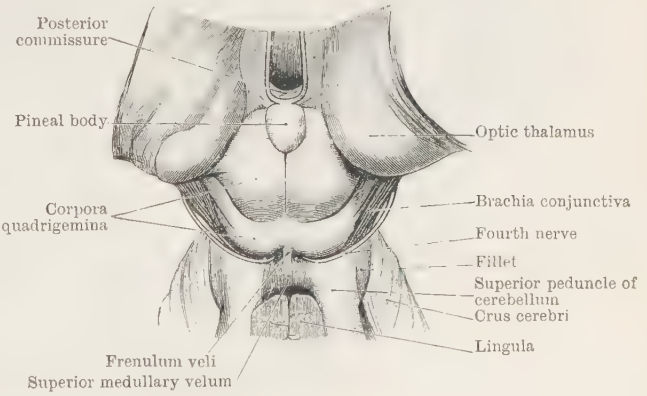

Fig. 521.—Dorsal Surface of the Mid-Brain, to show the origin of the trochlear (fourth) nerve.

**Communications.**—1. In the cavernous sinus the third nerve communicates with the cavernous plexus on the internal carotid artery. 2. In the cavernous sinus it also receives a slender communication from the ophthalmic division of the fifth nerve. 3. The **short root of the ciliary ganglion** passes upwards from the branch of the nerve which supplies the inferior oblique muscle.

## The Fourth or Trochlear Nerve.

The trochlear nerve (n. trochlearis or patheticus) emerges from the dorsal surface of the mid-brain. It springs at the side of the *frenulum* from the anterior end of the superior medullary velum, just behind the corpora quadrigemina (for deep origin, see p. 540). It is extremely slender, and of considerable length. Passing round the crus cerebri, the nerve appears in the base of the brain behind the optic tract, in the interval between the crus cerebri internally and the temporal lobe of the cerebrum externally. Continued forwards to the base of the skull, it pierces the free border of the tentorium cerebelli, on the outer side

of the third nerve, and proceeds forwards in the outer wall of the cavernous sinus, to the sphenoidal fissure lying between the third and ophthalmic nerves. It enters the orbit above the muscles of the eyeball, and terminates in the orbital (superior) surface of the superior oblique muscle.

**Communications.**—In the cavernous sinus the nerve receives (1) a communicating

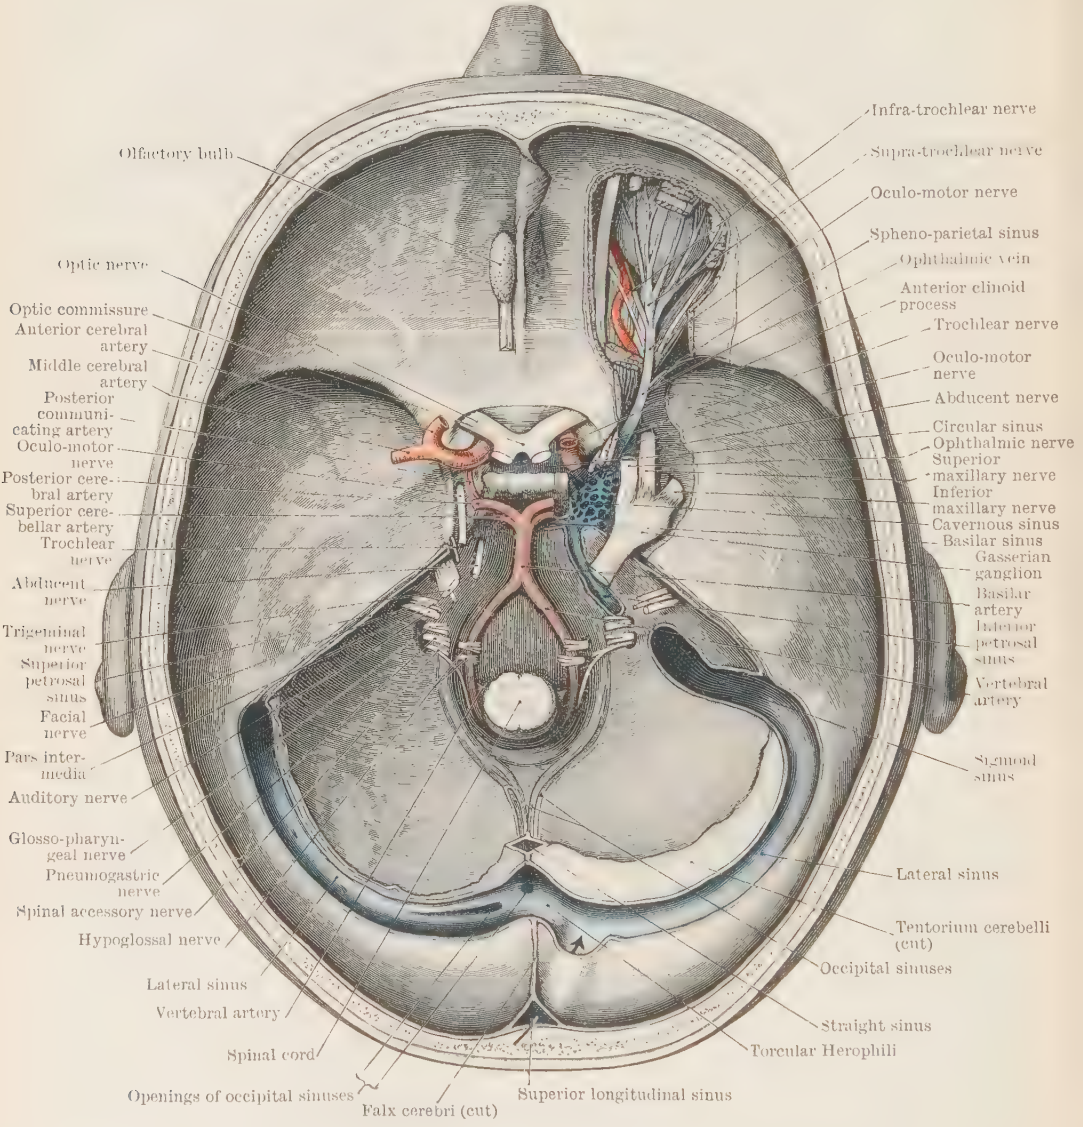

FIG. 522.—THE BASE OF THE SKULL, to show the dura mater, sinuses, arteries, and nerves.

branch from the cavernous or carotid plexus on the internal carotid artery, and (2) a slender filament from the ophthalmic division of the fifth nerve.

## THE FIFTH, TRIGEMINAL OR TRIFACIAL NERVE.

The trigeminal nerve (n. trigeminus) arises from the surface of the pons Varolii in its outer part by two roots, a large **sensory root** (portio major) and a small **motor root** (portio minor) (Fig. 517, p. 675). The two roots proceed forwards in the posterior fossa of the base of the skull, and piercing the dura mater beneath the attachment of the tentorium cerebelli to the superior border of the petrous portion of the

temporal bone, enter a cavity in the dura mater (cavum Meckelii) over the apex of the petrous bone. The large sensory root gradually conceals the small motor root in its course forwards, and expands beneath the dura mater into a large flattened ganglion,—the **Gasserian ganglion** (ganglion semilunare). This ganglion occupies an impression on the apex of the petrous portion of the temporal bone, and from it three large trunks arise—the ophthalmic or first, the superior maxillary or second, and the inferior maxillary or third divisions of the nerve. The small motor root of the nerve passes forward beneath the Gasserian ganglion, and is wholly incorporated with the inferior maxillary division of the nerve.

**Ophthalmic Division** (n. ophthalmicus).—The ophthalmic nerve passes forwards to the orbit through the middle fossa of the base of the skull, beneath the dura mater. It lies in the outer wall of the cavernous sinus, at a lower level than the fourth nerve, and reaches the orbit through the sphenoidal fissure (Fig. 520).

*In the wall of the cavernous sinus* the ophthalmic nerve gives off (1) a small recurrent branch to the dura mater (n. tentorii), (2) communicating branches to the cavernous plexus of the sympathetic on the internal carotid artery, and (3) small communicating twigs to the trunks of the third, fourth, and sixth nerves.

*In the sphenoidal fissure* the nerve divides into three main branches—lachrymal, frontal, and nasal (Fig. 524).

The **lachrymal nerve** (n. lacrymalis) enters the orbit through the outer angle of the sphenoidal fissure, above the orbital muscles. Passing forwards beneath the periosteum to the anterior part of the orbit, the nerve ends by supplying branches (*a*) to the lachrymal gland, (*b*) to the conjunctiva, and (*c*) to the skin of the outer canthus of the eye.

The lachrymal nerve *communicates* in the orbit with the orbital branch of the superior maxillary nerve, and on the face, by its terminal branches, with the temporal branches of the facial nerve (Fig. 523).

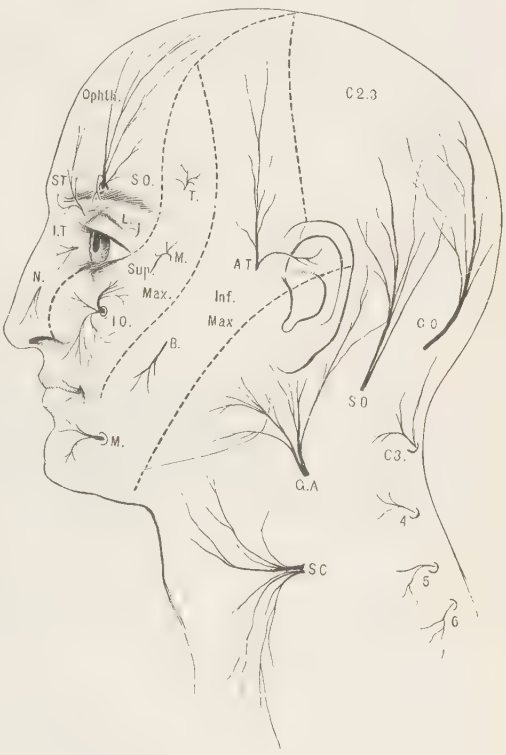

FIG. 523.—DISTRIBUTION OF SENSORY NERVES TO THE HEAD AND NECK.

Ophth, Ophthalmic division of the fifth nerve; St, Supra-trochlear branch; S.O, Supra-orbital branch; I.T, Infra-trochlear branch; L, Lachrymal branch; N, External nasal branch; Sup.Max, Superior maxillary division; T, Temporal branch; M, Malar branch; I.O, Infra-orbital branch; Inf.Max, Inferior maxillary division; A.T, Auriculo-temporal branch; B, Buccal branch; M, Mental branch; C2, 3, Branches of the second and third cervical nerves; G.O, Great occipital nerve; S.O, Small occipital nerve; G.A, Great auricular nerve; S.C, Superficial cervical nerve; C3, Least occipital nerve; 4, 5, 6, Posterior primary division of 4th, 5th, and 6th cervical nerves.

The **frontal nerve** (n. frontalis), entering the orbital cavity through the sphenoidal fissure, courses forwards above the ocular muscles, and divides at a variable point into two branches—a larger supra-orbital and a smaller supra-trochlear nerve. The **supra-orbital nerve** (n. supra-orbitalis) passes directly forwards, and leaves the orbit through the supra-orbital groove or foramen to reach the forehead. It gives off the following secondary branches: (1) the principal branches (rr. frontales) are distributed to the forehead and scalp, reaching backwards as far as the vertex; (2) small branches supply the upper eyelid; and (3) twigs are distributed to the frontal sinus. On the forehead the supra-orbital nerve communicates with the temporal branches of the facial nerve. The **supra-trochlear nerve** (n. supra-trochlearis) courses obliquely forwards and inwards over the tendon

of the superior oblique muscle to reach the inner side of the supra-orbital arch. Leaving the cavity of the orbit, the nerve is distributed to the skin of the mesial part of the forehead, the root of the nose, and the inner canthus of the eye.

It *communicates* with the infra-trochlear branch of the nasal nerve, either before or after leaving the orbital cavity.

The **nasal nerve** (n. naso-ciliaris) enters the orbit through the sphenoidal fissure, between the heads of the external rectus muscle, and between the two divisions of the third nerve (Fig. 520, p. 677). It crosses the orbital cavity obliquely to reach the anterior ethmoidal foramen, lying in its course below the superior rectus and superior oblique muscles, and above the optic nerve and internal rectus muscle. The nerve is transmitted through the anterior ethmoidal foramen into the cranial cavity, where it lies on the cribriform plate of the ethmoid bone. It enters the nasal cavity through the nasal fissure, and terminates by dividing into internal and external branches. The internal division supplies the mucous membrane over the upper and anterior part of the nasal septum (rr. mediales). The external branch, after supplying collateral offsets to the outer wall of the nose (rr. laterales), finally appears on the face between the nasal bone and lateral cartilage, and supplies branches to the skin of the lower part and tip of the nose.

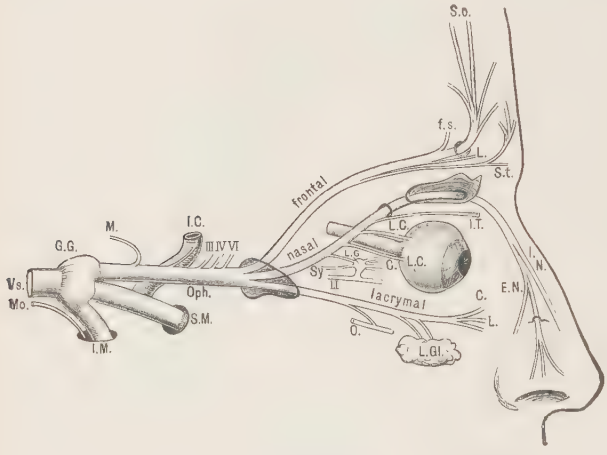

FIG. 524.—SCHEME OF THE DISTRIBUTION OF THE OPHTHALMIC NERVE.

Vs, Trigeminal nerve, afferent root; Mo, Efferent root; G.G, Gasserian ganglion; M, Meningeal branch; I.C, Branch to internal carotid artery; Oph, Ophthalmic nerve; S.M, Superior maxillary nerve; I.M, Inferior maxillary nerve; III, Communication to oculo-motor nerve; IV, To trochlear nerve; VI, To abducent nerve. Frontal nerve; f.s, Branches to frontal sinus; S.o, Supra-orbital nerve; S.t, Supra-trochlear nerve; L, Branches to upper eyelid. Nasal nerve; L.G, Long root to lenticular ganglion; Sy, Root from sympathetic (on carotid artery); III, Short root from motor oculi nerve; C, Short ciliary branches; L.C, Long ciliary nerves; I.T, Infra-trochlear nerve; E.N, External, and I.N, Internal nasal nerves. Lachrymal nerve; O, Orbital branch of superior maxillary nerve; L.Gl, Lachrymal gland; C, Conjunctival branch; L, Branch to eyelids and face.

The **branches** of the nasal nerve may be divided into three sets, arising (*a*) in the orbit, (*b*) in the nose, and (*c*) on the face.

*In the orbit* the branches are given off in three situations—external to, over, and internal to the optic nerve. (*a*) As the nasal nerve lies external to the optic nerve, it gives off the **long root of the ciliary ganglion** (radix longa). (*b*) As it crosses the optic nerve **two long ciliary branches** (nn. ciliaris longi) arise, and pass forwards alongside the optic nerve to the eyeball. (*c*) On the inner side of the optic nerve the **infra-trochlear nerve** (n. infra-trochlearis) arises, a slender branch which courses forward beneath the pulley of the superior oblique muscle to the front of the orbit. It ends on the face by supplying the skin of the root of the nose and the eyelids, and communicates either in the orbit or on the face with the supra-trochlear nerve. On the face it also communicates with infra-orbital branches of the facial nerve.

*In the nose* the **internal nasal branch** supplies the mucous membrane of the fore-part of the nasal septum; the **external nasal branch** supplies the fore-part of the outer wall of the nose.

*On the face* the terminal filaments of the nerve are distributed to the skin of the lower half and tip of the nose. The superficial terminal branch communicates with the infra-orbital branches of the facial nerve (Fig. 523).

The **ciliary** or **lenticular ganglion** (ganglion ciliare) is associated with the nasal branch of the ophthalmic nerve and with the lower division of the third nerve. It is a small reddish ganglion, placed between the external rectus muscle

and the optic nerve, and in front of the ophthalmic artery. Its *roots* are three in number: (1) **sensory** or long (radix longa), derived from the nasal branch of the ophthalmic nerve; (2) **motor** or short (radix brevis), derived from the inferior division of the third nerve; and (3) **sympathetic**, a slender filament from the cavernous plexus on the internal carotid artery, which may exist as an independent root or may be incorporated with the long root from the nasal nerve. The branches from the ganglion are twelve to fifteen **short ciliary nerves** (nn. ciliares breves), which pass to the eyeball in two groups above and below the optic nerve. They supply the coats of the eyeball, including the iris and ciliary muscles. *The circular fibres of the iris* and the *ciliary muscle* are innervated by the third nerve; *the radial fibres of the iris* by the sympathetic.

**Superior Maxillary Division of the Fifth Nerve** (n. maxillaris).—This large nerve courses forwards from its origin in the Gasserian ganglion through the middle fossa of the base of the skull, beneath the dura mater, and in relation to the lower part of the cavernous sinus (Fig. 520, p. 677). Passing through the foramen rotundum in the root of the pterygoid process, it traverses the spheno-maxillary fossa. It enters the orbit as the infra-orbital nerve, through the spheno-maxillary

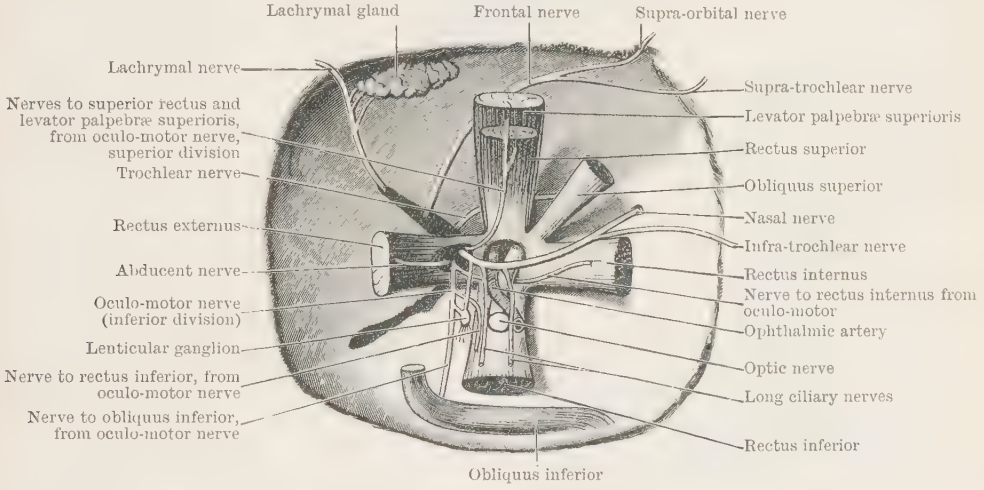

FIG. 525.—SCHEMATIC REPRESENTATION OF THE NERVES WHICH TRAVERSE THE CAVITY OF THE ORBIT.

fissure, and occupying successively the infra-orbital groove and canal, it finally appears on the face through the infra-orbital foramen (Fig. 526).

The branches and communications of this nerve occur (*a*) in the cavity of the cranium, (*b*) in the spheno-maxillary fossa, (*c*) in the infra-orbital canal, and (*d*) on the face.

*In the cavity of the cranium* the nerve gives off a minute **recurrent branch** (n. meningeus) to the dura mater of the middle fossa of the base of the skull.

*In the spheno-maxillary fossa* the nerve gives off—(1) two short thick **spheno-palatine nerves** (nn. spheno-palatini), the short or sensory roots of the spheno-palatine (Meckel's) ganglion. (2) A **posterior dental nerve**, which may be double (nn. alveolares superiores), descends through the pterygo-maxillary fissure to the outer side of the upper jaw, and proceeds forwards along the alveolar arch, in company with the posterior dental artery. It supplies the gum and the upper molar teeth by branches which perforate the bone to reach the alveoli. The nerve forms a fine plexus joined by the middle dental nerve before finally reaching the teeth. (3) A small **orbital branch** (n. zygomaticus) enters the orbital cavity through the spheno-maxillary fissure, and proceeding along the outer wall, communicates with the lachrymal nerve, and passes through the orbital canal in the malar bone, where it divides into malar and temporal branches. The **malar branch** (n. zygomatico-facialis) appears on the face, after traversing the malar bone, and supplies the skin over that bone. It communicates with the malar branches of the facial nerve. The **temporal branch** (n. zygomatico-temporalis) perforates the zygomatic

surface of the malar bone, and is distributed, after piercing the temporal fascia, to the skin over the fore-part of the temple. It communicates with the temporal branches of the facial nerve. It may be very minute, and not pass further than the temporal fascia, between the two layers of which it may form a communication with the facial nerve. (4) The **infra-orbital nerve** (n. infra-orbitalis) is the terminal branch of the superior maxillary nerve, which enters the orbit through the spheno-maxillary fissure and traverses the infra-orbital canal to reach the face.

*In the infra-orbital canal* the infra-orbital nerve supplies one and sometimes two branches to the teeth—the **middle** and **anterior dental nerves** (rr. alveolares superiores medius and anterior). The former may be only a secondary branch of the latter nerve, or they may arise independently from the infra-orbital nerve. However formed, the nerves descend in bony canals in the wall of the antrum of Highmore (to the lining of which branches are given), and reach the alveolar arch, where they form minute plexuses and supply the teeth (joining posteriorly with the branches of the posterior dental nerve). The anterior dental nerve supplies the incisor and canine teeth; the middle dental nerve supplies the premolar teeth.

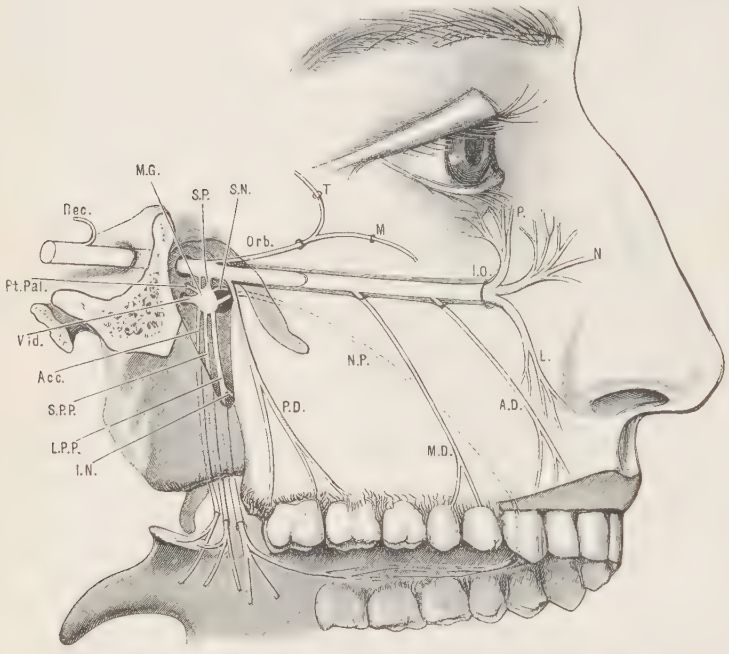

FIG. 526.—SCHEME OF THE COURSE AND DISTRIBUTION OF THE SUPERIOR MAXILLARY NERVE.

Rec, Recurrent branch in the middle fossa of the skull; M.G, Meckel's ganglion in the spheno-maxillary fossa; S.P, Spheno-palatine nerves; S.N, Superior nasal branch; Orb, Orbital nerve; T, Temporal, and M, Malar branches; I.O, Infra-orbital nerve, appearing on the face; P, Palpebral; N, Nasal, and L, Labial branches; A.D, Anterior dental branch; M.D, Middle dental branch; N.P, Naso-palatine nerve; P.D, Posterior dental branch; I.N, Inferior nasal branch; L.P.P, Large posterior palatine nerve; S.P.P, Small posterior palatine nerve; Acc, Accessory posterior palatine nerve; Vid, Vidian nerve; Pt.Pal, Pterygo-palatine branch.

*After emerging on the face* from the infra-orbital foramen, the infra-orbital nerve divides into a number of radiating branches arranged in three sets—(*a*) **palpebral**, for the lower eyelid; (*b*) **nasal**, for the skin of the side of the nose; and (*c*) **labial**, for the cheek and upper lip. These branches form communications with the infra-orbital branches of the facial nerve, and give rise to the *infra-orbital plexus* (Fig. 523, p. 679).

The **spheno-palatine** or **Meckel's ganglion** (g. spheno-palatinum) occupies the upper part of the spheno-maxillary fossa. It is a small reddish-gray ganglion, suspended from the superior maxillary nerve by the two **spheno-palatine branches** which constitute its sensory roots. The **motor** and **sympathetic roots** of the ganglion are derived from the **vidian nerve**. This nerve is formed in the cavity of the skull upon the cartilage filling up the foramen lacerum medium, by the union of the *great superficial petrosal nerve* from the geniculate ganglion of the facial nerve (emerging from the temporal bone through the hiatus Fallopii) with the *great deep petrosal nerve*, a branch of the carotid plexus of the sympathetic on the internal carotid artery. The vidian nerve passes through the vidian canal to the spheno-maxillary fossa, where it ends in Meckel's ganglion.

The **branches from the ganglion** are seven in number. (*a*) The **pterygo-palatine** or **pharyngeal** branch passes backwards through the pterygo-palatine canal to supply the mucous membrane of the roof of the pharynx.

(*b*) The **posterior palatine nerves**, three in number, are directed downwards to the palate through the posterior palatine canals. The **large posterior palatine nerve** emerges on the under surface of the palate through the large posterior palatine canal, and at once separates into numerous branches for the supply of the mucous membrane of the soft and the hard palate. Its anterior filaments communicate with branches of the naso-palatine nerve. The main nerve gives off, as it lies in the posterior palatine canal, a small **inferior nasal nerve** which enters the nasal cavity and supplies the mucous membrane of the lower part of the outer wall of the nose. The **small posterior palatine nerve** descends through the small posterior palatine canal, and, piercing the tuberosity of the palate bone, is distributed to the mucous membrane of the soft palate, uvula, and tonsil. It possibly conveys motor fibres to the levator palati and azygos uvulæ muscles. The **accessory posterior palatine nerves** are one or more small twigs which pass through accessory posterior palatine canals, and supply branches to the mucous membrane of the tonsil, soft palate, and uvula.

(*c*) The branches directed inwards from Meckel's ganglion enter the nasal cavity through the spheno-palatine foramen. They are two in number—the superior nasal and the naso-palatine. The **superior nasal nerve** is a small nerve destined for the mucous membrane of the upper and back part of the outer wall of the nose. The **naso-palatine nerve**, after passing through the spheno-palatine foramen, crosses the roof of the nose, and extends obliquely downwards and forwards along the nasal septum, grooving the vomer in its course, to reach the incisor foramen near the front of the hard palate. The nerves pass through the subordinate mesial foramina (of Scarpa), the left nerve in front of the right. In the incisor foramen the two nerves communicate together. They then turn backwards and supply the mucous membrane of the hard palate. They communicate posteriorly with terminal filaments of the large posterior palatine nerves. In its course through the nasal cavity the naso-palatine nerve furnishes collateral branches to the mucous membrane of the roof and septum of the nose (Fig. 518, p. 676).

(*d*) The **orbital branches**, one or more minute branches, pass upwards to the periosteum of the orbit from Meckel's ganglion.

**Inferior Maxillary Nerve** (n. mandibularis).—The inferior maxillary nerve is formed by the union of two roots: a large **sensory root**, from the Gasserian ganglion, and the small **motor root** of the trigeminal nerve, which is wholly incorporated with this trunk. The two roots pass together beneath the dura mater of the middle fossa of the base of the skull to the foramen ovale, through which they emerge into the pterygoid region. Outside the skull they combine to form a single trunk, which soon separates into anterior and posterior divisions.

At its emergence from the skull the nerve is deeply placed beneath the middle of the zygomatic arch, and is concealed by the ramus of the lower jaw, and by the temporal, masseter, and external pterygoid muscles.

The branches of the inferior maxillary nerve may be divided into two series—(1) those derived from the undivided nerve, and (2) those derived from the terminal divisions of the nerve.

The branches of the undivided nerve are two in number. (*a*) A small **recurrent branch** (n. spinosus) arises just outside the skull, and accompanying the middle meningeal artery through the foramen spinosum, supplies the dura mater. (*b*) In the pterygoid region a small branch arises for the supply of the **internal pterygoid muscle**. This nerve forms a connexion with the otic ganglion.

The terminal divisions of the nerve are a small anterior and a large posterior trunk.

The small **anterior trunk** passes downwards and forwards beneath the external pterygoid muscle, and separates into the following branches:—(1) A branch for the external pterygoid muscle (n. pterygoideus externus), which supplies it on its deep surface; (2) a branch to the masseter muscle (n. masseterieus), which passes over the upper border of the external pterygoid and through the sigmoid notch of the lower jaw; (3) and (4) two branches to the temporal muscle (nn. temporales pro-

fundi, anterior et posterior), which also ascend above the external pterygoid muscle; and (5) the **buccal nerve** (n. buccinatorius), which passes obliquely forwards between the two heads of the external pterygoid to reach the buccinator muscle. This nerve is sensory, and its fibres are in part distributed to the skin of the cheek (communicating with buccal branches of the facial nerve); they are also in part distributed to the mucous membrane of the inside of the mouth, to reach which they pierce the fibres of the buccinator muscle. The buccal nerve usually supplies a third branch to the temporal muscle, after emerging between the two heads of the external pterygoid muscle (Fig. 523, p. 679).

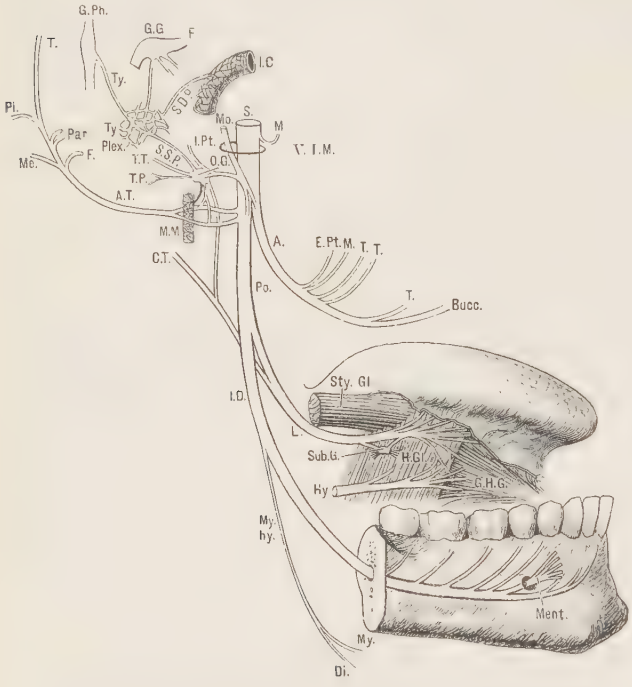

FIG. 527.—SCHEME OF THE DISTRIBUTION OF THE INFERIOR MAXILLARY NERVE.

V.I.M, Inferior maxillary nerve; S, Afferent, and Mo, Efferent roots; M, Meningeal branch; O.G, Otic ganglion; I.Pt, Nerve to internal pterygoid; S.S.P, Small superficial petrosal nerve; T.T, Nerves to tensor tympani, and T.P, Tensor palati; Ty.Plex, Tympanic plexus; I.C, Internal carotid artery; S.D.P, Small deep petrosal nerve; G.G, Geniculate ganglion; F, Facial nerve; Ty, Tympanic branch; G.Ph, Glosso-pharyngeal nerve; M.M, Middle meningeal artery; A.T, Auriculo-temporal nerve; F, Communication with facial nerve; Par, Nerve to parotid gland; Me, Branch to meatus of ear; Pi, Branch to pinna; T, Temporal branch; A, Anterior division of inferior maxillary nerve; E.Pt, Nerves to external pterygoid; M, Masseter; T.T.T, Temporal, and Bucc, Buccinator muscles; Po, Posterior division of inferior maxillary nerve; L, Lingual nerve; C.T, Chorda tympani nerve; Sub.G, Sub-maxillary ganglion; Hy, Hypoglossal nerve; I.D, Inferior dental nerve; My.hy, Mylohyoid nerve; My, Nerve to mylohyoid; Di, Nerve to digastric (anterior belly); Ment., Mental Branch; Sty.Gl, Stylo-glossus; H.Gl, Hyoglossus; G.H.G, Genio-hyoglossus muscles.

The large **posterior trunk** extends downwards a short way beneath the external pterygoid muscle. After giving off by two roots the auriculo-temporal nerve, it ends by dividing into two, the lingual and the inferior dental nerves.

The **auriculo-temporal nerve** (n. auriculo-temporalis) is formed by the union of two roots which embrace the middle meningeal artery. The nerve passes backwards beneath the external pterygoid muscle and between the internal lateral ligament and the neck of the lower jaw. Entering the substance of the parotid gland, it is directed upwards to the temple over the zygoma in company with the temporal artery. It is finally distributed as a cutaneous nerve of the temple and scalp, and reaches almost to the vertex of the skull.

The auriculo-temporal nerve gives off the following branches:—(1) A small branch to the temporo-maxillary articulation. (2) Branches to the parotid gland. (3) A twig for the supply of the skin of the external auditory meatus (and membrana tympani). (4) Branches to the upper half of the pinna on its outer aspect. (5) Terminal branches to the skin of the temple and scalp.

It has the following **communications** with other nerves:—(1) Important communications are effected by the roots of the nerve, which are separately joined by small branches from the otic ganglion. (2) The parotid branches of the nerve are connected with branches of the facial nerve in the substance of the gland. (3) The temporal branch of the nerve is in communication superficially with the temporal branches of the facial nerve.

The **lingual nerve** (n. lingualis) is the smaller of the two terminal branches

of the posterior division of the inferior maxillary nerve. It proceeds downwards in front of the inferior dental nerve, beneath the external pterygoid muscle, to its lower border. After passing between the internal pterygoid muscle, and the ramus of the lower jaw, it crosses beneath the mucous membrane of the floor of the mouth in the interval between the mylohyoid and hyoglossus muscles and beneath the duct of the submaxillary gland. It sweeps forwards and inwards to the side of the tongue, to the mucous membrane over the anterior two-thirds of which it is distributed.

Two nerves communicate with the lingual nerve in its course to the tongue :—(1) The **chorda tympani branch** of the facial nerve joins it beneath the external pterygoid muscle, and is incorporated with it in its distribution to the tongue. (2) The **hypoglossal nerve** forms larger or smaller loops of communication with the lingual nerve as they course forwards together over the hyoglossus muscle.

Besides supplying the aforesaid branches to the mucous membrane over the sides and dorsum of the tongue in its anterior two-thirds, the lingual nerve supplies the mucous membrane of the outer wall and floor of the mouth. It also assists, along with the chorda tympani nerve, in forming the roots of the submaxillary ganglion.

The **submaxillary ganglion** (ganglion submaxillare) is a minute reddish ganglion placed on the hyoglossus muscle, between the lingual nerve and the duct of the submaxillary gland. It is suspended from the former by two trunks, consisting for the most part of fibres of the lingual and chorda tympani nerves which at this point become separated from the lingual nerve and incorporated with the ganglion. The **roots** of the ganglion are—(1) an afferent root, derived from the lingual nerve; (2) an efferent root, derived from the chorda tympani; and (3) a sympathetic root, from the sympathetic plexus upon the facial artery.

The **branches from the ganglion** are distributed to the submaxillary gland and Wharton's duct, and by fibres which become reunited with the trunk of the lingual nerve, to the sublingual gland.

The **inferior dental nerve** (n. alveolaris inferior) is larger than the lingual nerve. It passes from beneath the lower border of the external pterygoid muscle to reach the interval between the ramus and internal lateral ligament of the lower jaw. Entering the inferior dental canal through the inferior dental foramen, it traverses the substance of the ramus and body of the lower jaw, distributing branches in its course to the teeth. A fine plexus is formed by the dental branches before they finally supply the teeth.

**Branches and Communications.**—(1) The **mylohyoid nerve** is a small branch arising just before the inferior dental nerve passes through the inferior dental foramen. Grooving the ramus of the jaw in its course, it descends into the submaxillary triangle on the superficial aspect of the mylohyoid muscle. Concealed in this situation by the submaxillary gland and the facial artery, it is distributed to the mylohyoid and anterior belly of the digastric muscles. (2) The **mental branch** of the inferior dental nerve is a trunk of considerable size arising from the main nerve in the inferior dental canal. It emerges from the lower jaw through the mental foramen, and is distributed by many branches to the chin and lower lip. It communicates beneath the facial muscles with the supra-mandibular branches of the facial nerve (Fig. 523, p. 679). (3) The **incisor branch** is the terminal part of the inferior dental nerve remaining after the origin of the mental branch. It supplies the incisor and canine teeth.

The **otic ganglion** (g. oticum) is situated beneath the inferior maxillary nerve just below the foramen ovale. Like the other ganglia described above, it possesses three roots :—(1) A *motor root*, derived from the nerve to the internal pterygoid muscle; (2) a *sensory root*, formed by the *small superficial petrosal nerve* from the tympanic plexus (through which communications are effected with the tympanic branch of the glosso-pharyngeal nerve, and a branch from the geniculate ganglion of the facial nerve); (3) a *sympathetic root*, from the plexus on the middle meningeal artery (Fig. 527).

Five branches arise from the ganglion—three communicating and two motor branches. The three **communicating nerves** are fine branches which join respectively

the vidian nerve, the roots of the auriculo-temporal, and the chorda tympani nerve. The two **motor nerves** supply the tensor tympani and tensor palati muscles.

**Summary.**—The trigeminal, the largest and most complex of the cranial nerves, is (1) the chief sensory nerve for the face, the anterior half of the scalp, the orbit and eyeball, the nose and nasal cavity, the lips, teeth, mouth, and two-thirds of the tongue; (2) the motor fibres of the nerve supply the muscles of mastication, the mylohyoid and anterior belly of the digastric, possibly the levator palati and azygos uvulæ (through Meckel's ganglion), and the tensor tympani and tensor palati muscles (through the otic ganglion); (3) through the ganglia placed on the three divisions of the nerve, not only are important organs, areas, and muscles innervated, but communications are also effected with the sympathetic system, with the third nerve (lenticular ganglion), facial nerve (spheno-palatine and otic ganglia), and glosso-pharyngeal nerve (otic ganglion).

In its distribution to the skin of the face the branches of the fifth nerve present two striking peculiarities:—(1) While the branches to the skin reach the surface at many points and in diverse ways, the three main divisions are severally, by their branches, responsible for the supply of three clearly demarcated cutaneous areas (Fig. 523, p. 679). (2) By numerous communications with the facial nerve, sensory fibres are given to the muscles of expression supplied by the facial nerve.

### The Sixth or Abducent Nerve.

The abducent nerve (n. abducens) issues from the brain at the lower border of the pons Varolii, just above the pyramid of the medulla oblongata (for deep origin, see p. 524). It is directed forwards, and pierces the dura mater in the posterior fossa of the base of the skull alongside the dorsum sellæ (Fig. 522, p. 678). It then occupies the inner wall of the cavernous sinus and is placed on the outer side of the internal carotid artery. It passes through the sphenoidal fissure below the third and nasal nerves and between the two heads of the external rectus muscle (Fig. 520, p. 677). In the cavity of the orbit it supplies the external rectus muscle on its inner (ocular) surface.

**Communications.**—In the wall of the cavernous sinus the sixth nerve receives two communicating filaments:—(1) From the carotid plexus of the sympathetic, and (2) from the ophthalmic division of the trigeminal nerve.

### The Seventh or Facial Nerve.

The facial nerve (n. facialis) emerges from the brain at the posterior border of the pons Varolii, below the trigeminal nerve and internal to the auditory nerve (for deep origin, see p. 522). Between it and the latter nerve is the minute **pars intermedia** of Wrisberg (Fig. 517, p. 675). The nerve passes outwards through the internal auditory meatus, courses through the aqueduct of Fallopius in the petrous portion of the temporal bone, emerges in the base of the skull by the stylo-mastoid foramen, and passes forwards through the parotid gland to supply the muscles of the face. *In the internal auditory meatus* the nerve is placed upon the auditory nerve, the *pars intermedia* intervening. *In the aqueduct of Fallopius* the nerve first passes backwards on the inner side of the tympanum, and then downwards behind the tympanum, in the inner wall of the tympanic antrum. *In the parotid gland* the nerve crosses superficially the external carotid artery and the temporo-maxillary vein. *On the face* its branches radiate from the anterior border of the parotid gland and enter the deep surface of the facial muscles.

**Branches and Communications.**—(i.) *In the internal auditory meatus* the *pars intermedia* (n. intermedius), lying between the facial and auditory, sends communicating branches to both nerves. The branch to the auditory nerve probably separates from it again to join the geniculate ganglion of the facial nerve.

(ii.) *In the aqueduct of Fallopius* the **geniculate ganglion** (g. geniculi) is formed at the point where the facial nerve bends backwards (geniculum n. facialis). It is an oval swelling on the nerve, and is joined by a branch from the upper (vestibular) trunk of the auditory nerve, by which it probably receives fibres of the *pars intermedia*. From the ganglion three small nerves arise:—(1) The **large superficial petrosal nerve** passes forwards through the hiatus Fallopii to the middle fossa of the base of the skull. On the upper surface of the foramen lacerum medium it is

joined by the **great deep petrosal nerve** from the sympathetic plexus on the internal carotid artery to form the **vidian nerve**, which, after traversing the vidian canal, ends in Meckel's ganglion. (2) A minute nerve pierces the temporal bone and joins the tympanic branch of the glosso-pharyngeal in the substance of the bone. By their union the **small superficial petrosal nerve** is formed, which pierces the temporal bone and ends in the otic ganglion. (3) The **external superficial petrosal nerve** is a minute inconstant branch which joins the sympathetic plexus on the middle meningeal artery.

In the course of the facial nerve in the lower part of the aqueduct of Fallopius, behind the tympanum, three branches arise—(1) The small nerve to the **stapedius muscle**, which passes forwards to the tympanum. (2) The **chorda tympani nerve** (probably associated with the *pars intermedia*), which enters the tympanic cavity through the *iter chordæ posterius*, passes over the membrana tympani and the handle of the malleus, and leaves the cavity through the *iter chordæ anterius* to reach the pterygoid region. Beneath the external pterygoid muscle it becomes incorporated with the lingual branch of the inferior maxillary nerve, and in its further course is inseparable from that nerve. It supplies a root to the sub-maxillary ganglion, and is finally distributed (probably as a nerve of taste) to the side and dorsum of the tongue in its anterior two-thirds. The chorda tympani nerve receives beneath the external pterygoid muscle a fine communication from the otic ganglion. (3) Before it leaves the aqueduct of Fallopius a fine **communicating branch** arises from the facial nerve to join the auricular branch of the pneumogastric nerve.

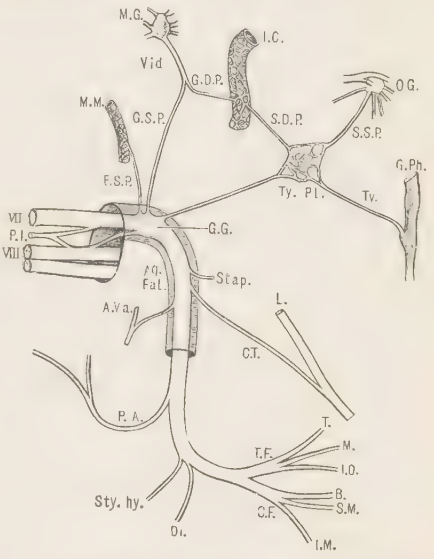

FIG. 528.—THE FACIAL NERVE WITH ITS BRANCHES AND COMMUNICATIONS IN THE AQUEDUCT OF FALLOPIUS.

VII, Facial nerve; P.I, Pars intermedia; VIII, Auditory nerve; Aq.Fal, Aqueduct of Fallopius; G.G, Geniculate ganglion; E.S.P, External superficial petrosal nerve; M.M, Middle meningeal artery; G.S.P, Great superficial petrosal nerve; G.P.D, Great deep petrosal nerve; I.C, Internal carotid artery; Vid, Vidian nerve; M.G, Meckel's ganglion; Ty. Pl, Tympanic plexus; S.D.P, Small deep petrosal nerve; G.Ph, Glosso-pharyngeal nerve; Ty, Tympanic branch; S.S.P, Small superficial petrosal nerve; O.G, Otic ganglion; Stap, Nerve to stapedius; C.T, Chorda tympani nerve; L, Lingual nerve; A.Va, Communication with auricular branch of vagus; P.A, Posterior auricular nerve; Sty.hy, Nerve to stylo-hyoid; Di, Nerve to digastric (posterior belly); T.F, Temporo-facial division; C.F, Cervico-facial division; T. Temporal; M, Malar; I.O, Infra-orbital; B. Buccal; S.M, Supra-mandibular, and I.M, Infra-mandibular branches.

(iii.) *In the neck* the facial nerve gives off three muscular branches: (1) and (2) small branches supply the stylo-hyoid and the posterior belly of the digastric, the latter nerve sometimes communicating with the glosso-pharyngeal. (3) The **posterior auricular nerve** bends backwards and upwards over the anterior border of the mastoid process along with the posterior auricular artery. It divides into two branches—an *auricular branch* for the retrahens aurem and the intrinsic muscles of the pinna, and an *occipital branch* for the posterior belly of the occipito-frontalis muscle. The posterior auricular nerve communicates with the great auricular, small occipital, and auricular branch of the pneumogastric nerves in its course.

(iv.) *In the parotid gland* the facial nerve spreads out in an irregular series of branches (**pes anserinus**), indefinitely divided into a temporo-facial and a cervico-facial division. Communications occur in the substance of the gland between the main trunks and the great auricular and auriculo-temporal nerves.

The **temporo-facial division** gives off three series of subordinate branches which radiate forwards and upwards from the parotid gland.

1. The **temporal branches** are of large size, and, sweeping out of the parotid gland over the zygomatic arch, are distributed to the orbicularis palpebrarum, frontalis, corrugator supercilii, attrahens, and attollens aurem. The temporal branches com-

municate in their course with the auriculo-temporal, temporal (of the superior maxillary), lachrymal, and supra-orbital branches of the trigeminal nerve.

2. The **malar branches** are small, and sometimes are inseparable from the temporal or infra-orbital nerves. Extending forwards across the malar bone, they supply the orbicularis palpebrarum and zygomatic muscles, and communicate with the malar branch of the superior maxillary nerve.

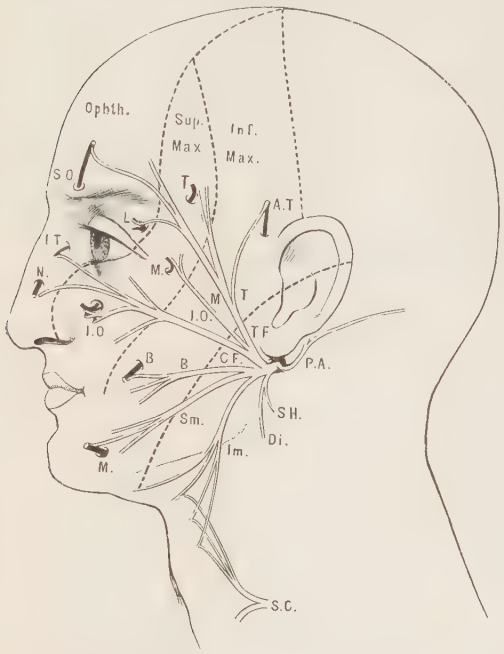

FIG. 529. — DISTRIBUTION OF FACIAL NERVE OUTSIDE THE SKULL, AND COMMUNICATIONS WITH TRIGEMINAL NERVE ON THE FACE.

**Facial nerve.** — P.A, Posterior auricular nerve; S.H, Nerve to stylo-hyoid; Di, Nerve to digastric (posterior belly); T.F, Temporo-facial division; T, Temporal; M, Malar; I.O, Infra-orbital branches; C.F, Cervico-facial division; B, Buccal; Sm, Supra-mandibular; Im, Infra-mandibular branches.

**Trigeminal nerve.** — Ophth, Ophthalmic division; S.O, Supra-orbital; I.T, Infra-trochlear; N, External nasal; L, Lachrymal branches. Sup. Max, Superior maxillary division; T, Temporal; M, Malar; I.O, Infra-orbital branches. Inf. Max, Inferior maxillary division; A.T, Auriculo-temporal; B, Buccal; M, Mental branches; S.C, Superficial cervical nerve.

3. The **infra-orbital branches** are of considerable size. Passing forwards over the masseter muscle in company with Stenson's duct, they supply the orbicularis palpebrarum, the zygomatici, buccinator, and the muscles of the nose and upper lip. The **infra-orbital plexus** is formed by the union of these nerves with the infra-orbital branch of the superior maxillary nerve below the lower eyelid. Smaller communications occur with the infra-trochlear and nasal nerves on the side of the nose.

The **cervico-facial division** of the facial nerve also supplies three series of secondary branches.

1. The **buccal branch** (or branches) extends forwards to the angle of the mouth to supply the muscles converging to the mouth, including the buccinator. It communicates with the buccal branch of the inferior maxillary nerve in front of the anterior border of the masseter muscle.

2. The **supra-mandibular branch** passes along the lower jaw to the interval between the lower lip and chin, and supplies the depressor anguli oris, depressor labii inferioris, and orbicularis oris. It communicates with the mental branch of the inferior dental nerve.

3. The **infra-mandibular branch** emerges from the parotid gland near its lower end, and sweeps forwards below the angle of the jaw to the front of the neck. It supplies the platysma myoides, and forms loops of communication with the superficial cervical nerve from the cervical plexus.

## THE EIGHTH OR AUDITORY NERVE.

The auditory nerve (n. acusticus) arises from the brain by two roots, mesial and lateral. The **mesial root** (radix vestibularis) emerges between the olive and the restiform body. The **lateral root** (radix cochlearis), continuous through the cochlear nucleus with the striæ acusticæ of the fourth ventricle, winds round the outer side of the restiform body (for deep connexions, see p. 519). The two roots become incorporated to form the trunk of the nerve, which is attached to the brain on the outer side of the facial nerve and pars intermedia at the posterior border of the pons Varolii (Fig. 517, p. 675).

The nerve extends outwards through the internal auditory meatus, lying beneath the facial nerve and pars intermedia (Fig. 522, p. 678). In the meatus its two component parts separate from one another, forming a superior or vestibular trunk continuous with the mesial root, and an inferior or cochlear trunk continuous with

the lateral root. These trunks again subdivide, and piercing the lamina cribrosa, supply the several parts of the labyrinth.

The **superior** or **vestibular trunk** (n. vestibuli) in the internal auditory meatus usually receives fibres from the *pars intermedia*, and gives off a communicating branch

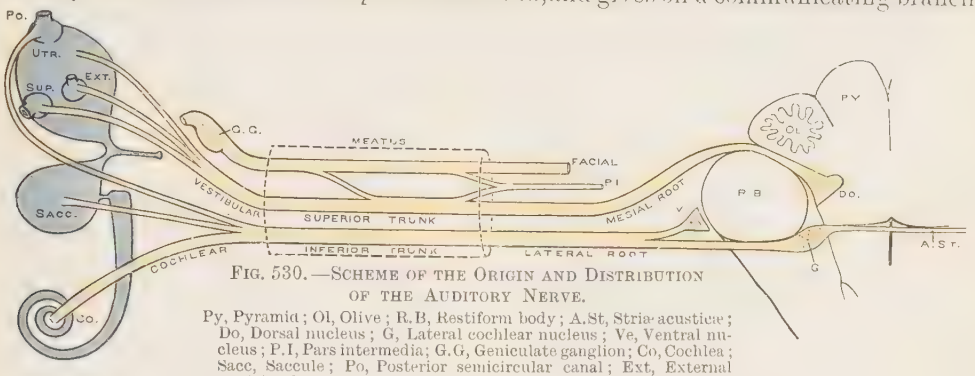

FIG. 530.—SCHEME OF THE ORIGIN AND DISTRIBUTION OF THE AUDITORY NERVE.

Py, Pyramid; Ol, Olive; R.B, Restiform body; A.St, Striæ acusticæ; Do, Dorsal nucleus; G, Lateral cochlear nucleus; Ve, Ventral nucleus; P.I, Pars intermedia; G.G, Geniculate ganglion; Co, Cochlea; Sacc, Saccule; Po, Posterior semicircular canal; Ext, External semicircular canal; Sup, Superior semicircular canal; Utr, Utricle.

to the geniculate ganglion of the facial nerve. It then separates into three terminal branches which pierce the lamina cribrosa, and supply (1) the macula acustica of the **utricle** and the ampullæ of (2) the **superior** and (3) **external semicircular canals.**

The **inferior** or **cochlear trunk** (n. cochleæ) gives off branches (1) to the macula acustica of the **saccule**, (2) to the ampulla of the **posterior semicircular canal,** and (3) is continued through the lamina cribrosa to the labyrinth as the **cochlear nerve**, which is distributed through the modiolus and osseous spiral lamina to the organ of Corti in the cochlea.

Both the vestibular and cochlear nerves contain among their fibres collections of nerve cells, forming in each nerve a distinct ganglion—the **vestibular ganglion** (g. vestibulare) on the vestibular trunk, and the **spiral ganglion of the cochlea** (g. spirale) on the cochlear trunk.

## THE NINTH OR GLOSSO-PHARYNGEAL NERVE.

The glosso-pharyngeal nerve (n. glosso-pharyngeus) (Fig. 517, p. 675) arises from the brain by five or six fine radicles which emerge from the medulla oblongata between the olive and the restiform body, close to the facial nerve above, and in series with the roots of the pneumogastric nerve below (for deep connexions, see p. 517). The rootlets combine to form a nerve which extends outwards to the jugular foramen, through which it passes, along with the pneumogastric and spinal accessory nerves, but enveloped in a separate sheath of dura mater (Fig. 522, p. 678). Reaching the neck, the nerve arches downwards and forwards to the interval between the hyoid bone and the lower jaw. It lies at first between the internal carotid artery and the internal jugular vein, and then between the internal and external carotid arteries, in its course to the side of the pharynx. It sweeps round the stylo-pharyngeus muscle and the stylo-hyoid ligament, and disappears beneath the hyoglossus muscle, to reach its termination in the tongue.

The branches of the nerve may be classified in three series according to their origin—(i.) in the jugular foramen; (ii.) in the neck; (iii.) in relation to the tongue.

*In the jugular foramen* there are two enlargements upon the trunk of the nerve —the jugular and petrous ganglia. The **jugular ganglion** (g. superius) is small, does not implicate the whole width of the nerve, and may be fused with the petrous ganglion, or even absent altogether. No branches arise from it.

The **petrous ganglion** (g. petrosum) is distinct and constant. It is placed upon the nerve at the lower part of its course through the jugular foramen.

**Branches and Communications of the Petrous Ganglion.**—The **tympanic branch** (n. tympanicus, Jacobson's nerve) is the most important offset from this ganglion. It passes through a small canal in the bridge of bone between the jugular foramen and the carotid canal to reach the cavity of the tympanum, where it breaks up into branches, to form, along with branches from the carotid plexus of the sympathetic on the internal carotid artery (**small deep petrosal nerve**), the **tympanic plexus** for the supply of the mucous lining of the tympanum, mastoid cells, and Eustachian tube (Fig. 528,

p. 687). The fibres of the tympanic branch of the glosso-pharyngeal nerve become reunited to form, by their union with a small nerve from the geniculate ganglion of the facial nerve, the **small superficial petrosal nerve** in the substance of the temporal bone. This passes forwards through the temporal bone, and eventually joins the otic ganglion.

Besides forming the tympanic branch, the petrous ganglion of the glosso-pharyngeal nerve communicates with three other nerves—(1) with the superior cervical ganglion of the sympathetic; (2) with the auricular branch of the pneumogastric; and (3) sometimes with the ganglion of the root of the pneumogastric.

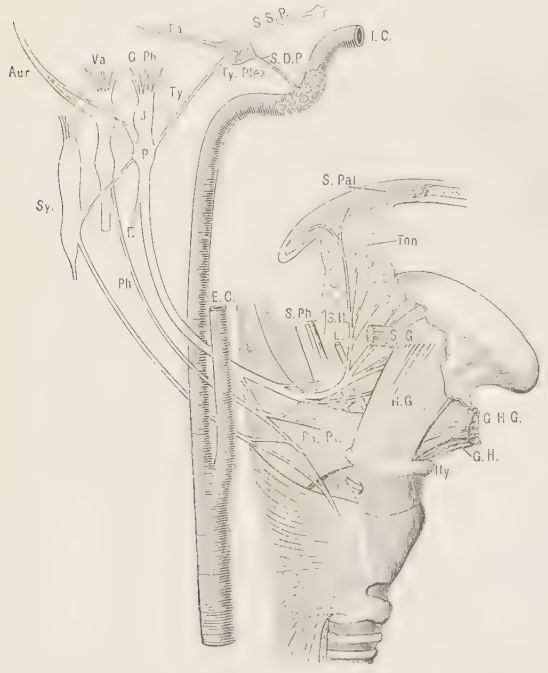

Fig. 531.—Scheme of the Distribution of the Glosso-pharyngeal Nerve.

G.Ph, Glosso-pharyngeal nerve; J, Jugular, and P, Petrous ganglia; Ty, Tympanic branch (Jacobson's nerve); Ty.Plex., Tympanic plexus; Fa, Root from geniculate ganglion of facial nerve; S.S.P, Small superficial petrosal nerve to the otic ganglion; S.D.P, Small deep petrosal nerve; I.C, Internal carotid artery; Va, Pneumogastric nerve; Aur., Auricular branch (Arnold's nerve); Sy., Superior cervical sympathetic ganglion; F, Communicating branch to facial nerve; Ph, Pharyngeal branch of vagus; E.C, External carotid artery; Ph.Pl, Pharyngeal plexus; S.Ph, Stylo-pharyngeus muscle; S.H.L, Stylo-hyoid ligament; H.G, Hyo-glossus; S.G, Stylo-glossus; Ton, Tonsil; S. Pal., Soft palate; G.H.G, Genio-hyoglossus; G.H, Genio-hyoid; Hy, Hyoid bone.

*In the neck* the glosso-pharyngeal nerve gives off two branches. (1) As it crosses over the **stylo-pharyngeus muscle** it supplies the nerve to that muscle, which sends fibres through it to reach the mucous membrane of the pharynx. (2) The **pharyngeal branches** of the nerve supply the mucous membrane of the pharynx directly after piercing the superior constrictor muscle, and indirectly after joining, along with the pharyngeal offsets from the pneumogastric and the superior cervical ganglion of the sympathetic, in the formation of the **pharyngeal plexus**.

The **terminal branches** of the nerve supply the mucous membrane of the tongue and adjacent parts. A **tonsillitic branch** forms a plexus (circulus tonsillaris) to supply the mucous membrane covering the tonsil, the adjacent part of the soft palate, and the pillars of the fauces. **Lingual branches** supply the mucous membrane of the dorsal third and lateral half of the tongue, extending backwards to the glosso-epiglottidean folds and the front of the epiglottis.

## The Tenth or Pneumogastric Nerve.

The pneumogastric or vagus nerve (n. vagus) arises from the brain by numerous radicles attached to the front of the restiform body of the medulla oblongata, in series with the glosso-pharyngeal nerve above and the spinal accessory nerve below it (for deep connexions, see p. 517). Uniting to form a single trunk, the roots of the nerve pass outwards to the jugular foramen, through which they emerge into the neck.

*In the jugular foramen* the nerve occupies the same sheath of dura mater as the spinal accessory nerve, and is placed behind the glosso-pharyngeal nerve. Two ganglia are present on the trunk in this situation. The higher and smaller is the **ganglion of the root** (g. jugulare); the lower and larger is the **ganglion of the trunk** of the nerve (g. nodosum).

*In the neck* the pneumogastric nerve pursues a vertical course in front of the spinal column. It occupies the carotid sheath, lying between and behind the internal and common carotid arteries and the internal jugular vein. It enters the

thorax behind the large veins: *on the right side,* after crossing over the subclavian artery; *on the left side,* in the interval between the left common carotid and subclavian arteries.

*In the thorax* the nerves occupy the superior and posterior mediastinal spaces, and their relations are different on the two sides. (*a*) *In the superior mediastinum* the *right nerve* continues its course alongside the innominate artery and the trachea, and behind the right innominate vein and superior vena cava, to the back of the root of the lung. The *left nerve* courses downwards between the left common carotid and subclavian arteries, and behind the left innominate vein and the phrenic nerve. It passes over the aortic arch, and then proceeds to the back of the root of the left lung. (*b*) *In the posterior mediastinum* the pneumogastric nerves are concerned in the formation of two great plexuses—the pulmonary and the œsophageal. Behind the root of each lung the nerve breaks up to form the large **posterior pulmonary plexus**, from the lower end of which two nerves emerge on each side. These nerves on the right side pass obliquely over the vena azygos major; on the left side they cross the thoracic aorta. Both series reach the œsophagus, and divide into small anastomosing branches which form the **œsophageal plexus**. At the œsophageal opening of the diaphragm the two nerves become separated from the plexus, and entering the abdomen—the left nerve in front of the œsophagus, the right nerve behind it—they terminate by supplying the stomach and other abdominal organs.

The communications and branches of the pneumogastric nerve may be described as (i.) ganglionic, (ii.) cervical, (iii.) thoracic, and (iv.) abdominal (Fig. 532).

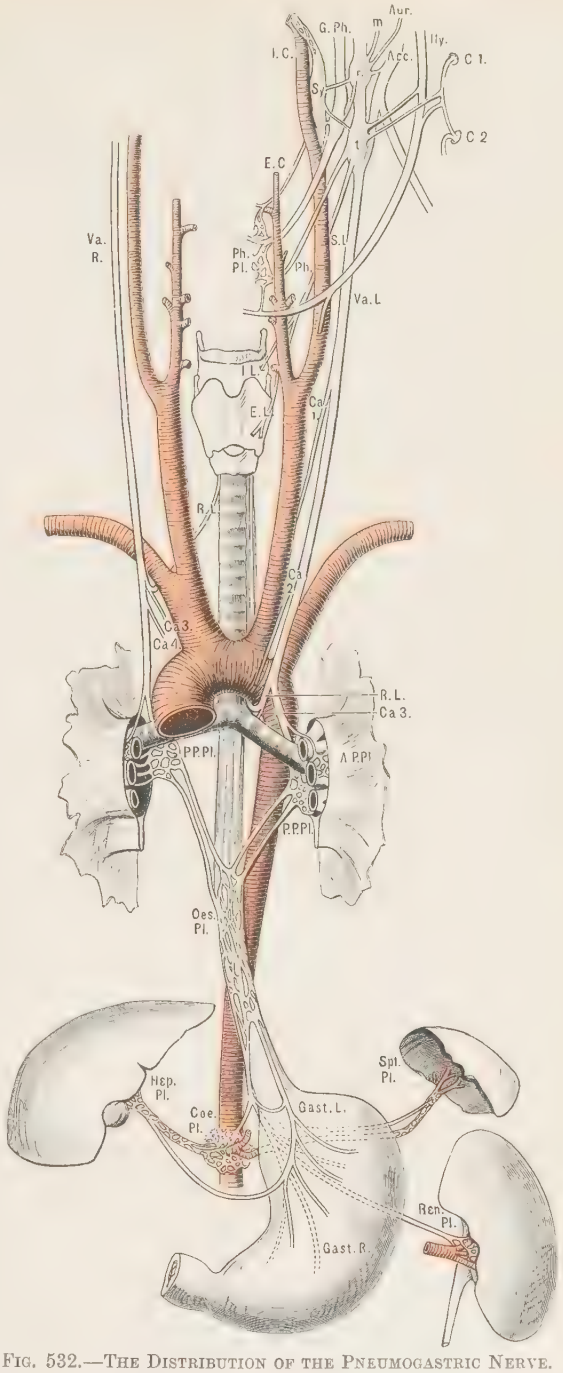

FIG. 532.—THE DISTRIBUTION OF THE PNEUMOGASTRIC NERVE.

Var.R, Va.L, Right and left vagi; r, Ganglion of the root and connexions with Sy, Sympathetic, superior cervical ganglion; G.Ph, Glosso-pharyngeal; Acc, Spinal accessory nerve; m, Meningeal branch; Aur, Auricular branch; t, Ganglion of the trunk and connexions with Hy, Hypoglossal nerve; C1, C2, Loop between the first two cervical nerves; Sy, Sympathetic; Acc, Spinal accessory nerve; Ph, Pharyngeal branch; Ph.Pl, Pharyngeal plexus; S.L, Superior laryngeal nerve; I.L, Internal laryngeal branch; E.L, External laryngeal branch; I.C, Internal, and E.C, External carotid arteries; Ca1, Superior cervical cardiac branch; Ca2, Inferior cervical cardiac branch; R.L, Recurrent laryngeal nerve; Ca3, Cardiac branches from recurrent laryngeal nerves; Ca4, Thoracic cardiac branch (right vagus); A.P.Pl, Anterior, and P.P.Pl, Posterior pulmonary plexuses; Oes.Pl, Œsophageal plexus; Gast.R, and Gast.L, Gastric branches of vagus (right and left); Coe.Pl, Cœliac plexus; Hep.Pl, Hepatic plexus; Spl.Pl, Splenic plexus; Ren.Pl, Renal plexus.

The **ganglion of the root** (g. jugulare) is small and spherical. It occupies the jugular foramen, and gives off two branches—meningeal and auricular.

The **meningeal branch** passes backwards to supply the dura mater of the posterior fossa of the base of the skull.

The **auricular branch** (Arnold's nerve) ascends to the ear in a fissure between the jugular and stylo-mastoid foramina. It receives near its origin a twig from the tympanic branch of the glosso-pharyngeal nerve, and usually communicates with the facial nerve by a branch arising from the latter in the aqueduct of Fallopius. The nerve is distributed to the back of the pinna and the external auditory meatus, and communicates superficially with the posterior auricular nerve.

**Communications.**—Besides supplying the meningeal and auricular branches, the ganglion of the root of the pneumogastric nerve receives communications from (1) the superior cervical ganglion of the sympathetic; (2) the spinal accessory nerve; and (3) the petrous ganglion of the glosso-pharyngeal nerve (sometimes).

The **ganglion of the trunk** of the nerve (g. nodosum), placed immediately below the preceding, is large and fusiform. Like the previous ganglion, it supplies two branches—the pharyngeal and superior laryngeal nerves.

The **pharyngeal branch** receives its fibres (through the ganglion) from the spinal accessory nerve. It passes obliquely downwards and inwards to the pharynx between the internal and external carotid arteries, and combines with the pharyngeal nerves from the glosso-pharyngeal and superior cervical ganglion of the sympathetic to form the **pharyngeal plexus**. From this plexus the muscles of the pharynx and soft palate (except the stylo-pharyngeus and tensor palati) are supplied. The **lingual branch** is a small nerve which separates itself from the plexus and joins the hypoglossal nerve in the anterior triangle of the neck.

The **superior laryngeal nerve** (n. laryngeus superior) passes obliquely downwards and inwards, behind the external and internal carotid arteries, towards the thyroid cartilage. It divides in its course into two unequal parts—a larger internal and a smaller external laryngeal nerve.

The **internal laryngeal nerve** (ramus internus) passes inwards into the larynx between the middle and inferior constrictor muscles of the pharynx and through the thyro-hyoid membrane. It supplies the mucous membrane of the larynx, reaching upwards to the epiglottis and base of the tongue, and forms communications beneath the ala of the thyroid cartilage with the branches of the inferior laryngeal nerve.

The **external laryngeal nerve** (ramus externus) passes downwards upon the inferior constrictor muscle of the pharynx. It supplies branches to that muscle, and ends in the crico-thyroid muscle.

**Communications.**—Besides supplying these pharyngeal and laryngeal nerves, the ganglion of the trunk of the pneumogastric has the following communications with other nerves: (1) with the superior cervical ganglion of the sympathetic; (2) with the hypoglossal; (3) with the loop between the first and second cervical nerves; and (4) with the accessory part of the spinal accessory nerve. This part of the nerve applies itself to the ganglion, and thereby supplies to the vagus nerve the inhibitory fibres for the heart, as well as the motor fibres for the pharynx, œsophagus, stomach and intestines, larynx and respiratory organs.

**Branches of the Pneumogastric in the Neck.**—In the neck the pneumogastric nerve supplies cardiac branches and (on the right side) the inferior or recurrent laryngeal nerve (Fig. 532).

The **cardiac branches** are **superior** and **inferior**. *On the right side* both cardiac branches pass downwards into the thorax behind the subclavian artery, and proceed alongside the trachea to join the deep cardiac plexus. *On the left side* the two nerves separate on reaching the thorax. The *superior nerve* passes deeply alongside the trachea to join the deep cardiac plexus. The *inferior nerve* accompanies the pneumogastric nerve over the aortic arch, along with the superior cervical cardiac branch of the sympathetic, to end in the superficial cardiac plexus.

The **right inferior laryngeal nerve** arises at the root of the neck, as the pneumogastric nerve crosses over the first part of the subclavian artery. It hooks round the artery, and passes obliquely upwards and inwards behind the subclavian,

the common carotid, and the inferior thyroid artery and the thyroid body. It finally disappears beneath the lower border of the inferior constrictor muscle, and ends in supplying the muscles of the larynx. In its course it gives off the following branches:—

(1) **Cardiac branches** arise as the nerve winds round the subclavian artery, and course downwards alongside the trachea to end in the deep cardiac plexus.

(2) **Communicating branches** to the inferior cervical ganglion of the sympathetic arise from the nerve behind the subclavian artery.

(3) **Muscular branches** supply the trachea, œsophagus, and the inferior constrictor of the pharynx.

(4) **Terminal branches** supply the muscles of the larynx (except the crico-thyroid) and communicate beneath the ala of the thyroid cartilage with branches of the internal laryngeal nerve.

**Branches of the Vagus in the Thorax.**—In the thorax the pneumogastric nerve forms the great pulmonary and œsophageal plexuses. The right nerve, in addition, furnishes cardiac branches; and the left nerve gives off the inferior or recurrent laryngeal nerve.

The **left inferior laryngeal nerve** differs from the nerve of the right side only in its point of origin and in the early part of its course. It springs from the pneumogastric nerve as it crosses the aortic arch, and, after hooking round the arch external to the *ligamentum arteriosum*, it passes upwards in the superior mediastinum in the interval between the trachea and œsophagus to the neck. In the neck its course and relations are similar to those of the nerve of the right side. The branches of the nerve are the same as those of the right nerve. The **cardiac branches** are larger, and, arising below the aortic arch, proceed to the deep cardiac plexus.

**Cardiac branches** from the right pneumogastric nerve arise in the superior mediastinum, and pass downwards alongside the trachea to join the deep cardiac plexus. On the *right side* thoracic cardiac branches are thus supplied from both the trunk of the nerve and its recurrent branch; *on the left side* the cardiac branches in the thorax arise solely from the recurrent branch.

**Abdominal Branches.**—After the formation of the œsophageal plexus the two pneumogastric nerves resume their course, and passing along with the gullet through the diaphragm, terminate by supplying the stomach. The *right nerve* enters the abdominal cavity behind the gullet, and is distributed to the posterior surface of the stomach. It sends communicating offsets to the cœliac, splenic, and renal plexuses. The *left nerve* applies itself to the anterior surface and lesser curvature of the stomach, to which it is distributed. It sends communicating offsets along the lesser curvature of the stomach to the right pneumogastric, and between the layers of the small omentum to the hepatic plexus.

## The Thoracic Plexuses.

**Cardiac Plexuses.**—The cardiac branches of the pneumogastric nerve (both cervical and thoracic) combine with the cervical cardiac branches of the sympathetic to form the superficial and deep cardiac plexuses.

The **superficial cardiac plexus** is placed in the hollow of the aortic arch, superficial to the pericardium. It contains a small ganglion (**ganglion of Wrisberg**), and is joined by two small nerves—(1) the cardiac branch from the superior cervical ganglion of the sympathetic, and (2) the inferior cervical cardiac branch of the pneumogastric—both of the left side—which reach it after passing over the arch of the aorta.

**Branches** and **Communications.**—From the plexus branches of communication pass (1) to the left half of the **deep cardiac plexus**, between the aortic arch and the bifurcation of the pulmonary artery; (2) to the left **anterior pulmonary plexus** along the left branch of the pulmonary artery; (3) the branches of distribution to the heart extend along the pulmonary artery to join the **anterior** or **right coronary plexus**, which supplies the substance of the heart in the course of the right coronary artery.

The **deep cardiac plexus** is much the larger. It is placed behind the arch of the aorta, on the sides of the trachea, just above its bifurcation. It consists of two lateral parts, joined together by numerous communications around the termination of the trachea. The two portions of the plexus are different in their constitution and distribution. The *right half* of the plexus is joined by both the cervical and thoracic branches of the right pneumogastric and by the branches of the right inferior laryngeal nerve, as well as by branches from the superior, middle, and inferior cervical ganglia of the sympathetic. The *left half* of the plexus is joined by the superior cervical cardiac branch of the left pneumogastric, by branches from the left inferior laryngeal nerve, and by branches from the middle and inferior cervical ganglia of the left sympathetic; it also receives a contribution from the superficial cardiac plexus.

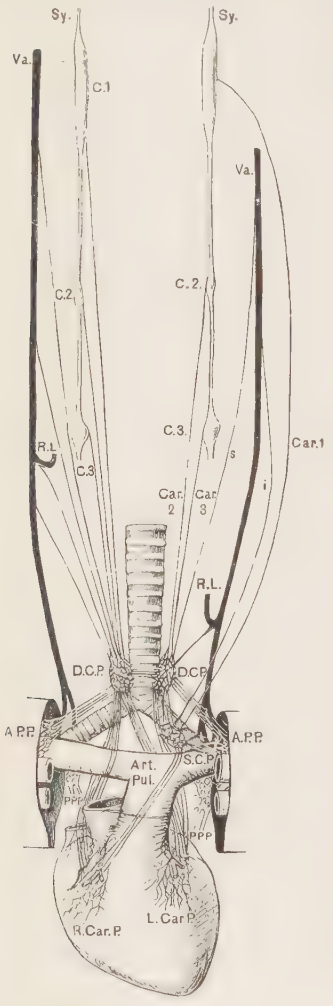

FIG. 533.—THE CONSTITUTION OF THE CARDIAC PLEXUSES.

Sy, Cervical sympathetic cord; C.1, Superior, C.2, Middle, and C.3, Inferior cervical ganglia; Car. 1, Superior, Car. 2, Middle, and Car.3, Inferior cervical cardiac sympathetic branches; Va, Pneumogastric nerve; R.L, Recurrent laryngeal nerve; s, Superior, and i, Inferior cervical cardiac branches of vagus; D.C.P, Deep cardiac plexus; S.C.P, Superficial cardiac plexus; A.P.P, Anterior pulmonary plexus; P.P.P, Posterior pulmonary plexus; R.Car.P, Right, and L.Car.P, Left coronary plexuses; Art.Pul, Pulmonary artery.

The deep cardiac plexus is distributed to the heart and lungs. The *right half* of the plexus for the most part constitutes the **anterior** or **right coronary plexus**, reaching the heart alongside the ascending aorta, and is distributed to the heart substance in the course of the right coronary artery. It is reinforced by fibres from the superficial cardiac plexus, which reach the heart along the pulmonary artery. Fibres from the right half of the deep cardiac plexus pass also to join the **posterior** or **left coronary plexus**, and others extend outwards to join the **anterior pulmonary plexus** of the right side.

The *left half* of the deep cardiac plexus, reinforced by fibres from the superficial cardiac plexus, is distributed to the heart in the form of the **left** or **posterior coronary plexus**, which is joined by a few fibres behind the pulmonary artery from the right half of the plexus, and supplies the heart substance in the course of the left coronary artery. The left half of the plexus contributes also to the **left anterior pulmonary plexus** by fibres which extend outwards to the root of the lung along the left branch of the pulmonary artery.

**Pulmonary Plexuses.**—As already stated, the pneumogastric nerve on each side, on reaching the back of the root of the lung, breaks up into numerous plexiform branches for the formation of the posterior pulmonary plexus. From each nerve a few fibres pass to the front of the root of the lung, above its upper border, to form the much smaller anterior pulmonary plexus.

The **anterior pulmonary plexus** on each side is joined by a few fibres from the corresponding part of the deep cardiac plexus, and on the left side from the superficial cardiac plexus as well. It surrounds and supplies the constituents of the root of the lung anteriorly.

The **posterior pulmonary plexus**, placed behind the root of the lung, is formed by the greater part of the pneumogastric nerve, reinforced by fine branches from the second, third, and fourth thoracic ganglia of the sympathetic. Numerous branches proceed from it in a plexiform manner along the bronchi and vessels into the substance of the lung.

**Œsophageal Plexus** (plexus gulæ). — The œsophagus in the thorax is supplied by the pneumogastric nerve both in the superior and posterior mediastinum. *In the superior mediastinum* it receives branches from the pneumogastric nerve on the right side, and from its recurrent laryngeal branch on the left side.

*In the posterior mediastinum* it is surrounded by the œsophageal plexus, formed from the trunks of the pneumogastric nerves emerging from the posterior pulmonary plexus, which form a large plexus surrounding the gullet. This part of the œsophagus also receives fibres from the great splanchnic nerve and ganglion. From the œsophageal plexus branches supply the muscular wall and mucous membrane of the œsophagus.

**Pericardiac branches** are also supplied from the plexus to the posterior surface of the pericardium.

## The Eleventh or Spinal Accessory Nerve.

The spinal accessory nerve (n. accessorius) consists of two essentially separate parts, different both in origin and in distribution. One portion is **accessory to the vagus nerve**, and arises, in series with the fibres of that nerve, from the side of the medulla oblongata. The other, **spinal portion**, arises from the lateral aspect of the spinal cord, between the ventral and dorsal roots of the spinal nerves, its origin extending from the level of the accessory portion as low as the origin of the sixth cervical nerve (for the deep origin, see p. 516). Successively joining together, the rootlets form a trunk which ascends in the subdural space of the spinal cord, behind the ligamentum denticulatum, to the foramen magnum. There the

accessory and spinal portions unite into a single trunk, which leaves the cranial cavity through the jugular foramen in the same compartment of dura mater as the pneumogastric nerve (Fig. 522, p. 678).

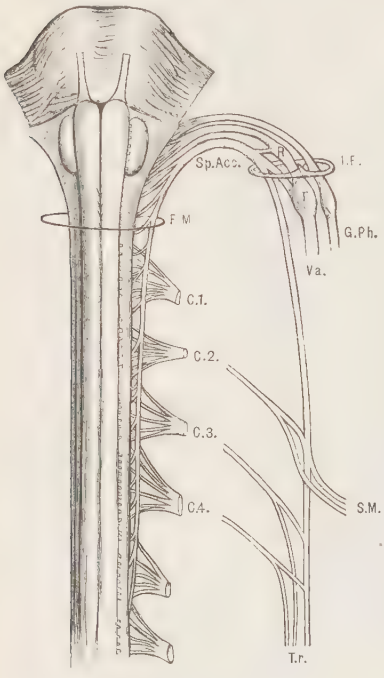

FIG. 535.—SCHEME OF THE ORIGIN, CONNEXIONS, AND DISTRIBUTION OF THE SPINAL ACCESSORY NERVE.

Sp.Acc, Spinal accessory nerve; C.1-4, First four cervical nerves (dorsal roots); Va, Pneumogastric nerve; R, Ganglion of the root; T, Ganglion of the trunk; G.Ph, Glosso-pharyngeal nerve; S.M, Nerves to sterno-cleido-mastoid; Tr, Nerves to trapezius; F.M, Foramen magnum; J.F, Jugular foramen.

In the jugular foramen the **accessory portion of the nerve** (after furnishing a small branch to the ganglion of the root of the pneumogastric nerve) applies itself to the ganglion of the trunk, and in part joins the ganglion, in part the trunk of the nerve beyond the ganglion. By means of these connexions the pneumogastric receives viscero-motor and cardio-inhibitory fibres.

The **spinal portion** of the nerve extends into the neck, where at first it lies along with other nerves, in the interval between the internal carotid artery and the internal jugular vein. Passing obliquely downwards and outwards over the vein, it descends beneath the sterno-mastoid muscle, which it supplies as it pierces it on its deep surface. After crossing the posterior triangle the nerve ends by supplying the trapezius muscle on its under surface. The spinal portion of the nerve *communicates* in three situations with nerves from the cervical plexus—(1) in or beneath the sterno-mastoid, with the branch for the muscle derived from the second cervical nerve; (2) in the posterior triangle, with branches from the third and fourth cervical nerves; (3) beneath the trapezius, with the branches for the muscle derived from the third and fourth cervical nerves.

### THE TWELFTH OR HYPOGLOSSAL NERVE.

The hypoglossal nerve (n. hypoglossus) arises by numerous radicles from the front of the medulla oblongata between the pyramid and the olive (Fig. 517, p. 675) (for deep origin, see p. 515). The root fibres arrange themselves in two bundles which separately pierce the dura mater, and unite in the anterior condyloid foramen, or after emerging from the skull. In the neck the nerve arches downwards and forwards towards the hyoid bone, and then turns inwards among the supra-hyoid muscles to the tongue. At first it is placed deeply, along with other cranial nerves, on the outer side of the internal carotid artery; it then curves forwards and downwards over the two carotid arteries lying beneath the digastric and stylo-hyoid muscles. As it crosses the external carotid artery it hooks round the occipital artery. Above the great cornu of the hyoid bone the nerve conceals the lingual artery; and it then disappears between the mylo-hyoid and hyo-glossus muscles to reach the tongue, in the muscular substance of which it terminates.

**Communications.**—In its course the hypoglossal nerve has the following communications with other nerves:—Near the base of the skull it is connected by small branches with (1) the superior cervical ganglion of the sympathetic; (2) the ganglion of the trunk of the pneumogastric; (3) by a larger branch, with the loop between the first two cervical nerves; (4) as it crosses the external carotid artery it receives a communication from the pharyngeal plexus (*lingual branch of the vagus*); and (5) beneath the mylo-hyoid muscle, at the anterior border of the hyo-glossus, it forms loops of communication with the lingual branch of the inferior maxillary nerve.

The **branches** of the nerve are:—(1) Recurrent; (2) Descending; (3) Thyro-hyoid; and (4) Lingual.

The **recurrent branch** passes from the nerve near its origin to supply the dura mater of the posterior fossa of the base of the skull. It probably derives its fibres from the communication with the first and second cervical nerves.

The **descending hypoglossal nerve** (n. descendens) is the chief branch given off in the neck. It arises from the hypoglossal nerve as it crosses the internal carotid artery, and descends in the anterior triangle in front of the carotid sheath. It is joined about the middle of the neck by the **descending cervical nerve** (from the second and third cervical nerves). By their union the **hypoglossal loop** (ansa

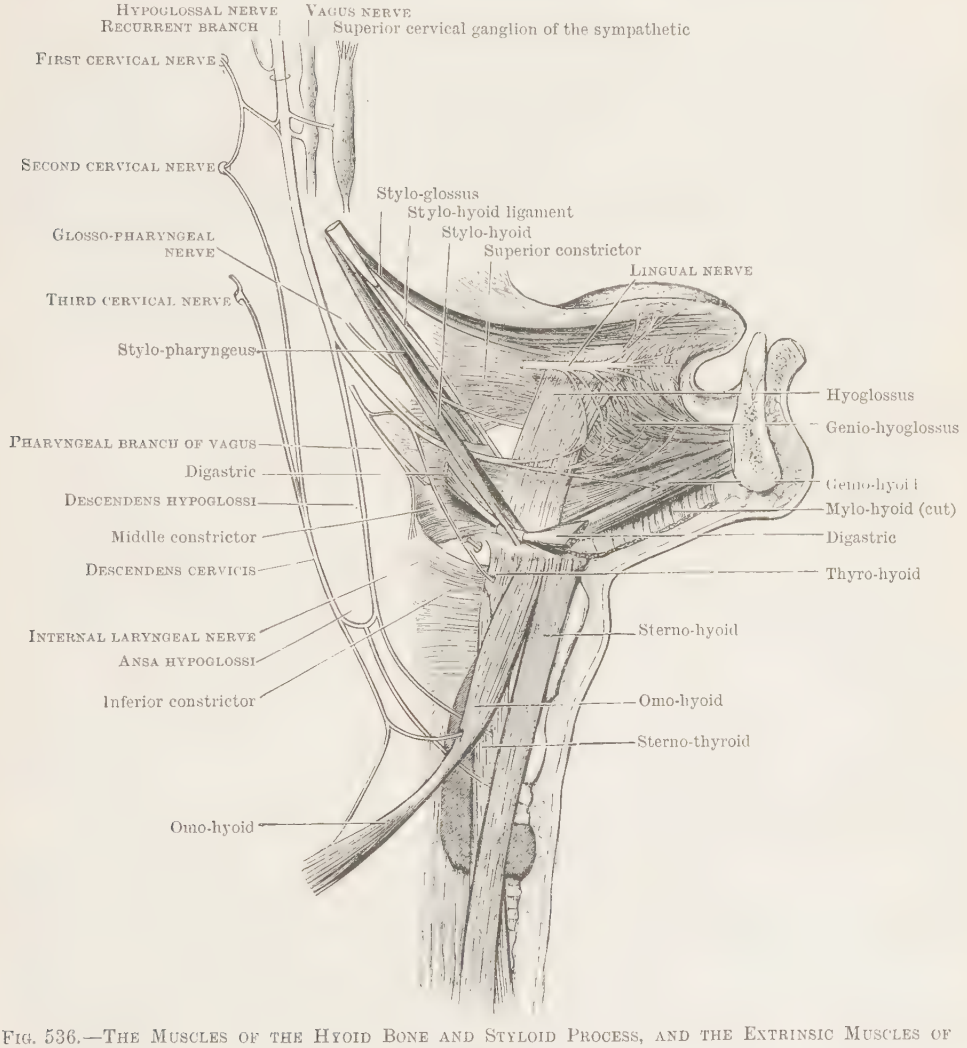

Fig. 536.—The Muscles of the Hyoid Bone and Styloid Process, and the Extrinsic Muscles of the Tongue with their Nerves.

hypoglossi) is formed, from which branches are distributed to the majority of the infra-hyoid muscles—both bellies of the omo-hyoid, the sterno-hyoid, and the sterno-thyroid. The descending hypoglossal nerve derives its fibres from the communication to the hypoglossal nerve from the loop between the first and second cervical nerves; so that the ansa hypoglossi is made up of fibres of the first three cervical nerves.

The **nerve to the thyro-hyoid muscle** is a small branch which arises from the hypoglossal nerve before it passes beneath the mylo-hyoid muscle. It descends behind the great cornu of the hyoid bone to reach the muscle. When traced backwards this nerve is found associated with the loop between the first and second cervical nerves.

The **lingual branches** of the hypoglossal nerve are distributed to the hyo-glossus, genio-hyoid, and genio-hyo-glossus, and to all the intrinsic muscles of the tongue. The nerve to the genio-hyoid is said to be derived from the loop between the first and second cervical nerves. It is not known if these two nerves are implicated in the innervation of the proper muscles of the tongue, but it appears certain that the muscles named—the genio-hyoid, thyro-hyoid, sterno-hyoid, omo-hyoid, and sterno-thyroid—are not supplied by the hypoglossal, but only by cervical nerves, the genio-hyoid by the first two, the other muscles by the first three cervical nerves.

## THE DEVELOPMENT OF THE CRANIAL NERVES.

Omitting the first and second nerves, there is an obvious likeness in the development of the several cranial nerves to the formation of the dorsal, afferent or sensory, and the ventral, efferent or motor, roots of the spinal nerves. The **afferent roots** of the cranial nerves arise from collections of cells which bud off from the alar lamina of the brain, homologous with the dorso-lateral part of the spinal cord. These cells give rise to central and peripheral processes, like the similar processes from the dorsal ganglia of the spinal nerves, producing on the one hand the root fibres connected with the brain, and on the other hand the fibres of the nerve proceeding to the periphery. The **efferent roots**, like the ventral roots of the spinal nerves, arise as the peripheral processes of neuroblasts located in the basal lamina of the primitive brain, which is homologous with the ventro-lateral portion of the spinal cord. The different efferent nerves may be separated into two series, according as they arise from the mesial or lateral parts of the basal lamina. The third, fourth, sixth, and twelfth nerves arise from the mesial part of the lamina; the efferent fibres of the fifth, seventh, ninth, tenth, and eleventh nerves arise from the lateral part of the lamina.

The **olfactory nerves** are associated in their development with the formation of the nasal pit and the olfactory bulb.

The **nasal pits** appear in each side of the front of the head at a little later period than the formation of the lens and the auditory vesicle. They become converted into the nasal cavities by the formation of the pre-oral visceral clefts and arches,—fronto-nasal and ethmo-vomerine in the middle line, and lateral ethmoid and maxillary processes at the sides (p. 38).

The **Rhinencephalon** or **olfactory bulb** is a hollow outgrowth from each telencephalon or cerebral hemisphere, which appears in the first month. It grows forwards into relation with the deep surface of the nasal pit. In many animals (as in the horse) the olfactory bulb remains hollow; but in the human subject it loses its lumen and becomes a solid bulb (**olfactory bulb**) connected to the brain by a narrow stalk, the **olfactory tract.**

The **epithelium of the nasal pit** is responsible for the formation of the olfactory nerves. There are two views as to the mode of their development from the epithelial cells. Both views admit the proliferation of the epithelium of the nasal pit so as to produce *neuroblasts.* According to the one view these neuroblasts detach themselves from the epithelial surface, and constitute **an olfactory ganglion** which becomes applied to and incorporated with the olfactory bulb. The cells of the ganglion become bi-polar, and the peripheral axons constitute the *olfactory nerves,* while the central axons (in the second month) proceed backwards to the brain along the olfactory tract. According to the other view (based on Disse's investigations), the proliferating cells of the nasal epithelium remain in the wall of the nasal pit, and become the *olfactory cells* of the nasal cavity, with peripheral processes projecting to the surface of the epithelium. Their central axons become the olfactory nerve fibres which end in the olfactory bulb, forming dendrites associated with the dendritic processes of the nerve-cells of the bulb. The central axons of these latter cells develop into the fibres of the olfactory tract.

The **optic nerve** is developed wholly from the brain. Its formation begins with the outgrowth of the optic vesicle, a paired hollow outgrowth from the ventral surface of the thalamencephalon. The epiblastic invagination of the lens, growing inwards from the surface of the head, causes the collapse of the vesicle and its conversion into the **optic cup**, the narrow tube connecting the vesicle to the brain becoming the **optic stalk.** This stalk becomes solid, and forms the basis of the optic tract, optic commissure, and optic nerve. The optic cup, bilaminar in form, and by its edge clasping the lens, is embedded in mesoblastic tissue, which gives rise to the envelopes of the eyeball, etc. The *outer*

*layer* of the optic cup produces the layer of hexagonal pigment cells of the retina. The cells of the *inner layer* produce the tissue of the retina proper. They form neuroblasts with peripheral and central processes. The peripheral processes are converted into retinal nerve tissues; the central processes extend backwards along the optic stalk, and give rise to the fibrous structure of the optic nerve, optic commissure, and optic tract. Spongioblasts in the inner lamina of the optic cup produce the sustentacular tissue of the retina (Müller's fibres). The mesoblastic tissue surrounding the optic cup and lens gives rise to the rest of the structure of the eyeball, the formation of which is described in the section which deals with the organs of sense.

The **oculo-motor nerve** arises, like the ventral root of a spinal nerve, from a group of neuroblasts in the mesial part of the basal lamina of the mid-brain. The peripheral fibres extend forwards, to end around the optic cup in the mesoblastic tissue, from which the eye muscles are derived. Numerous cells are carried along with the cell processes in their course, and these have been described as being concerned in the formation of the ciliary ganglion.

The **trochlear nerve** also arises from a group of neuroblasts occupying the mesial part of the basal lamina of the mid-brain, close to its junction with the hind-brain. The peripheral processes do not emerge directly from the brain, but extend dorsally from their origin along the side of the brain to its dorsal aspect, where they appear, after decussating with the fibres of the opposite nerve, just behind the quadrigeminal lamina.

The **trigeminal nerve** is developed by means of a large dorsal and a small ventral root. Their origin to a large extent resembles the mode of formation of the roots of a spinal nerve.

The large **dorsal (afferent) root** is formed by means of a cellular bud from the alar lamina of the hind-brain. This bud separates from the brain, and forms the Gasserian ganglion. Its cells becoming bipolar, like the cells of a spinal ganglion, are secondarily connected with the brain by means of their central processes; while the peripheral processes, separating into three groups, proceed along the fronto-nasal and maxillary processes, and along the mandibular arch, to form the three main divisions of the nerve. Numerous cells accompany each main division in its course from the ganglion, and form eventually the subordinate ganglia—the *ciliary* on the ophthalmic nerve, the *spheno-palatine* on the superior maxillary nerve, and the *otic ganglion* on the inferior maxillary nerve.

The small **ventral (efferent) root** of the trigeminal nerve, like the motor ventral root of a spinal nerve, is later in its appearance than the sensory root. It arises as the peripheral fibres of a group of neuroblasts occupying the lateral part of the basal lamina of the hind-brain, which proceed directly to the surface to join the inferior maxillary division of the nerve.

The **abducent nerve** resembles in its mode of development the oculo-motor and trochlear nerves with which in its origin it is in series. It is formed by the peripheral processes of a group of neuroblasts in the mesial part of the basal lamina in the upper part of the hind-brain. These processes pierce the part of the brain in which, at a later stage, the fibres of the pyramid are developed. They then proceed to the mesoblastic tissue round the optic cup, which is destined to form the eye muscles.

The **facial nerve** has developmentally a double origin. (1) In connexion with the formation of the auditory nerve a group of cells becomes separated from the alar lamina of the hind-brain opposite the auditory vesicle. This group becomes separated into three parts, of which the middle portion is the rudiment of the **geniculate ganglion** (or afferent root). (2) The **efferent root** of the nerve arises from a group of neuroblasts in the lateral part of the basal lamina of the hind-brain, in series with efferent fibres of the vago-glosso-pharyngeal nerves; after a tortuous course within the brain its fibres emerge beneath the above-mentioned cellular mass, opposite the auditory vesicle. They are joined by the ganglionic root, and in their course round the auditory vesicle become embedded in the auditory capsule (aqueduct of Fallopius). The chorda tympani nerve appears early as a branch of the facial nerve. It is probable that the pars intermedia, the geniculate ganglion, and the chorda tympani nerve together represent the **dorsal afferent element** in the constitution of this nerve.

The **auditory nerve** arises as a cellular bud from the alar lamina of the hind-brain, dorsal to the efferent portion of the facial nerve and opposite to the auditory vesicle, and in close association with the latter.

Becoming separated from the brain, the cellular mass separates into three portions, of which the middle part is associated with the facial nerve and pars intermedia (as the geniculate ganglion), while the mesial and lateral parts are converted into the mesial (vestibular) and lateral (cochlear) ganglia and roots of the auditory nerve. The cells

becoming bipolar, their central processes are secondarily connected with the brain on the dorsal (lateral) aspect of the facial nerve; the peripheral processes proceed to the auditory vesicle, to which they are distributed as the vestibular and cochlear nerves. Numerous cells are carried along with the nerve trunks into relation with the auditory capsule, and constitute the vestibular and cochlear ganglia.

The **glosso-pharyngeal** and **pneumogastric nerves** are developed from the side of the hind-brain, both in the same way, and each by two roots. A collection of cells separates itself from the alar lamina of the hind-brain behind the auditory vesicle to form the **ganglionic afferent root**. The ganglion of the pneumogastric is much larger than that of the glosso-pharyngeal. Each ganglion becomes divided into two parts, a proximal and a distal portion, connected together by a commissural band of fibres. The proximal ganglion (jugular ganglion of the glosso-pharyngeal; ganglion of the root of the pneumogastric) is secondarily connected by centripetal fibres to the hind-brain. From the distal ganglion (petrous ganglion of the glosso-pharyngeal; ganglion of the trunk of the pneumogastric) peripheral fibres grow outwards to form the nerve trunk.

Each nerve is also provided with a small **efferent root**, consisting of nerve fibres, arising from a collection of neuroblasts in the lateral part of the basal lamina of the hind-

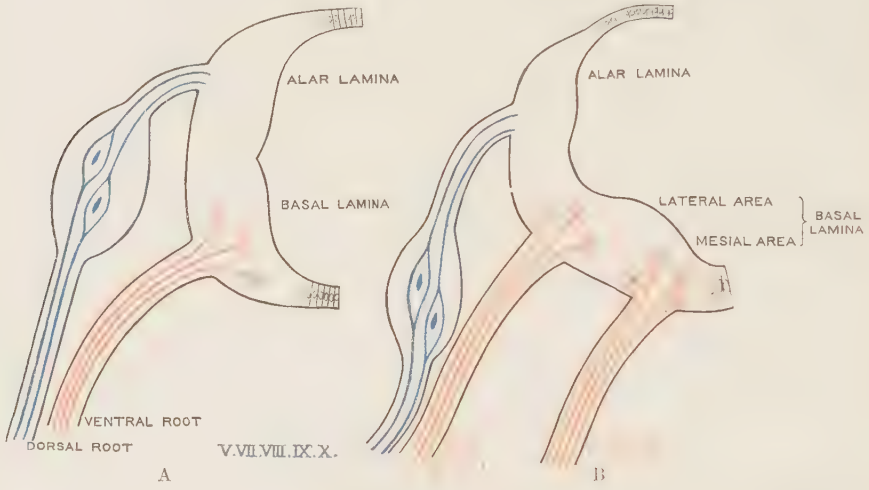

FIG. 537.—COMPARISON OF ORIGINS OF NERVE ROOTS FROM SPINAL CORD AND HIND-BRAIN (after His).
A. Spinal cord; B. Hind-brain.

brain, and emerging beneath the ganglionic root at the junction of the alar and basal laminæ (in series with the fibres of the efferent root of the facial nerve above and of the spinal accessory nerve below).

The **spinal accessory nerve** arises in two parts—one medullary, the other spinal. The **medullary** (accessory) portion develops as the processes of a series of neuroblasts in the lateral portion of the basal lamina of the hind-brain, which emerge in series with the efferent roots of the glosso-pharyngeal and pneumogastric nerves. The **spinal portion** arises as the processes of a group of neuroblasts in the ventral part of the medullary tube (anterior cornu), which, turning outwards, emerge as a series of roots on the lateral aspect of the spinal cord.

The **hypoglossal nerve** is developed, not in series with the nerves above mentioned, but like the third, fourth, and sixth nerves, from the mesial part of the basal lamina of the hind-brain, in the space between the glosso-pharyngeal and other nerves above, and the first cervical nerve below. It is formed as a series of peripheral processes from a collection of neuroblasts occupying the hind-brain. **Froriep's ganglion** is a transitory collection of nerve cells developed from the alar lamina of the hind-brain on the dorsal aspect of the nerve, and represents in a rudimentary condition its dorsal ganglionic root. It gives off no branches and soon disappears.

## THE MORPHOLOGY OF THE CRANIAL NERVES.

The head and face, possibly the oldest, and from every point of view the most fundamental and important portion of the bodily fabric, present in some respects a more conservative type of structure, and in other aspects have been subject to more profound alterations than other parts

of the body. Segmentation is characteristic of the trunk, pervading bones, muscles, vessels, and nerves. An absence of true segmentation is characteristic of the head region—omitting for the moment the cranial nerves. The head is characterised by the possession of an unsegmented tubular nervous system, enclosed in a bony capsule not obviously segmental, with which the capsules of the sense-organs become united. The pre-oral and post-oral visceral arches and clefts are not truly segmental like the costal arches of the trunk. The branchial clefts are said to be inter-segmental; and their muscles (associated with the myoblast surrounding the developing heart) are described as visceral, and not myotomic, so that the branchial vessels and nerves (similarly) are not to be regarded as comparable to the segmental vessels and nerves of the trunk. The truly segmental structures present are certain persistent myotomes or muscle plates, which give rise to muscles innervated by the third, fourth, sixth, and twelfth cranial nerves.

Another difficulty in the morphology of the head arises in the absence of body cavity, and the consequent difficulty of differentiating the somatic and splanchnic mesoblast, and the somatic and splanchnic distribution of a given nerve.

Under these circumstances there is little help to be derived from head structures other than the nerves themselves in seeking a solution of the question of the morphological relations of the cranial nerves. The spinal nerves are, generally speaking, all alike. The cranial nerves, on the other hand, are all different. Scarcely any two nerves are alike; and no single cranial nerve possesses in itself all the characteristic features of a spinal nerve. As seen in relation to their development, the cranial nervous system possesses a series of dorsal ganglia, comparable in position and development to the spinal ganglia from which afferent nerves arise; and the efferent roots are developed in the same way, and occupy somewhat the same position as the ventral roots of the spinal nerves. But there is no single complete segmental nerve in the head. The very essence of the architecture of the head is a want of segmentation; and this character is shared by the cranial nerves. In addition it must be borne in mind that, in relation to the mammalian head, there are organs which have no homologues in the trunk, and on whose existence the arrangement of the cranial nerves depends—*e.g.* sense-organs and gill-arches.

Among the cranial nerves there are several which possess a resemblance to one or other of the elements of a typical spinal nerve. In the neck the origin of the fibres of the spinal accessory nerve is from the side of the spinal cord, and it is in series with the motor roots of the vago-glosso-pharyngeal, facial, and fifth nerves. His (as shown in the account of the development of the nerves) has described the neuroblastic origin of the motor roots of these nerves from the lateral part of the basal lamina of the primitive brain. They thus form a series apart—lateral motor roots—separable from the series of motor roots originating from the mesial part of the basal lamina, comprising those of the third, fourth, sixth, and twelfth nerves; the latter nerve roots being comparable to and in series with the ventral roots of the spinal nerves. The lateral motor roots are not represented in the spinal series except in the neck. It is questionable if there is any fundamental distinction between the lateral and ventral motor roots of the cranial nerves. The spinal accessory fibres, for example, when traced into the spinal cord, have an origin from the anterior cornu of the cord, and only differ from the motor or ventral root fibres of a spinal nerve in their different course to the surface. The ganglia in association with the cranial nerves are comparable to the spinal ganglia. The fifth nerve, with the Gasserian ganglion, the ganglion of the facial, the ganglia of the auditory, of the glosso-pharyngeal and the vagus, and the transitory (Froriep's) ganglion of the hypoglossal nerves, arise from the brain in a comparable position, and in the same way as the spinal ganglia. But another series of structures —the sense organs of the lateral line, and the so-called "epibranchial" organs which are highly developed in lower vertebrates (*e.g.* elasmobranchs), and which appear transitorily only, or are absent altogether in mammalian development, may possibly have a share in the formation of certain of these ganglia or parts of them (*e.g.* ciliary ganglion, geniculate ganglion, ganglia of the auditory nerve, petrosal ganglion of the glosso-pharyngeal, and the ganglion of the trunk of the vagus).

Certain of the cranial nerves are apparently distinctly **segmental**, supplying muscles derived from the persisting myotomes of the head. The **first three myotomes** are said to give rise to the muscles of the eyeball. The *first* produces the superior rectus, inferior rectus, internal rectus, and inferior oblique muscles, and its segmental nerve is the **oculo-motor**. The *second myotome* is said to produce the superior oblique muscle, and its segmental nerve is the **trochlear**. The *third myotome* is said to produce the external rectus muscle, and its segmental nerve is the **abducent**. It has been asserted that the tongue muscles are derived from the **last three or four cephalic and first cervical myotomes**, and that the **hypoglossal nerve** is the segmental nerve for these myotomes, comprising the motor elements of several (four or five) segmental nerves. The intervening myotomes between the first three and this occipital series disappearing, the corresponding elements of segmental nerves are supposed to be absent also (Fig. 538).

Certain of the cranial nerves are essentially related to the structures derived from and associated with the pre-oral and post-oral **visceral clefts and arches** (Fig. 539). The **trigeminal nerve** is essentially the nerve of the **mandibular arch**. By its efferent root it supplies the muscles of that arch. By its afferent root and branches it is related to (1) the fronto-nasal process (ophthalmic division and ciliary ganglion); (2) the maxillary arch (superior maxillary nerve); and (3) the mandibular arch (inferior maxillary nerve). The mandibular is at first the main nerve: and the maxillary division is sometimes regarded as a subordinate branch (præ-branchial, præ-trematic) for the supply of the anterior margin of the cleft (mouth), with which the nerve is in relation. The ophthalmic nerve is sometimes regarded as a morphologically separate nerve. The nerves to these arches have been compared to the anterior primary divisions of spinal

nerves, the branches which they supply to the forehead and temple (frontal, orbital, and auriculo-temporal) representing the posterior primary divisions. The ganglia on each division of the nerve are formed as extensions from the Gasserian ganglion.

The **facial nerve** is essentially the nerve of the **second (hyoid) arch**, and the cleft in front of that arch (spiracular cleft, Eustachian tube). Its motor root supplies the muscles of that arch (stapedius, stylo-hyoid, and digastric), and the epicranial and facial muscles and platysma myoides, which are developments from the hyoid arch (Rabl). The **chorda tympani nerve** is regarded as the subordinate (præ-branchial, præ-trematic) branch to supply the anterior margin of the first post-oral cleft. It is possible that the geniculate ganglion, with the pars intermedia and the chorda tympani, may, in part at least, represent the ganglionic and afferent element of the nerve. Or the geniculate ganglion, and the nerves in relation to it, may be associated with an "epibranchial" sense-organ.

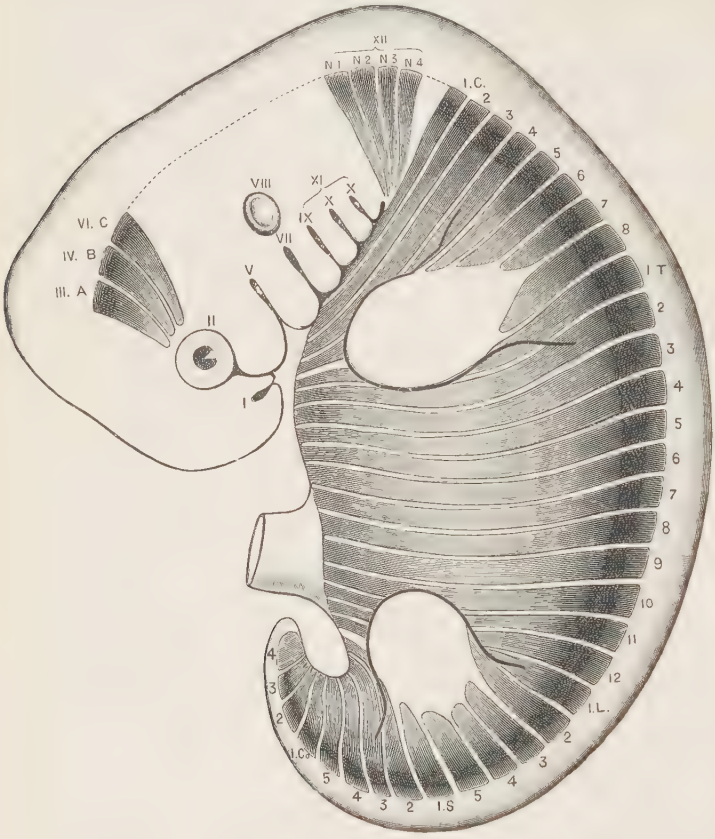

Fig. 538.—Scheme to illustrate the Disposition of the Myotomes in the Embryo in Relation to the Head, Trunk, and Limbs.

A, B, C, First three cephalic myotomes; N, 1, 2, 3, 4, Last persisting cephalic myotomes; C, T, L, S, Co, The myotomes of the cervical, thoracic, lumbar, sacral, and caudal regions; I., II., III., IV., V., VI., VII., VIII., IX., X., XI., XII., refer to the cranial nerves, and the structures with which they may be embryologically associated.

The **auditory nerve**, on the other hand, may be either the sensory element of the branchial nerve, associated with the **hyoid arch** and first post-oral cleft, or it may represent the nerve or nerves belonging to ancestral sense-organs of the lateral line.

The **glosso-pharyngeal** is the branchial nerve of the **third post-oral** (*thyro-hyoid*) **arch** and the cleft in front. Its efferent fibres supply the muscle of this arch, —the stylo-pharyngeus. The superior constrictor of the pharynx is also assigned to this arch; the middle and inferior muscles to the fourth (first branchial) arch. The afferent portion of the nerve is possibly composed of two separate parts; the petrous ganglion being associated with an epibranchial or lateral line sense-organ, and the rest of the nerve forming the afferent fibres for the gill-cleft and arch. The lingual branches are regarded as the main stem (post-trematic), the pharyngeal branches as subordinate branches; the tympanic branch being the præ-branchial or præ-trematic branch for the anterior margin of the third gill-cleft.

The **pneumogastric nerve** is generally regarded as representing the fusion of all the branchial nerves behind the glosso-pharyngeal. Its efferent fibres are in series with those of the glosso-pharyngeal above and the spinal accessory nerve below, and belong to the lateral series of His. Its afferent fibres, like those of the glosso-pharyngeal, represent two elements. The lower ganglion has possible connexions with epibranchial sense-organs—the rest of the nerve representing the fused branchial branches of fishes. The **superior laryngeal nerve** is looked upon as the branchial nerve of the **fourth**, and the **inferior laryngeal nerve** as the branchial nerve of the **fifth arch**. While the relation of the nerve to the hinder gill-arches and clefts makes it possible to understand the innervation by the vagus of the heart and lungs, no satisfactory explanation is forthcoming of the passage of the nerve into the abdomen, and its distribution to the stomach and other organs below the diaphragm.

The **spinal accessory nerve** consists of two parts. The *accessory portion* of the nerve consists of efferent fibres for the **branchial region**, in series with the lateral motor roots of the glosso-pharyngeal and vagus nerves. The *spinal portion* of the nerve is also composed of efferent fibres, and represents the only lateral motor elements arising from the spinal cord.

**Olfactory Nerve.**—There is absolute uncertainty regarding the morphology of this nerve. It consists of three elements: (1) the **olfactory bulb**, derived from the cerebral hemisphere, solid in man, but a hollow cerebral diverticulum in certain animals, and forming the rhinencephalon; (2) the **olfactory ganglion**, with its central and peripheral processes, derived from the ectoderm; (3) the **nasal pit**. Attention has been specially fixed on the olfactory ganglion, which has been compared to (1) a dorsal spinal ganglion, derived from the anterior end of the medullary groove; and to (2) a lateral line sense-organ.

The **optic nerve** also presents an insoluble problem in regard to its morphological position in the series of cranial nerves. The optic stalk and optic cup have been regarded as a highly-modified dorsal ganglion; but there is insuperable difficulty in accepting this view. The peripheral processes do not become connected with either ectodermal or mesoblastic structures, but become the tissue of the retina; while the central processes, growing backwards, envelop the optic stalk, and obtain connexions with the brain. The retina must be regarded as a highly-modified layer, morphologically in series with the wall of the fore-brain; and the ectodermal structure of superficial origin comparable to the olfactory ganglion or the auditory vesicle is the lens (which may possibly be homologous with a lateral line sense-organ). The optic nerve, optic commissure, and optic tract are then to be looked upon as cerebral commissures, and not as nerves in the ordinary sense.

The simplest and most primitive condition of the head, in relation to the morphology of the cranial nerves, is found before the formation of the gill-clefts, when the salient features are a tubular and simple brain, and a series of superficial invaginations which pass from the surface inwards to become connected with outgrowths corresponding to them from the primitive brain. On either side of the head three hollow invaginations occur:—(1) The **nasal pit** bearing the olfactory epithelium becomes connected by the olfactory ganglion with the rhinencephalon, an outgrowth from the fore-brain, and so forms the basis of an olfactory organ and nerve; (2) a similar invagination produces the **lens**, connected with a protrusion of the optic vesicle from the fore-brain, by which the basis of the eye and the optic nerve is formed; (3) behind the buccal cavity a third invagination forms the **auditory vesicle**, which is connected with the solid extension from the hind-brain of the acoustic ganglia, to form the essentials of the organ of hearing and auditory nerve.

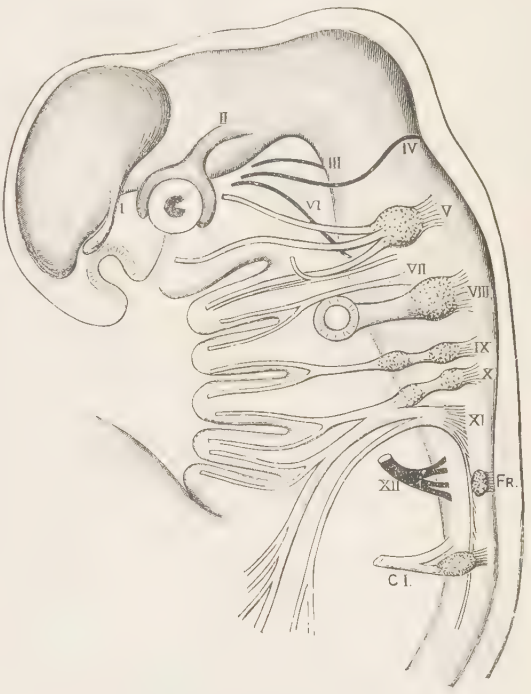

Fig. 539.—Scheme to illustrate the Embryological Arrangement of the Cranial Nerves.

I. to XII. Cranial Nerves; Fr, Froriep's ganglion; CI., Roots and trunk of the first cervical nerve.

The trigeminal nerve is essentially the nerve of the buccal cavity and the subordinate cavities, nasal and oral, derived from it. The **branchial arches and clefts** are secondary structures, and their nerves are (1) the trigeminal for the first (mandibular) arch and the cleft in front of it; (2) the facial for the second (hyoid) arch and cleft; (3) the glosso-pharyngeal for the third (thyro-hyoid) arch and cleft; and (4) the pneumogastric for the succeeding arches and clefts. The bulbar part of the spinal accessory nerve is inseparable from the motor portion of the vago-glosso-pharyngeal nerves; the spinal part is beyond the series of the cranial nerves.

Lastly, there are certain truly **segmental nerve elements**, motor fibres which, remaining associated with certain persistent cephalic myotomes, give rise to the oculo-motor, trochlear, abducent, and hypoglossal nerves.

## THE SYMPATHETIC NERVOUS SYSTEM.

The sympathetic nervous system consists of a pair of elongated gangliated cords (nervi sympathici), extending from the base of the skull to the coccyx; connected, on the one hand, by a series of branches to the spinal nervous system, and on the other hand giving off an irregular series of branches to the viscera. At its cephalic end each sympathetic cord is continued in a plexiform manner into the cranial cavity along with the internal carotid artery, and forms complex relation-

ships with certain cranial nerves. At their caudal ends the two sympathetic cords become joined together by fine filaments, and are connected by the coccygeal ganglion (g. impar).

The sympathetic system (1) serves to rearrange and distribute fibres derived from the cerebro-spinal system to the viscera and vessels of the splanchnic area; (2) it transmits to the cerebro-spinal system afferent fibres from the viscera; and (3) it transmits fibres to the vessels, involuntary muscles, and glands, in the course of the somatic divisions of the spinal nerves.

**General Structure of the Sympathetic System.**—The sympathetic system is composed of two elements—ganglia and nerve fibres.

The **ganglia** (g. trunci sympathici) are variable in number, form, size, and position. They are not definitely segmental in position, but they are always connected together by a system of narrow commissural cords of nerve fibres. A ganglion consists of a larger or smaller number of multipolar nerve cells, enclosed in a capsule of connective tissue. Each cell is provided with one *axon* and a number of *dendrites*. The axon may enter into the composition of (*a*) the commissural cord; (*b*) a central branch (gray ramus communicans); or (*c*) a peripheral branch from the sympathetic cord. These axons are commonly medullated at their origin, but become non-medullated in their course from the parent cell. Besides these ganglia, two other series of ganglia are present in connexion with the peripheral branches of the sympathetic: intermediate or **collateral ganglia**, on the branches or in the sympathetic plexuses; and **terminal ganglia**, in close relation to the endings of the nerves in the viscera.

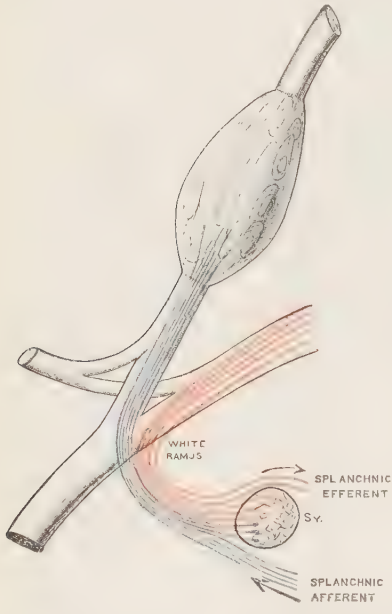

Fig. 540.– Scheme of the Constitution of the White Ramus Communicans of the Sympathetic.

The roots and trunks of a spinal nerve are shown, with the white ramus passing between the spinal nerve and a sympathetic ganglion (Sy). The splanchnic efferent fibres (in red) are shown, partly ending in the ganglion, and partly passing beyond the ganglion into a peripheral branch. The splanchnic afferent fibres (in blue) are shown, partly entering the ganglion, and passing upwards or downwards in the gangliated cord; partly passing over the cord into peripheral branches.

The **nerve fibres** in the sympathetic system are of two classes, medullated and non-medullated. The distinction is not absolute. The medullated fibres may lose their medullary sheaths before reaching their terminations; and the non-medullated fibres may at their origin possess a medullary sheath. The **medullated fibres** form the series of *white rami communicantes* (the visceral branches of the spinal nerves). They take origin from the anterior primary divisions of certain spinal nerves in two streams; **thoracico-lumbar** from the first or second thoracic to the second or third lumbar nerve, and **pelvic**, or **sacral**, from the second and third, or third and fourth sacral nerves. The roots of these nerves arise from both dorsal and ventral roots of the spinal nerves, but in largest numbers from the ventral root. The *fibres from the ventral root* are of very small size. They are the axons of nerve cells within the spinal cord, which enter the sympathetic cord through the white ramus, and end by forming arborisations around the cells of a sympathetic ganglion. There are three known courses for such a fibre to take in relation to the sympathetic system—(*a*) It may end in the ganglion with which it is immediately related; (*b*) it may course upwards or downwards in the commissural cord to reach a neighbouring ganglion; (*c*) it may pass beyond the gangliated cord to end in relation to cells of the peripheral (collateral) ganglia along with fibres of distribution from the sympathetic ganglia. These fibres are *splanchnic efferent fibres*; motor for the unstriped muscular tissue of the vessels and viscera, and secretory for the glands in the splanchnic area. The *fibres from the dorsal root* of the spinal nerve entering into the composition of the white ramus communicans are the axons of spinal

ganglion cells. They constitute the *splanchnic afferent fibres*, and probably traverse the sympathetic gangliated cord, passing upwards, downwards, and outwards, without being connected with its cells. They are the sensory fibres for the viscera, which they reach along with the peripheral branches arising from the sympathetic cord itself. It is not certain that fibres from the dorsal ganglia are only found in connexion with nerves provided with distinct white rami. Similar medullated fibres are found also in the gray rami communicantes.

The **non-medullated fibres** in the sympathetic system are derived from the axons of the sympathetic ganglion cells. They have different destinations. (*a*) Some fibres appear to contribute to the *formation of the commissural cord* connecting the ganglia together, and to end in arborisations round the cells of a neighbouring ganglion. (*b*) Non-medullated fibres form a large part of the system of *peripheral (splanchnic efferent) branches*, streaming into the splanchnic area in an irregular manner, both from the ganglia and the connecting commissures. (*c*) The *gray rami communicantes* form a series of non-medullated fibres (with a small number of medullated fibres intermingled) proceeding *centrally from the ganglia to the spinal nerves*. These gray rami are found in connexion with each and all of the spinal nerves. Their origin from the gangliated cord is irregular: they may come from the ganglia or the commissure; they may divide after their origin, so that two spinal nerves are supplied from one ganglion; or two ganglia may supply branches to a single spinal nerve. The gray ramus is distributed along the somatic divisions of the spinal nerves, supplying branches to unstriped muscular fibres (vaso-motor, pilo-motor) and glands (secretory). They also provide small recurrent branches, ending in the membranes enveloping the spinal nerve-roots. Mingled with the non-medullated fibres of the gray rami are found a small number of medullated fibres, regarded as medullated sympathetic fibres, and axons from the dorsal spinal ganglia incorporated with this ramus.

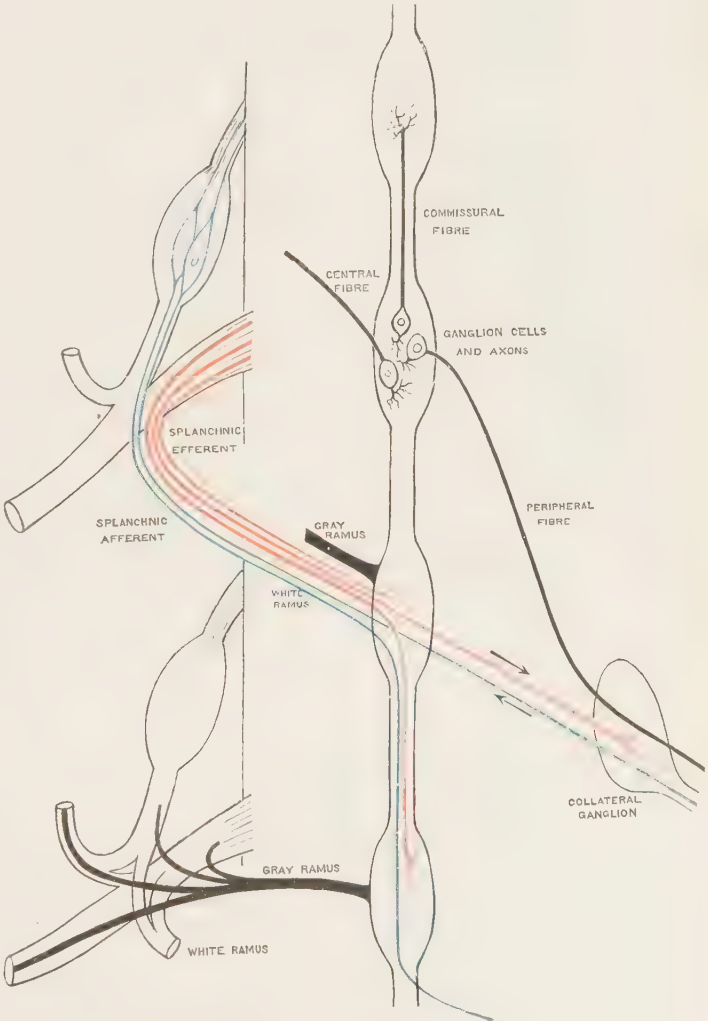

FIG. 541.—SCHEME OF THE CONSTITUTION AND CONNEXIONS OF THE GANGLIATED CORD OF THE SYMPATHETIC.

The gangliated cord is indicated on the right, with the arrangement of the fibres arising from the ganglion cells. On the left the roots and trunks of spinal nerves are shown, with the arrangement of the white ramus communicans above and of the gray ramus below.

The **commissural cords** of the sympathetic system are composed of white and gray fibres. The *white fibres* are: (1) splanchnic efferent fibres, passing to a ganglion above or below the point of entrance into the sympathetic system; (2) splanchnic afferent fibres, guided along the commissure and over or through the ganglia. The *gray fibres* are the axons of sympathetic ganglion cells: (1) true commissural fibres passing into connexion with the cells of a neighbouring ganglion; (2) fibres passing along the commissure for a certain distance upwards or downwards before entering the splanchnic area as peripheral branches.

The **peripheral (splanchnic) branches** from the sympathetic cord consist of—(1) white fibres—splanchnic afferent fibres unconnected with cells, and splanchnic efferent fibres which, after passing over the gangliated cord, are on their way to join peripheral (collateral) or terminal ganglia in relation to the viscera; and of (2) gray fibres, splanchnic efferent branches, the axons of sympathetic ganglion cells distributed to the vessels and viscera in the splanchnic area.

## THE CERVICAL PART OF THE SYMPATHETIC CORD.

The cervical part of the sympathetic cord may be regarded as an upward prolongation of the primitive sympathetic system along the great vessels of the neck. It is characterised by the absence of **white rami communicantes** connecting it with the cervical spinal nerves. Its spinal fibres ascend in the commissural cord from the upper thoracic nerves to be connected with the cells of the cervical ganglia. The branches from the ganglia in the neck are distributed to structures in the head, neck, and thorax: (1) motor fibres to involuntary muscles (*e.g.* dilator of the pupil); (2) vaso-motor fibres along the arteries of the head and neck and upper limbs; (3) pilo-motor fibres along the cervical spinal nerves to the skin of the head and neck; (4) cardio-motor fibres; (5) and secretory fibres (for the submaxillary gland).

The gangliated cord in the neck is placed upon the prevertebral muscles and behind the carotid vessels. It extends from the root of the neck, where it is continuous behind the subclavian artery with the thoracic portion of the cord, to the base of the skull, where it ends in the formation of plexiform branches upon the internal carotid artery. It consists of a narrow commissural cord composed of medullated and non-medullated fibres, on which are two or three ganglia—a superior ganglion at the upper end, an inferior ganglion at the point of junction with the thoracic portion of the cord, and an intermediate middle ganglion varying in position and often absent.

The **superior cervical ganglion** (g. cervicale superius) situated at the base of the skull, lies between the internal jugular vein and the internal carotid artery. It is the largest of the sympathetic ganglia, measuring an inch or more in length. The commissural cord connects it with the **middle ganglion** (g. cervicale medium), which is of small size, is frequently absent, and may be divided into two parts. It is usually placed over the inferior thyroid artery as it passes behind the carotid sheath.

The **inferior ganglion** (g. cervicale inferius) is joined by the commissural cord to the middle (or superior) ganglion above, and is only imperfectly separated from the first thoracic ganglion below. It is of considerable size, irregular in shape, and is placed behind the first part of the subclavian artery in the interval between the last cervical transverse process and the neck of the first rib.

The **branches** from the cervical sympathetic ganglia and cord are divisible into two sets—(*A*) Central communicating branches for other nerves; (*B*) peripheral branches of distribution, which alone, or along with other nerves, form plexuses, accompanying and supplying vessels and viscera of the head, neck, and thorax. Although this distinction is made, it is to be borne in mind that the branches of communication are as much nerves of distribution as the others.

### Superior Cervical Ganglion.

**Central Communicating Branches.**—1. **Gray rami communicantes** pass from the ganglion to the anterior primary divisions of the first four cervical nerves.

2. **Communications with Cranial Nerves.**—Just outside the skull, in the deep

part of the neck, communicating branches pass to the following cranial nerves: (*a*) to the petrous ganglion of the glosso-pharyngeal and the ganglion of the root of the pneumogastric (n. jugularis); (*b*) to the ganglion of the trunk of the pneumogastric; (*c*) to the hypoglossal nerve.

**Peripheral Branches of Distribution.**—1. Pharynx.—A pharyngeal branch courses downwards and inwards behind the carotid sheath to reach the wall of the pharynx, where it joins (along with the pharyngeal branches of the glosso-pharyngeal and pneumogastric nerves) in the formation of the **pharyngeal plexus**, and assists in supplying the muscles and mucous membrane of the pharynx.

2. Heart.—The **superior cervical cardiac** branch is a slender nerve which, on the *right side*, descends behind the large vessels into the thorax to join the deep cardiac plexus. On the *left side* the course of the nerve is similar in the neck, but in the superior mediastinum it passes between the left carotid and subclavian arteries, and over the aortic arch, to join with the inferior cervical cardiac branch of the pneumogastric in the formation of the superficial cardiac plexus. In their course both nerves form connexions with the other cervical cardiac nerves of the sympathetic, and with cardiac and other branches of the pneumogastric (external and inferior laryngeal).

3. Vessels.—(*a*) The **external carotid branch** passes forwards to the external carotid artery, and forms the **external carotid plexus**, which supplies offsets to that artery and its branches, as well as to the inter-carotid body. From the subordinate plexuses on the facial and middle meningeal arteries sympathetic fibres are supplied to the submaxillary and otic ganglia respectively.

(*b*) The **internal carotid branches** form an upward prolongation of the ganglion, which applies itself in the form of bundles of nerve-fibres to the internal carotid artery as it enters the carotid canal in the temporal bone. The branches separate into outer and inner parts, which form plexuses investing the artery in the cranium. The outer division forms the lower or **carotid plexus** (pl. caroticus internus); the inner division gives rise to the upper or **cavernous plexus** (pl. cavernosus). Both plexuses supply offsets to the artery and its branches, and form communications with certain cranial nerves.

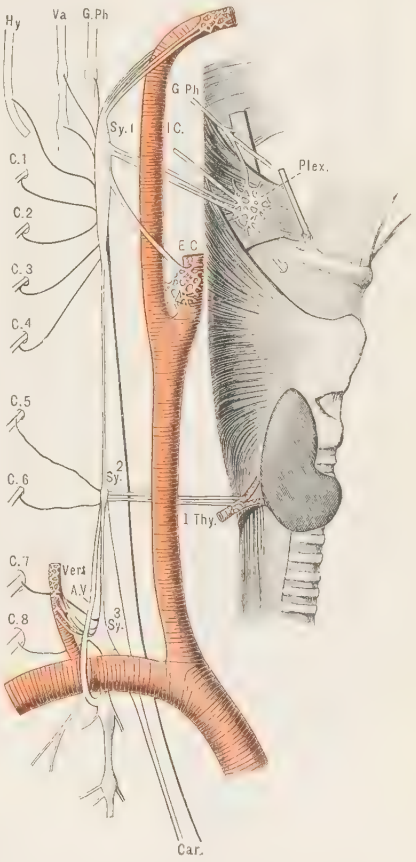

FIG. 542.—THE DISTRIBUTION OF THE SYMPATHETIC GANGLIATED CORD IN THE NECK.

Sy.1, Superior cervical ganglion, and connexions and branches; I.C, Internal carotid artery; G.Ph, Glosso-pharyngeal; Va, Vagus; Hy, Hypoglossal; C.1, 2, 3, 4, First four cervical nerves; Plex, Pharyngeal plexus; G.Ph, Glosso-pharyngeal nerve; E.C, To external carotid artery; Sy.2, Middle cervical ganglion, connexions, and branches; C.5, 6, Fifth and sixth cervical nerves; I.Thy, Inferior thyroid artery; A.V, Ansa Vieussenii; Sy.3, Inferior cervical ganglion, connexions, and branches; C.7, 8, Seventh and eighth cervical nerves; Vert, Vertebral plexus; Car, Cardiac branches.

The **carotid plexus** communicates by fine branches with (*a*) the abducent nerve, and (*b*) the Gasserian ganglion, and gives off (*c*) the great deep petrosal and (*d*) the small deep petrosal nerves. The **great deep petrosal nerve** joins the great superficial petrosal nerve from the geniculate ganglion of the facial, over the foramen lacerum medium. By their union the **Vidian nerve** is formed, which, after traversing the Vidian canal, ends in Meckel's ganglion. The **small deep petrosal nerve** passes to the **tympanic plexus**. This plexus, formed by the small deep petrosal nerve, the tympanic branch of the glosso-pharyngeal, and a twig

from the geniculate ganglion of the facial nerve, is placed on the inner wall of the tympanum. It supplies the mucous lining of the tympanum and Eustachian tube; and the **small superficial petrosal** nerve passes from it to the otic ganglion.

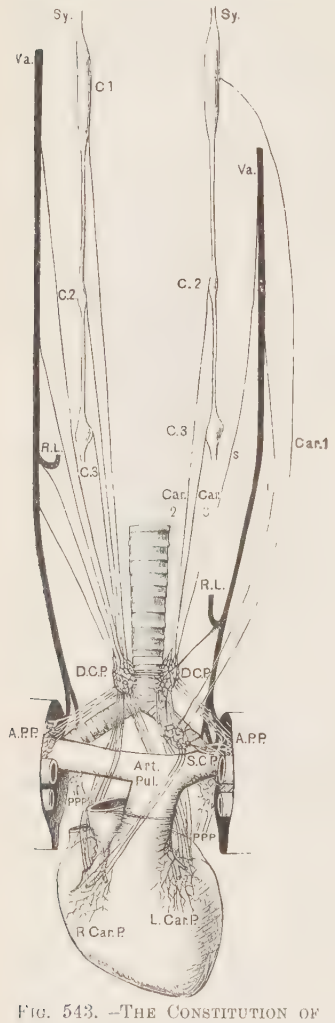

FIG. 543.—THE CONSTITUTION OF THE CARDIAC PLEXUSES.

Sy, Cervical sympathetic cord; C.1, Superior, C.2, Middle, and C.3, Inferior cervical ganglia; Car. 1, Superior, Car.2, Middle, and Car.3, Inferior cervical cardiac sympathetic branches; Va, Pneumogastric nerve; R.L, Recurrent laryngeal nerve; s, Superior, and i, Inferior cervical cardiac branches of vagus; D.C.P, Deep cardiac plexus; S.C.P, Superficial cardiac plexus; A.P.P, Anterior pulmonary plexus; P.P.P, Posterior pulmonary plexus; R.Car.P, Right, and L.Car.P, Left coronary plexuses; Art.Pul, Pulmonary artery.

The **cavernous plexus** communicates with (*a*) the oculo-motor, and (*b*) the trochlear nerves, and (*c*) the ophthalmic division of the trigeminal nerve; it also (*d*) supplies twigs to the pituitary body, and (*e*) forms the sympathetic root of the ciliary ganglion. This may pass to the ganglion independently, or it may be incorporated in the long root of the ganglion from the nasal branch of the ophthalmic nerve.

### Middle Cervical Ganglion.

**Central Communicating Branches.**—1. **Gray rami communicantes** arise from the ganglion or from the cord for the anterior primary divisions of the fifth and sixth cervical nerves. 2. The subclavian loop (**ansa Vieussenii**) is a loop of communication from this ganglion, which, after passing over and supplying offsets to the subclavian artery and its branches, joins the inferior cervical ganglion.

**Peripheral Branches of Distribution.**—1. **Heart.**—A slender **middle cervical cardiac branch** descends, either separately or in company with other cardiac nerves, behind the large vessels into the thorax, where it ends in the deep part of the cardiac plexus on each side.

2. **Thyroid Body.** — Branches extend inwards along the inferior thyroid artery to supply the thyroid body.

When the middle ganglion is absent the branches described arise from the commissural cord.

### Inferior Cervical Ganglion.

**Central Communicating Branches.**—1. **Gray rami communicantes** arise from this ganglion for the anterior primary divisions of the seventh and eighth cervical nerves. 2. The **subclavian loop** already mentioned connects the middle and inferior ganglia over the front of the subclavian artery. 3. A communication frequently occurs with the inferior laryngeal nerve.

**Peripheral Branches of Distribution.**—1. **Heart.**—An **inferior cervical cardiac branch** is given off on each side to enter the deep cardiac plexus.

2. **Vessels.**—(*a*) The **vertebral plexus** is a dense plexus of fibres surrounding the vertebral artery and accompanying its branches in the neck and the cranial cavity. (*b*) The **subclavian plexus** is derived from the subclavian loop, and supplies small offsets to the subclavian artery. It gives branches to the internal mammary artery, and communicates with the phrenic nerve.

## THE THORACIC PART OF THE SYMPATHETIC CORD.

The thoracic part of the sympathetic cord consists of a variable number of ganglia of an irregularly angular or fusiform shape, joined together by commissural

cords of considerable thickness. The number of ganglia is usually ten or eleven; but the first and sometimes others may be so fused with the neighbouring ganglia as to still further reduce the number. This part of the sympathetic cord is characterised by its union with the thoracic spinal nerves. Each thoracic nerve, with the possible exception of the first, sends a **visceral branch** (white ramus communicans) to join the gangliated cord in the thorax. These white rami separate into two main streams in relation to the sympathetic cord. Those of the *upper five* nerves are for the most part directed upwards to be distributed through the cervical part of the sympathetic gangliated cord in the manner already described. The white rami of the *lower thoracic* nerves are for the most part directed downwards in the lower part of the sympathetic cord and its branches, to be distributed in the abdomen; at the same time some of their fibres are directly associated with the supply of certain thoracic viscera,—lungs, aorta, œsophagus.

These white rami are composed of (1) **splanchnic afferent fibres** passing from its peripheral branches through the sympathetic cord into the dorsal ganglia of the spinal nerves—medullated nerve-fibres unconnected with sympathetic ganglion cells; and (2) **somatic** and **splanchnic efferent fibres**, small medullated nerves which, after a longer or shorter course in the gangliated cord or its peripheral branches, become connected with the sympathetic ganglion cells, or with the cells of peripheral (collateral or terminal) ganglia, from which again (non-medullated) axons proceed to supply branches to viscera and vessels. The ultimate destination of the upper stream of white rami from the thoracic nerves has been mentioned in the description of the cervical sympathetic; the peripheral branches supplying thoracic organs contain vaso-motor fibres for the lungs and aorta. The peripheral branches from the lower part of the sympathetic cord in the thorax, receiving white rami from the lower thoracic nerves, are mainly destined for distribution to structures below the diaphragm. They comprise (*a*) viscero-inhibitory fibres for the stomach and intestines; (*b*) motor fibres for part of the rectum; (*c*) pilo-motor fibres for the lower part of the body; (*d*) vaso-motor fibres for the abdominal aorta and its branches, and

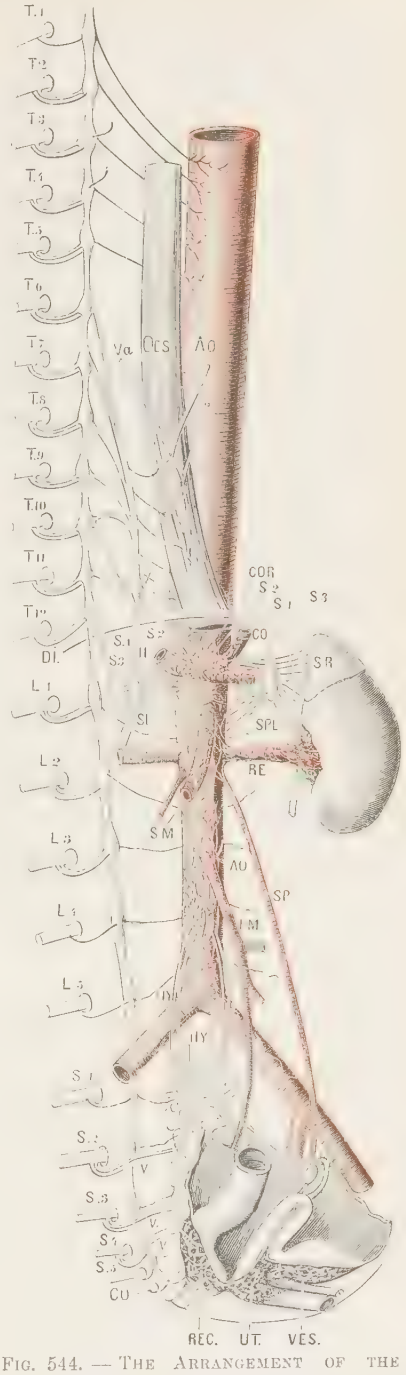

Fig. 544. — The Arrangement of the Sympathetic System in the Thorax, Abdomen, and Pelvis.

T.1-12; L.1-5; S.1-5; Co, Anterior primary divisions of spinal nerves, connected to the gangliated cord of the sympathetic by rami communicantes, white (double lines) and gray (single lines); Oes, Œsophagus and œsophageal plexus; Ao, Aorta and aorta plexus; Va, Vagus nerve joining œsophageal plexus; S.1, Great splanchnic nerve; X, Great splanchnic ganglion; S.2, Small splanchnic nerve; S.3, Least splanchnic nerve; Co, Coronary artery and plexus; Spl, Splenic artery and plexus; H, Hepatic artery and plexus; SL, Semilunar ganglion; Di, Diaphragm; S.R, Suprarenal capsule; Re, Renal artery and plexus; S.M, Superior mesenteric artery and plexus; Sp, Spermatic artery and plexus; I.M, Inferior mesenteric artery and plexus; Hy, Hypogastric nerves and plexus; Rec, Rectal plexus; Ut, Uterine plexus; Ves, Vesical plexus; V.V.V, Visceral branches from sacral nerves.

for the lower limbs; (*e*) secretory, and (*f*) sensory fibres for the abdominal viscera. The thoracic part of the sympathetic cord is placed upon the heads of the ribs, and is covered over by the pleura.

The **branches** from the gangliated cord are, as in the neck, divisible into two sets—(*A*) Central branches, communicating with other nerves, and (*B*) peripheral branches, distributed in a plexiform manner to the thoracic and abdominal viscera.

**Central Communicating Branches.**—The **white rami communicantes** from the thoracic nerves have already been described. Passing forwards from the beginning of the anterior primary divisions of the nerves, they become connected with the ganglia or the commissural cord of the sympathetic.

The **gray rami communicantes** are branches arising irregularly from each thoracic ganglion, which, passing backwards along with the white rami, join the anterior primary divisions of the thoracic nerves.

**Peripheral Branches of Distribution.**—These branches arise irregularly from the ganglia and the commissural cord. They are composed of non-medullated fibres (splanchnic efferent) derived from the ganglion cells, and medullated fibres (splanchnic efferent and afferent) derived directly from the white rami, without the intervention of the cells of the ganglia.

1. **Pulmonary Branches.**—From the gangliated cord opposite the second, third, and fourth ganglia fine filaments arise which join the posterior pulmonary plexus.

2. **Aortic Branches.**—The upper part of the thoracic aorta receives fine branches from the upper five thoracic ganglia.

3. **Splanchnic Nerves.**—Three nerves arise from the lower part of the gangliated cord, partly from the ganglia themselves, and partly from the commissural cord between the ganglia. Passing downwards over the bodies of the thoracic vertebræ they pierce the diaphragm, to end in the abdomen.

(*a*) The **great splanchnic nerve** (n. splanchnicus major) arises from the gangliated cord between the fifth and ninth ganglia. By the union of several irregular strands a nerve of considerable size is formed, which descends in the posterior mediastinum, and piercing the crus of the diaphragm, joins at once the upper end of the *semilunar ganglion* of the solar plexus. In its course in the thorax the **great splanchnic ganglion** (g. splanchnicum) is formed upon the nerve. It is more prominent in the fœtus than in the adult. From both nerve and ganglion branches arise in the thorax for the supply of the œsophagus and descending thoracic aorta (Fig. 544).

(*b*) The **small splanchnic nerve** (n. splanchnicus minor) arises from the gangliated cord opposite to the ninth and tenth ganglia. It passes over the bodies of the lower thoracic vertebræ, pierces the diaphragm near or along with the great splanchnic nerve, and ends in the **solar plexus** (*aortico-renal ganglion*).

(*c*) The **least splanchnic nerve** (n. splanchnicus imus) arises from the last thoracic ganglion of the sympathetic, or it may be a branch of the smaller splanchnic nerve. It pierces the diaphragm, and ends in the *renal plexus*.

## THE LUMBAR PART OF THE SYMPATHETIC CORD.

The lumbar part of the sympathetic cord is placed upon the bodies of the lumbar vertebræ, internal to the origins of the psoas muscle, and in front of the lumbar vessels. It is connected with the thoracic portion of the cord by an attenuated commissural cord, which either pierces or passes behind the diaphragm. It is continuous below with the sacral portion of the cord by a commissure, which passes behind the common iliac artery. It is joined by medullated fibres (white rami communicantes) from the first two lumbar spinal nerves, and it contains as well medullated fibres continued down from the lower part of the thoracic gangliated cord, and derived from the visceral branches (white rami communicantes) of the lower thoracic nerves. This part of the gangliated cord is characterised by great irregularity in the number of the ganglia. They are usually four in number, but there are frequently more (up to eight); and in extreme

cases fusion may occur to such an extent that the separation of individual ganglia becomes impossible.

**White rami communicantes.**—The first two (or three) lumbar spinal nerves possess visceral branches which form white rami communicantes joining the upper lumbar ganglia or the gangliated cord. These nerves form the lower limit of the thoracico-lumbar visceral branches of the spinal nerves. They comprise vaso-motor fibres (for the genital organs), and motor fibres for the bladder and uterus.

**Central Communicating Branches.** — **Gray rami communicantes** pass from the gangliated cord to the anterior primary divisions of the lumbar nerves in an irregular manner. One ramus may divide so as to supply branches to two adjacent spinal nerves; or a spinal nerve may be joined by two to five separate gray rami from the gangliated cord.

The rami course beneath the origin of the psoas magnus muscle and over the bodies of the vertebræ. Gray rami sometimes pierce the fibres of the psoas muscle.

**Peripheral Branches of Distribution.**—From the lumbar gangliated cord numbers of small branches arise irregularly, and pass inwards to supply the abdominal aorta, reinforcing the **aortic plexus** (from the solar plexus).

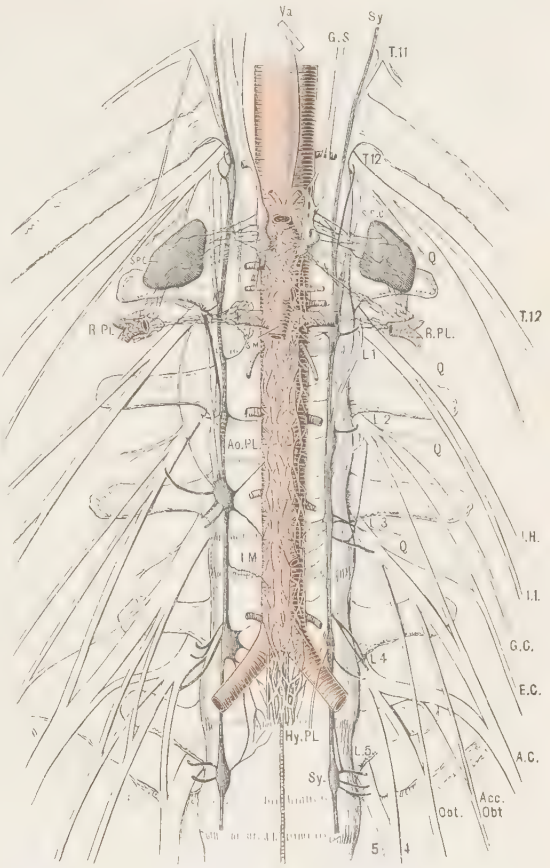

FIG. 545.—THE LUMBAR PORTION OF THE SYMPATHETIC GANGLIATED CORD AND LUMBAR PLEXUS. (From a dissection.)

T.11, T.12, L.1, L.2, L.3, L.4, L.5, Anterior primary divisions of spinal nerves, with white and gray rami communicantes.

Obt, Accessory obturator nerve; Obt, Obturator nerve 4, 5, Lumbo-sacral cord.

## THE SACRAL PART OF THE GANGLIATED CORD.

The sacral part of the gangliated cord, like the cervical and lower lumbar portions of this system, receives no white rami communicantes from the spinal nerves. The **visceral branches** (*pelvic splanchnic*) of the third, and usually, also the second or fourth sacral nerves, enter the pelvic plexus without being directly connected with the gangliated cord. These nerves, however, are to be regarded as homologous with the white rami communicantes of the thoracico-lumbar nerves (*abdominal splanchnic*). They convey to the pelvic viscera—(1) motor and inhibitory fibres for rectum, uterus, and bladder, (2) vaso-dilator fibres for the genitals, and (3) secretory fibres for the prostate gland.

This portion of the cord is placed in front of the sacrum, internal to the anterior sacral foramina. It is connected above by a commissural cord with the lumbar portion of the sympathetic, and below it ends in a plexiform union over the coccyx with the cord of the other side, the two being frequently connected by the **ganglion impar** or **coccygeal ganglion**. The number of ganglia is variable: there are

commonly four. They are of small size, gradually diminishing from above downwards.

**Central communicating branches** arise irregularly in the form of **gray rami communicantes** from the sacral ganglia, and join the anterior primary divisions of the sacral and coccygeal nerves.

**Peripheral Branches of Distribution.** (1) **Visceral branches** of small size arise from the upper part of the gangliated cord, and pass inwards to join the **pelvic plexus** (see below).

(2) **Parietal branches,** also of small size, ramify over the front of the sacrum, and form, in relation to the middle sacral artery, a plexiform union with branches from the gangliated cord of the other side.

## SYMPATHETIC PLEXUSES.

It has already been seen that the peripheral branches of the sympathetic gangliated cord throughout its length are characterised by forming or joining plexuses in their neighbourhood.

The **cervical sympathetic ganglia** and nerves give rise to the carotid and cavernous plexuses; the external carotid, pharyngeal, thyroid, vertebral, and subclavian plexuses; and they send important branches to the cardiac plexuses (described along with the pneumogastric nerve).

The **thoracic ganglia** send branches to join the pulmonary and œsophageal plexuses (described along with the pneumogastric nerve). They form plexuses on the thoracic aorta, and by means of the splanchnic nerves they form the chief source of the solar plexus.

### The Solar and Pelvic Plexuses.

These great plexuses serve to distribute nerves to the viscera and vessels of the abdominal and pelvic cavities. Taken together they include three plexuses—the solar plexus, hypogastric plexus, and the pelvic plexuses. They are constituted by peripheral branches of the lower thoracic, lumbar, and upper sacral parts of the gangliated cord of the sympathetic; and they are related to the central nervous system by means of the visceral branches (white rami communicantes) of the lower thoracic and upper lumbar nerves on the one hand, and by the visceral branches of the second and third, or third and fourth sacral nerves, on the other hand. The thoracico-lumbar series join the sympathetic cord, and reach the solar plexus mainly through the splanchnic nerves, and to a lesser extent through the lumbar gangliated cord. The sacral series enter the pelvic plexus without connexion with the sympathetic cord. The hypogastric plexus serves as a connecting link between the solar and pelvic plexuses.

The **solar plexus** lies on the posterior abdominal wall in relation to the abdominal aorta and behind the stomach. It is composed of three elements: the **cœliac plexus** surrounding the origin of the cœliac axis between the crura of the diaphragm, and two **semilunar ganglia,** each lying on the corresponding crus of the diaphragm, and overlapped by the suprarenal capsule, and on the right side by the inferior vena cava. The plexus is continuous with subordinate plexuses, diaphragmatic, suprarenal, renal, superior mesenteric and aortic; and by means of **the hypogastric nerves** the aortic plexus becomes continued into the **hypogastric plexus,** which again forms the chief origin of the **pelvic plexuses.**

The **semilunar ganglia** constitute the chief ganglionic centres in the solar plexus. They are irregular in form. They are often partially subdivided, and one detached portion at the lower end is named the **aortico-renal ganglion.** Other small scattered masses of cells are present in the cœliac plexus (**ganglia cœliaca**). At the upper end the semilunar ganglion receives the great splanchnic nerve. The aortico-renal ganglion at its lower end receives the smaller splanchnic nerve. Branches from the ganglion radiate in all directions—inwards to join the cœliac plexus, upwards to form the diaphragmatic plexus, outwards to the suprarenal plexus, downwards to the renal, superior mesenteric, and aortic plexuses.

The **cœliac plexus** forms a considerable plexiform mass surrounding the cœliac axis. It consists of a dense meshwork of fibres with ganglia intermingled (g. cœliaca), joined by numerous branches from the semilunar ganglion on each side, and by branches from the right pneumogastric nerve. It is continuous below with the superior mesenteric and aortic plexuses. Investing the cœliac axis, it forms subsidiary plexuses which accompany the branches of the artery. The **coronary plexus** supplies branches to the œsophagus and stomach; the **hepatic plexus** supplies branches to the liver and gall-bladder, stomach, duodenum, and pancreas; and the **splenic plexus** sends offsets to the spleen, pancreas, and stomach.

**Subordinate plexuses** are formed on the aorta and its branches by nerves derived from the solar plexus (semilunar ganglia and cœliac plexus).

*a.* The **diaphragmatic plexus** consists of fibres arising from the semilunar ganglion, and accompanies the inferior phrenic artery. Besides supplying the diaphragm, it gives branches to the suprarenal plexus, and (on the right side) to the inferior vena cava, (on the left side) to the œsophagus. It communicates on each side with the phrenic nerve. At the junction of the plexus and the phrenic nerve of the right side a ganglion is formed (**diaphragmatic ganglion**).

*b.* The **suprarenal plexus** is of most considerable size. It is mainly derived from branches of the semilunar ganglion, reinforced by nerves from the lower part of the solar plexus which stream outwards on the capsular arteries. It is joined by branches from the diaphragmatic plexus above and from the renal plexus below. The nerves enter the substance of the suprarenal capsule.

*c.* The **renal plexus** is derived from (1) branches of the semilunar ganglion, and (2) fibres from the aortic plexus, extending outwards along the renal artery to the hilum of the kidney. It receives also the least splanchnic nerve, and is connected by numerous branches to the suprarenal plexus.

*d.* The **superior mesenteric plexus** is inseparable above from the cœliac plexus, and is joined on either side by fibres from the semilunar ganglion. It is continuous below with the aortic plexus. A separate detached ganglionic mass (**superior mesenteric ganglion**) is present in

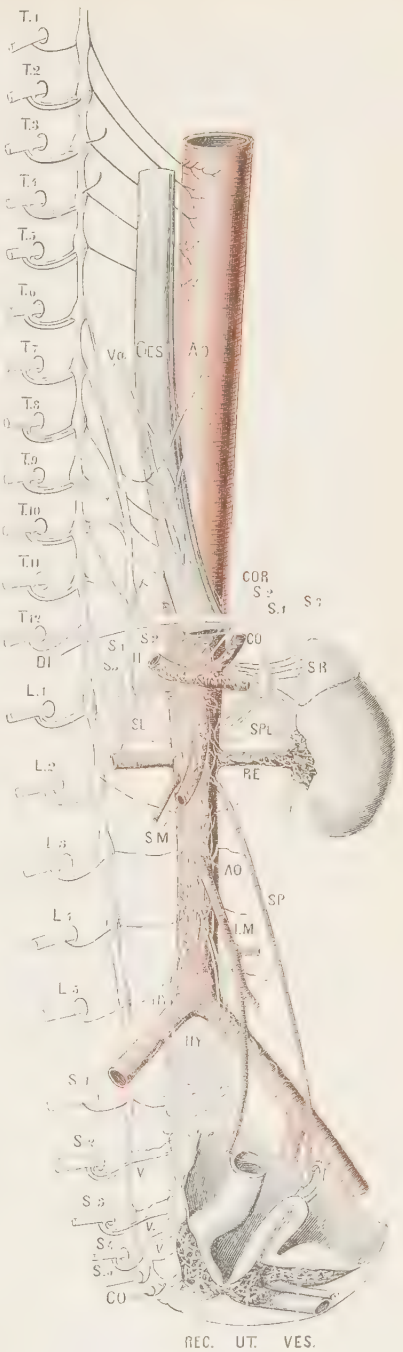

Fig. 546.—The Arrangement of the Sympathetic System in the Thorax, Abdomen, and Pelvis.

T.1-12; L.1-5; S.1-5; Co, Anterior primary divisions of spinal nerves, connected to the gangliated cord of the sympathetic by rami communicantes, white (double lines) and gray (single lines); Oes, Œsophagus and œsophageal plexus; Ao, Aorta and aortic plexus; Va, Vagus nerve joining œsophageal plexus; S.1, Great splanchnic nerve; X, Great splanchnic ganglion; S.2, Small splanchnic nerve; S.3, Least splanchnic nerve; Co, Coronary artery and plexus; Spl, Splenic artery and plexus; H, Hepatic artery and plexus; S.L, Semilunar ganglion; Di, Diaphragm; S.R, Suprarenal capsule; Re, Renal artery and plexus; S.M, Superior mesenteric artery and plexus; Sp, Spermatic artery and plexus; I.M, Inferior mesenteric artery and plexus; Hy, Hypogastric nerves and plexus; Rec, Rectal plexus; Ut, Uterine plexus; Ves, Vesical plexus; V.V.V, Visceral branches from sacral nerves.

the plexus. Accompanying the superior mesenteric artery the plexus forms subordinate plexuses around the branches of the vessel. The plexuses in the mesentery at first surround the intestinal arteries, but near the intestine they form fine plexuses between the layers of the mesentery, from which branches pass to the wall of the gut. This plexus supplies the small intestine, cæcum, vermiform appendix, ascending and transverse portions of the colon.

*e.* The **aortic plexus** is the continuation downwards of the solar plexus around the abdominal aorta. It is continuous above with the superior mesenteric and solar plexuses; it is reinforced by the peripheral branches of the lumbar gangliated cord of the sympathetic; and it is connected with the hypogastric plexus below by the **hypogastric nerves**. Besides investing and supplying the aorta, the plexus contributes to various subordinate plexuses on the branches of the artery. It contributes to the suprarenal and renal plexuses, and it gives rise to the spermatic or ovarian and the inferior mesenteric plexuses.

The **spermatic plexus** invests and accompanies the spermatic artery. It is derived from the aortic plexus, and receives a contribution from the renal plexus. It supplies the spermatic cord and testicle.

The **ovarian plexus** in the female arises like the spermatic plexus. It accompanies the ovarian artery to the pelvis, and supplies the ovary, broad ligament, and Fallopian tube. It forms communications in the broad ligament with the **uterine plexus** (from the pelvic plexus), and sends fibres to the uterus.

The **inferior mesenteric plexus** is a derivative from the aortic plexus, prolonged along the inferior mesenteric artery. It forms subordinate plexuses on the branches of the artery (colic, sigmoid, and superior hæmorrhoidal), and is distributed to the descending colon, iliac colon, pelvic colon, and upper part of the rectum.

The **hypogastric nerves** form the continuation of the aortic plexus into the pelvic cavity. They consist of numerous plexiform bundles of nerve-fibres which descend along the front and back of the bifurcation of the aorta and the origin of the common iliac arteries, and over the sacral promontory, where, becoming inextricably mingled, they constitute the hypogastric plexus.

The **hypogastric plexus** is continued downwards in front of the sacrum on either side of the rectum, and ends in the pelvic plexuses.

The **pelvic plexuses** are formed by the separation of the hypogastric plexus into two halves on either side of the rectum. Each is joined by fibres from the upper part of the sacral portion of the gangliated cord of the sympathetic, and by the **visceral branches** (white rami communicantes) from the second and third or third and fourth sacral nerves. Accompanying the internal iliac artery and its branches each pelvic plexus gives off subordinate plexuses for the pelvic viscera.

*a.* The **hæmorrhoidal plexus** supplies the rectum, and joins the superior hæmorrhoidal plexus from the inferior mesenteric plexus.

*b.* The **vesical plexus** accompanies the vesical arteries to the bladder-wall. Besides supplying the muscular wall and mucous membrane of the bladder, it forms subordinate plexuses for the lower part of the ureter, the vesicula seminalis, and the vas deferens.

*c.* The **prostatic plexus** is of considerable size. It is placed on either side of the gland, and in addition to supplying its substance and the prostatic urethra, it sends offsets to the neck of the bladder and the vesicula seminalis. It is continued forwards on each side to form the **cavernous plexus** of the penis (plex. cavernosus penis). Bundles of nerves pierce the layers of the triangular ligament, and after supplying the membranous urethra at the root of the penis, give off branches which enter and supply the corpus cavernosum. The cavernous nerves communicate with branches of the pudic nerve, and give offsets to the corpus spongiosum and the spongy portion of the urethra.

*d.* The **uterine plexus** passes upwards for a short distance with the uterine artery between the layers of the broad ligament, and is then distributed to the surfaces and substance of the organ. It communicates between the layers of the broad ligament with the ovarian plexus.

The **vaginal plexus** is formed mainly by the visceral branches of the sacral

nerves entering the pelvic plexus. It supplies the wall and mucous membrane of the vagina and urethra, and provides a **cavernous plexus** for the clitoris (plex. cavernosus clitoridis). The uterine and vaginal plexuses of the female correspond to the prostatic plexus of the male.

## DEVELOPMENT OF THE SYMPATHETIC SYSTEM.

There are two diametrically opposite views of the mode of development of the sympathetic system.

In birds and mammals the first rudiment of the sympathetic cord occurs in the formation of a longitudinal unsegmented column of mesoblastic cells (which stain more deeply than the mesoblast in which they lie) on either side of the aorta, and coterminous with it. This column of cells becomes joined at an early stage by the **visceral branches** of the spinal nerves which grow inwards from the main nerve trunks into the splanchnic area, and result from the division of the nerve into somatic and visceral parts. These visceral branches constitute the **white rami communicantes**. They receive contributions usually from both dorsal and ventral roots, and gradually approaching the above-mentioned column of mesoblastic cells, they become intimately associated with the cells. In some cases fibres of the visceral nerves pass over the cellular column into the splanchnic area without connexion with it (Fig. 548). By the junction of these visceral nerves with the cells of the column, certain cells persist and produce the **ganglia**. The intervening portions of the column, by changes in the cells, and by the addition possibly of fibres belonging to the visceral nerves, give rise to the **commissural cords**. The cellular column, besides producing the gangliated cord, by the further growth of its cells and their extension centrally and peripherally, produces the **gray rami communicantes**, parts of the **peripheral branches**, and the **peripheral** (collateral and terminal) **ganglia**, as well as the medullary portion of the **suprarenal capsule**. The cervical, lower lumbar, and sacral portions of the sympathetic gangliated cord are secondary extensions from the more primitive condition, gradually growing upwards and downwards along the main vessels. These portions of the system are not provided with white rami communicantes. The ganglia of the sympathetic assume their segmented appearance (1) from the persistence of the primitive cells and their connexion with the spinal nerves by means of the white and gray rami communicantes, and (2) from the way in which the primitive column is moulded by the surrounding structures (bones, segmental arteries, etc.)

Fig. 547.—The Development of the Sympathetic Gangliated Cord.

Sy, Sympathetic cord; Spl, Splanchnic branches of spinal nerves (white rami communicantes); V.S, Vertebral segments; D.G, Dorsal ganglia.

Another account of the development of the sympathetic system, supported by high authority, describes the gangliated cord as an outgrowth of the dorsal ganglia of the spinal nerves. It is said that each ganglion gives off a bud at its lower end, which, growing inwards into the splanchnic area, becomes attached to the trunk of the spinal nerve just beyond the union of the dorsal and ventral roots. The bud still extending inwards into the splanchnic area, remains associated with the nerve by an attenuated stalk. These buds, it is said, become the ganglia, which, after reaching their permanent place in the splanchnic area, are supposed to extend upwards and downwards so as to coalesce and form a beaded chain of ganglia. The stalks connecting the ganglia with the spinal nerves become the white rami communicantes. This mode of development does not satisfactorily account for several important features of the sympathetic system—the development of those parts of the gangliated cord which possess no white rami, the

absence of a real segmental character in the cord (remarkably shown in the fœtus), and the constancy of continuity in the gangliated cord. No instance is recorded of a hiatus between two ganglia. It is a tempting view on the other hand, as it ascribes to the one germinal layer (epiblast) the formation of all the elements of the nervous system, and it brings the sympathetic ganglia into serial homology with isolated ganglia on the cranial nerves (*e.g.* the ciliary, spheno-palatine, and otic, on the trigeminal nerve).

FIG. 548.—SECTION THROUGH THE SYMPATHETIC GANGLIATED CORD OF AN EMBRYO.

Showing the connexion with the ganglion (Sy) of the white rami communicans (Spl); (α) a portion of the ramus joining the ganglion; (β) fibres passing over the cord, accompanied by a stream of cells; (γ) continuous with those of the ganglion; (Ao) Aorta.

### The Morphology of the Sympathetic System.

From a consideration of its structure, functions, and development, there appear to be two separate structures represented in the sympathetic nervous system—the **spinal** and the **sympathetic elements**. The structure of the system presents a union of two distinct elements—fibres of cerebro-spinal origin and "sympathetic" cells and fibres. While the function of the gangliated cord and its branches seems to be absolutely dependent upon the cerebro-spinal nervous system, it is certain that the cells and fibres of the sympathetic system possess a vital activity apart from their connexion with the central nervous system. In the development of the sympathetic it is at least highly probable that a mesoblastic rudiment or precursor forms the basis of the sympathetic system, which is secondarily joined by nerve-fibres from the roots of the spinal nerves.

Morphologically this part of the nervous system is essentially a longitudinal cord or column, associated with involuntary muscles and glandular tissues, and particularly related to the organs in the splanchnic area. Like other longitudinal structures in the body, and especially like the organs of the splanchnic area, the sympathetic system is not truly segmental. The gangliated cord is only quasi-segmental, the segmentation being attributable to its junction with the visceral branches of the spinal nerves. The peripheral branches from the gangliated cord are not segmental; even the gray rami are not properly metameric, but, like the ganglia, assume a segmental character in consequence of their connexions with the spinal nerves.

The phylogenetic relation of the sympathetic and the cerebro-spinal elements in the system it is impossible to determine. It may be that the sympathetic system is the representative of an ancient architecture independent of the cerebro-spinal nervous system, the materials of which are utilised for a more modern nervous system; or it may be that the correlation of spinal nerves and sympathetic are both the consequences of the formation of new organs and structures in the splanchnic area. Examined in every light, it possesses features which effectually differentiate it from the cerebro-spinal system, although it has become inextricably united with it and subservient to it.

# THE ORGANS OF SENSE AND THE INTEGUMENT.

By Robert Howden.

## THE NOSE.

The nose constitutes the peripheral part of the organ of smell (organon olfactus), since to the upper portion of its mucous lining the branches of the olfactory nerve are distributed. It consists of an external portion, the outer nose, which projects from the face, and of an internal part, or cavum nasi, which is divided by a vertical septum into right and left cavities or fossæ.

The **outer nose**, or nasus externus, forms a more or less triangular pyramid, of which the upper angle is termed the **root** (radix nasi), and is usually separated from the glabella by a depression, while its **base** (basis nasi), directed downwards, is perforated by the apertures of the nostrils (anterior nares). Its free angle is named the **point** (apex nasi), and the anterior border, joining root and point, is termed the **dorsum nasi**; the upper part of the dorsum is supported by the nasal bones, and is named the **bridge**. The lateral aspects of the nose are continuous with the eyelids above and with the cheeks below, forming with the latter a varying angle. Each lateral surface ends inferiorly in a mobile and expanded portion, the **ala nasi**, which forms the outer boundary of the anterior nares, and is limited above by a furrow, the **alar sulcus**. The skin covering the nose is thin and movable over the root, but thick and adherent over the point and alæ, where it contains numerous large sebaceous glands.

The arterial supply of the outer nose is derived from the facial and ophthalmic arteries, and its veins drain themselves into the facial and ophthalmic trunks. Its principal lymphatic vessels follow the course of the facial vein and open into the submaxillary lymphatic glands. From the root of the nose one or two vessels curve backwards above the orbit to reach the upper parotid glands, while a third group runs below the orbit to the lower parotid glands. The facial nerve supplies its muscles, while the sensory nerves for the skin are the infratrochlear and nasal branches of the ophthalmic nerve and the infraorbital branch of the superior maxillary nerve.

The nose presents great variety as to its size and shape, and certain well-defined types, such as aquiline, Grecian, etc., are described. The relation which its breadth, measured across the alæ, bears to its length, measured from root to point, is termed the nasal index, and is expressed thus:

$$\frac{\text{greatest breadth} \times 100}{\text{greatest length.}}$$

In white races this index is below 70 (leptorhines); in yellow races, between 78 and 85 (mesorhines); and in black races, above 85 (platyrhines).

### CARTILAGES OF THE NOSE.

In addition to the bony skeleton of the nose there are five chief cartilages (cartilagines nasi) which contribute to the production and maintenance of its shape. These are named—(*a*) the cartilage of the septum, and (*b*) the upper and lower lateral cartilages on each side.

The **cartilage of the septum** (cartilago septi nasi, Fig. 549) is of an irregularly quadrilateral form. Its postero-superior edge is attached to the mesethmoid; its postero-inferior margin to the vomer and intermaxillary crest. Its antero-superior

border is thick, and is fixed above to the back of the internasal suture; below the level of the nasal bones it is continued, on either side, into the upper lateral cartilages, which may be looked upon as its wing-like expansions. The lower part

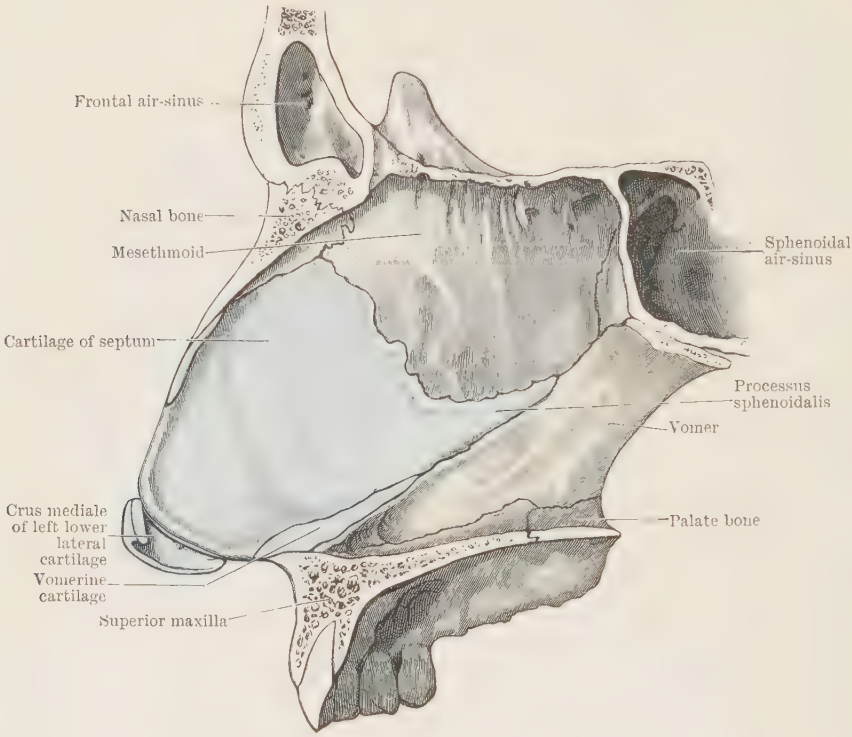

Fig. 549.—Lateral View of Nasal Septum.

of this border is separated by a fissure from the upper lateral cartilages, and extends downwards between the inferior lateral cartilages, to which it is attached by fibrous tissue. In this fibrous tissue a small sesamoid cartilage is usually seen on each side of the middle line. Its antero-inferior border is short, and is attached by fibrous tissue to the mesial plates of the lower lateral cartilages, while its anterior angle is rounded and does not reach as far as the point of the nose. The lowest part of the nasal septum is not formed by the septal cartilage, but by the mesial plates of the lower lateral cartilages and by the integument, and, being freely movable, is termed the **septum mobile nasi**. The cartilage of the septum may be prolonged backwards (especially in children) as a tongue-like process into the angle between the vomer and ethmoid. This process, varying in width from 4-6 mm., is named the **processus sphenoidalis septi cartilaginei**, and sometimes reaches as far as the body of the sphenoid.

Lying along the lower edge of the cartilage of the septum, and best seen on making a coronal section of the nose, are a couple of elongated cartilaginous strips. Each measures from 6-12 mm. in length, is attached to the vomer, and is named the **vomerine cartilage** (cartilago vomeronasalis, Jacobsoni).

The **upper lateral cartilage** (cartilago nasi lateralis, Figs. 550, 551) is triangular in shape and situated immediately below the nasal bone, to which and to the superior maxilla its thin posterior border is attached. Its anterior edge is thick and its upper part is directly continuous with the cartilage of the septum. Its lower margin is joined by fibrous tissue to the upper edge of the lower lateral cartilage.

The **lower lateral cartilage** (cartilago alaris major, Figs. 550, 551, 552) encircles the anterior part of the nostril and assists in keeping it open. It consists of two plates, outer and inner, which are continuous with each other in a rounded angle at the point of the nose. The **outer plate**, or crus laterale, is oval in shape and is attached to the upper lateral cartilage and to the superior maxilla by fibrous tissue.

Continuous with its postero-superior angle are two or three small cartilaginous pieces (cartilagines alares minores), while sometimes a horizontal furrow cuts off a narrow linear part from its upper aspect. The lower edge of the outer plate does not descend as far as the lateral boundary of the nostril, the ala being devoid of cartilage and composed merely of fatty and connective tissue covered by skin. The **inner plate**, or crus mediale (Fig. 552), bounds the inner aspect of the nostril and lies in the septum mobile nasi, below the anterior part of the cartilage of the septum. The mesial plates of the two cartilages are separated in front by a notch which corresponds with the point of the nose, and each curves slightly outwards posteriorly and ends in a rounded extremity.

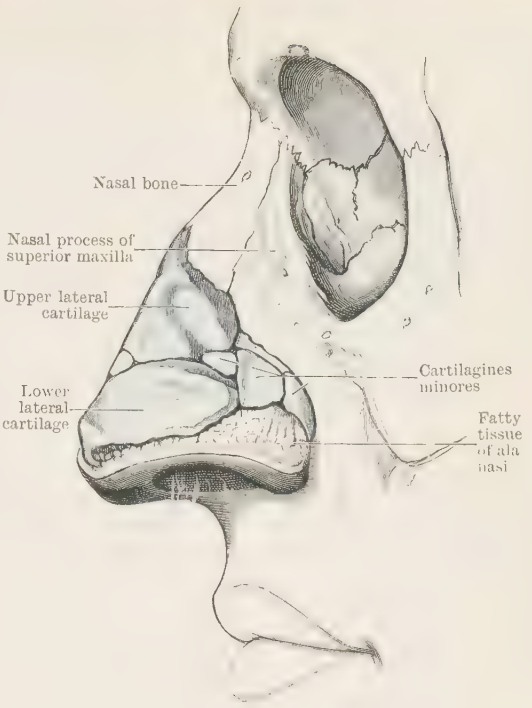

Fig. 550.—Profile View of the Bony and Cartilaginous Skeleton of the Nose.

## NASAL FOSSÆ.

The **nasal fossæ** (Fig. 553) are two in number and are placed one on either side of the middle line. They extend from the anterior to the posterior nares or choanæ, and open through the latter into the naso-pharynx. Their bony boundaries are described in the section on Osteology (p. 173). On the lateral wall of each are found the orifices of the frontal, ethmoidal, sphenoidal, and maxillary sinuses, together with that of the nasal duct.

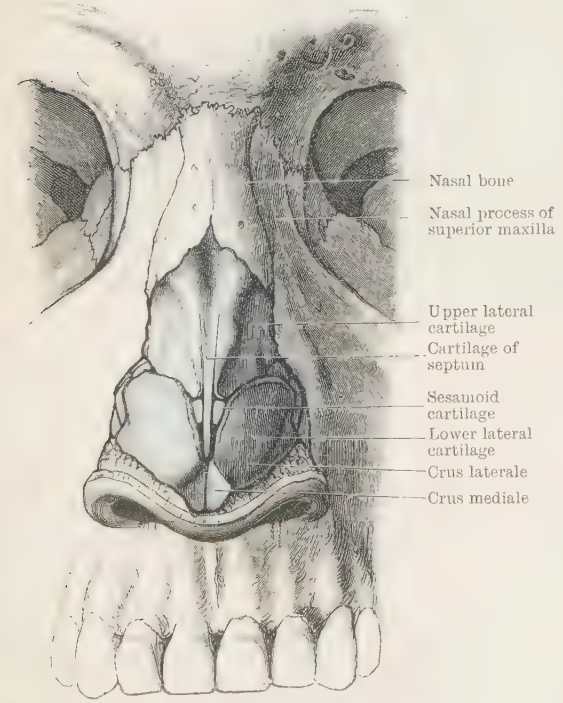

Fig. 551.—Front View of the Bony and Cartilaginous Skeleton of the Nose.

Immediately above the aperture of the nostril is a slightly expanded area, the **vestibule** (vestibulum nasi). This is bounded externally by the lower lateral cartilage, and, internally, by the lower part of the septum, and is prolonged towards the tip of the nose as a small pouch, termed the **ventricle**. Partly subdivided by a curved ridge, the vestibule is lined by skin and contains hairs and sebaceous glands. The hairs, or vibrissæ, springing from its lower half, are stout and curved downwards to guard the entrance to the nostril. The upper part of the vestibule is smooth, and is limited above and behind by a slightly-marked arched prominence, the **limen nasi**, beyond which the fossa is lined by mucous membrane.

The nasal fossa above and behind the vestibule is divided into two parts, viz. an upper or olfactory, and a lower or respiratory region. The **olfactory part,** or regio olfactoria, is a narrow, slit-like cavity, and comprises the region of the superior turbinated bone, together with a corresponding portion of the septum. The **respiratory part**, or regio respiratoria, is expanded, and includes the lower and remaining parts of the fossa.

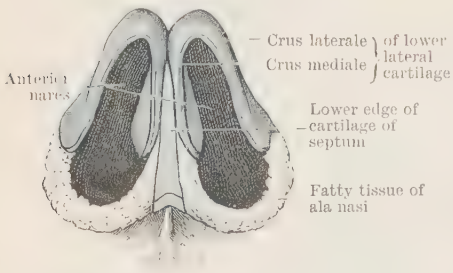

Fig. 552.—Cartilages of Nose from Below.

**Inner Wall or Septum Nasi** (Fig. 549).—Where the bony septum is deficient, below and in front, the gap is filled by the septal cartilage. Until the seventh year the nasal septum lies, as a rule, in the mesial plane, but after this age is very often deflected to one or other side—more frequently to the right—the deflection being usually greatest along the line of junction of the vomer and mesethmoid. Deflection of the septum is more common in European than in non-European skulls—occurring in about 53 per cent of the former and in about 28 per cent of the latter (Zuckerkandl, *Anatomie der Nasenhöhle*, 1892). Associated with, or apart from, this deviation, lateral crests or spurs of bone are found, in about 20 per cent of skulls, projecting from the septum into one or other nasal fossa. In the floor of the fossa, close to the lower edge of the septal cartilage and immediately over the incisive foramen, a slight depression, the **recessus naso-palatinus**, may be seen. It is directed downwards and forwards, and indicates the position of the communication which originally existed between the nasal and buccal cavities. In the septum, a little above and in front of this depression, is a minute orifice, not always recognisable, from which a blind pouch extends upwards and backwards for a distance of from 2 to 9 mm. This is the rudimentary **organ of Jacobson** (organon vomero-nasale) and is supported by the vomerine cartilage. In many of the lower animals this organ is well developed (Fig. 554), and probably plays a part in the sense of smell, being lined by epithelium similar to that in the olfactory part of the nose and supplied by branches of the olfactory nerve.

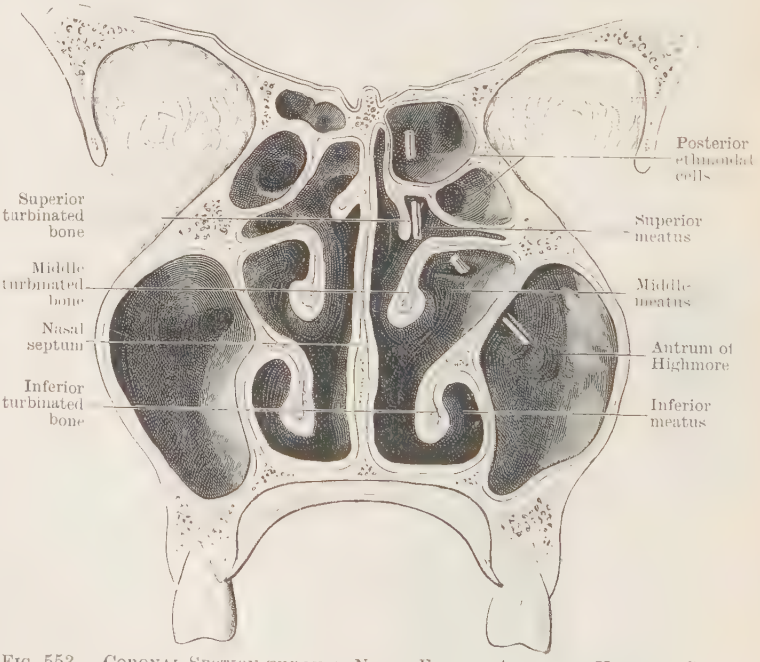

Fig. 553.—Coronal Section through Nasal Fossæ; Anterior Half of Section Viewed from Behind.

**Outer Wall** (Fig. 455).—Above the superior turbinated bone is a narrow recess, the **recessus spheno-ethmoidalis**, into the posterior part of which the sphenoidal air-sinus opens. The **superior meatus** (meatus nasi superior) is a short oblique fissure, directed downwards and backwards under cover of the superior turbinated bone; into its antero-superior portion the posterior ethmoidal cells open by one or more orifices.

The narrow slit-like interval between the nasal septum and the inner aspect of the middle turbinated bone is named the **olfactory cleft** or **sulcus**. The **middle meatus** (meatus nasi medius), situated below and to the outer side of the middle turbinated bone, is a roomy passage, and is continued forwards into a slightly depressed area termed the **atrium meatus nasi**, which lies immediately above the vestibule. The atrium is limited above and in front by a low ridge, the **agger nasi**, the representative of the naso-turbinal found in many animals. On raising or removing the middle turbinated bone a rounded elevation, **bulla ethmoidalis**, caused by the middle ethmoidal air-cells, is seen. This varies in size and is directed downwards and forwards, whilst opening either on it or above it are the orifices of the middle ethmoidal cells. Curving upwards and forwards, below and in front of the bulla ethmoidalis, is a deep, narrow groove, the **hiatus semilunaris**, into which the anterior ethmoidal cells and the antrum of Highmore open. The opening from the antrum (ostium maxillare) is situated near the lower and back part of the hiatus, and is placed near the

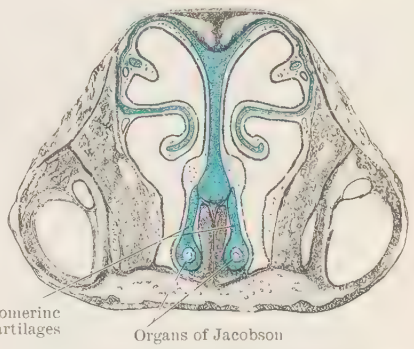

FIG. 554.—SECTION THROUGH NOSE OF KITTEN, showing position of Jacobson's organ.

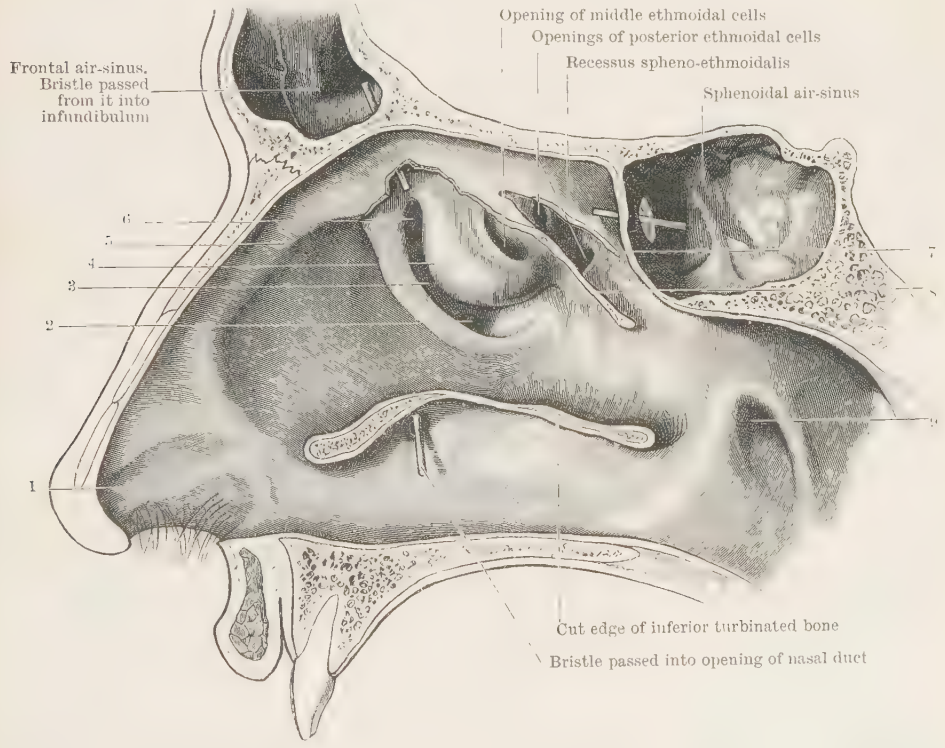

FIG. 555.—VIEW OF THE OUTER WALL OF THE NOSE—THE TURBINATED BONES HAVING BEEN REMOVED.

1. Vestibule.
2. Opening of antrum of Highmore.
3. Hiatus semilunaris.
4. Bulla ethmoidalis.
5. Agger nasi.
6. Opening of anterior ethmoidal cells.

8. Cut edge of middle turbinated bone.
9. Pharyngeal orifice of Eustachian tube.

roof of the antral cavity. A second opening (ostium accessorium) is not infrequently seen in the middle meatus above the posterior part of the inferior turbinated bone. The middle meatus extends upwards and forwards, and, becoming narrowed, is continued into the **infundibulum** or channel leading into the frontal air-sinus. The **inferior meatus** (meatus nasi inferior) lies below the inferior turbinated bone,

under cover of the anterior part of which is found the slit-like orifice of the nasal duct (see p. 741).

**Mucous Membrane** (membrana mucosa nasi).—The Schneiderian or nasal mucous membrane is thick, highly vascular, and firmly bound to the subjacent periosteum and perichondrium. It is continuous, through the choanæ, with the mucous lining of the nasopharynx; through the nasal duct and lachrymal canals, with the conjunctiva; and, through the apertures leading into the air-sinuses, with the delicate lining of these cavities.

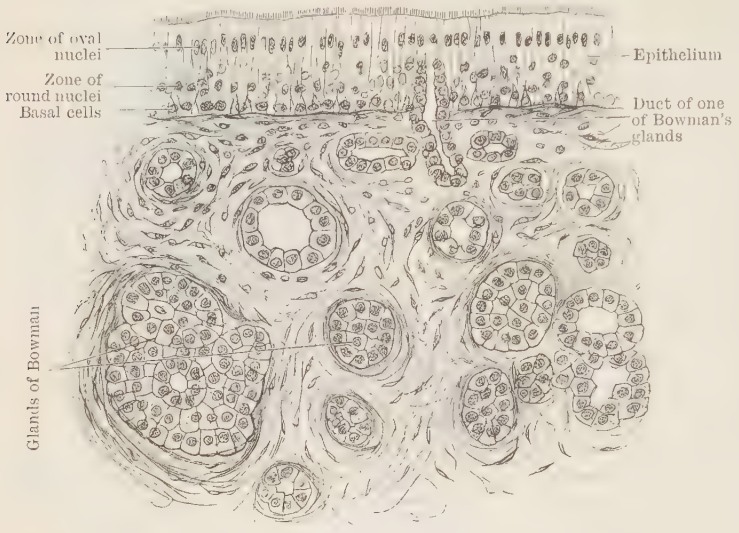

Fig. 556.—Section through the Olfactory Mucous Membrane.

Throughout the respiratory region it is covered by columnar, ciliated epithelium, interspersed amongst which are goblet or mucin cells, whilst between the bases of the columnar cells smaller pyramidal cells are interpolated. It contains a freely anastomosing venous plexus, which in some parts, *e.g.* over the inferior turbinated bones, forms a kind of cavernous tissue (plexus cavernosus concharum). Many acinous glands, secreting a watery fluid, are embedded in it, and are especially large and numerous in the posterior half of the nasal fossæ, while in children it contains a considerable amount of adenoid tissue.

In the olfactory region the mucous membrane is yellowish in colour, more delicate, and covered by non-ciliated columnar epithelium (Figs. 556, 557). Embedded in it are numerous tubular and often branched glands, the **glands of Bowman** (gl. olfactoriæ); these are lined by polygonal cells and open by fine ducts on its free surface. The epithelium covering the olfactory region consists of: (1) supporting cells, (2) olfactory cells, and (3) basal cells.

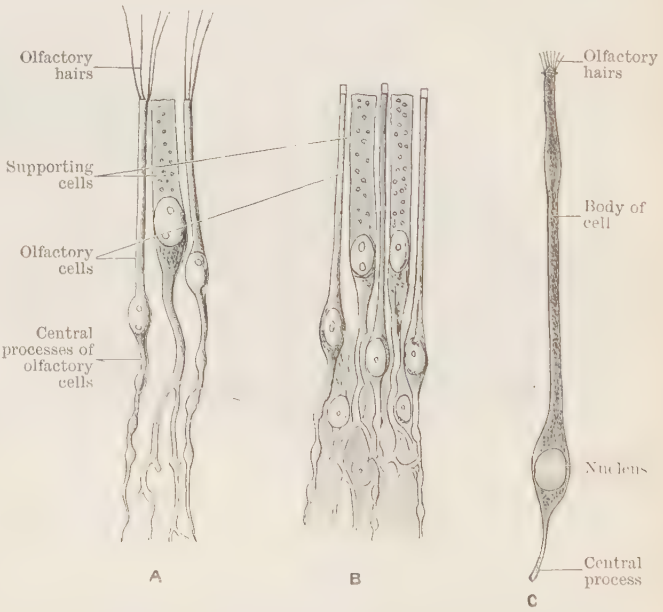

Fig. 557.—Olfactory and supporting Cells.

A. Frog, B. Human } M. Schultze C. Human (v. Brunn).

1. **Supporting Cells.**—The outer part of these cells is columnar in shape and contains fine granules of yellow pigment, whilst the deeper portion is attenuated and frequently branched. They contain elliptical or oval nuclei, which are situated

at the deep ends of the columnar parts of the cells, and form what is termed the zone of oval nuclei.

2. **Olfactory Cells.**—They are spindle-shaped and lie between the deeper, attenuated parts of the supporting cells; their nuclei are circular and form the zone of round nuclei. Each cell gives off a peripheral and a central process, the former of which is rod-like and ends on a level with the free extremities of the supporting cells, where it is surmounted by a pencil of short filaments, termed the **olfactory hairs**. A fine membrane, the membrana limitans externa, covers in many animals the free surface of the epithelium, and is pierced by the olfactory hairs and by the ducts of Bowman's glands.

The central process is a very delicate varicose filament, which passes inwards and is continuous with a fibril of the olfactory nerve. Each of these nerve fibrils probably retains its independence from its point of origin in an olfactory cell to its termination in the olfactory bulb, in the glomerular layer of which it forms a free arborisation.

3. **Basal Cells.**—These cells are branched, and lie on a basement membrane between the deep extremities of the supporting and olfactory cells.

**Olfactory Nerves.**—These nerves arise from the under aspect of the olfactory bulb and are transmitted through the foramina in the cribriform plate of the ethmoid bone. They are at first lodged in the bony canals or grooves situated on the inner and outer walls of the olfactory area, and, reaching the deep surface of the mucous membrane, are continued into the central processes of the olfactory cells. The olfactory nerves possess no medullary sheath.

The fifth cranial nerve supplies branches of ordinary sensation to the nasal mucous membrane as follows: The septum is chiefly supplied by the naso-palatine nerve, but its posterior part receives some filaments from Meckel's ganglion and the Vidian nerve, and its anterior portion from the nasal branch of the ophthalmic. The outer wall is supplied—(1) by the upper nasal branches of the Vidian nerve and Meckel's ganglion; (2) by the lower nasal branches derived from the anterior palatine; and in front by (3) the outer division of the nasal branch of the ophthalmic. The floor and anterior part of the inferior meatus are supplied by a nasal branch of the anterior superior dental nerve.

**Blood-vessels.—Arteries.**—The chief artery of the nose is the spheno-palatine branch of the internal maxillary artery. This reaches the nasal cavity through the spheno-palatine foramen, and divides into—(*a*) posterior nasal, which ramifies over the turbinated bones and sends branches to the antrum and to the frontal and ethmoidal cells; and (*b*) naso-palatine, the artery of the septum. Twigs are given to the upper portion of the cavity by the anterior and posterior ethmoidal arteries, while its posterior part receives some small branches from the descending palatine vessel. The nostrils are supplied by the lateral nasal branch of the facial, and by the septal artery of the superior coronary. The antrum is partly supplied by the infraorbital artery, whilst the sphenoidal sinus gets its chief supply from the pterygo-palatine vessel. The **veins** form a dense plexus almost resembling cavernous tissue in structure. This condition is well seen in the respiratory region, and especially so over the middle and inferior turbinated bones and on the lower part of the septum. The venous blood is carried in three chief directions, viz. *forwards* into the facial vein, *backwards* into the spheno-palatine vein, and *upwards* into the ethmoidal veins. The ethmoidal veins communicate with the ophthalmic veins and the veins of the dura mater; further, an ethmoidal vein passes up through the cribriform plate of the ethmoid, and either opens into the venous plexus of the olfactory bulb or directly into one of the veins of the orbital part of the frontal lobe of the brain. The **lymphatics** form an irregular network in the superficial part of the mucous membrane, and can be injected from the subdural or subarachnoid space. The larger vessels are directed backwards towards the choanæ, and are collected into two trunks, of which the larger passes to a lymphatic gland in front of the axis vertebra, and the smaller to one or two glands situated near the great cornu of the hyoid bone.

The development of the nose is described in the section which deals with "General Embryology" (p. 38).

## THE EYE.

The eyeball or globe of the eye (bulbus oculi) constitutes the chief part of the organ of sight (organon visus); but, associated with its description, certain accessory structures, such as the eyelids and the lachrymal apparatus, fall to be considered.

## THE EYEBALL.

Situated in the anterior part of the orbital cavity, the eyeball is protected in front by the eyelids and by their mucous lining, the conjunctiva, and is pierced behind by the optic nerve, or nerve of sight, which spreads out to form its innermost tunic, the retina. The tendons of the ocular muscles are attached to its outer surface a short distance in front of its equator, while its posterior two-thirds are

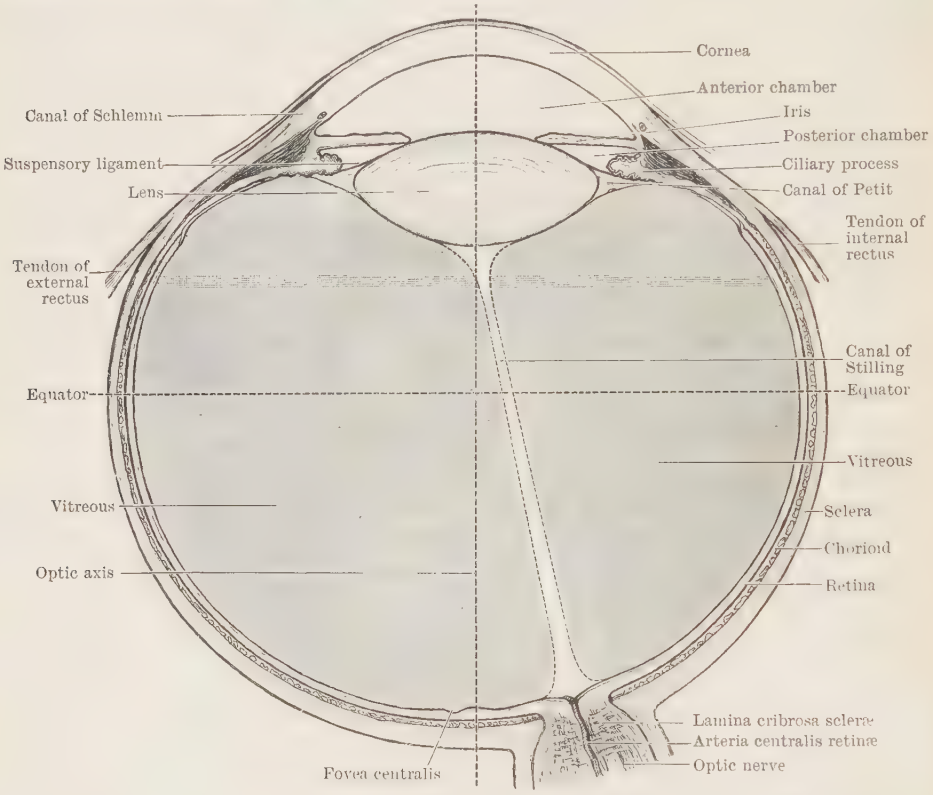

FIG. 558.—DIAGRAM OF A HORIZONTAL SECTION THROUGH LEFT EYEBALL AND OPTIC NERVE (four times enlarged).

enveloped by a loose membrane, termed the capsule of Tenon, or fascia bulbi, which separates it from the surrounding orbital fat.

The eyeball is not quite spherical, being composed of the segments of two spheres, viz. an anterior, transparent, corneal segment, possessing a radius of 7 or 8 mm., and a posterior, opaque, scleral segment, with a radius of about 12 mm. (Fig. 558). The anterior or corneal segment, in consequence of its shorter radius, projects as a dome in front of the scleral portion, the union of the two parts being indicated externally by a slight groove, the sulcus scleræ. The central points of the anterior and posterior curvatures of the eyeball constitute respectively its **anterior** and **posterior poles**, while a straight line joining the two poles is termed its **sagittal axis** (axis optica). The axes of the two eyeballs are almost parallel, diverging only slightly in front; but the axes of the optic nerves converge behind, and, if prolonged backwards, would meet in the region of the dorsum sellæ of the sphenoid. An imaginary line encircling the globe midway between its two poles is named its **equator**, and **meridional lines** (meridiani) may be drawn from pole to pole at right angles to the equator. Its sagittal and transverse diameters are nearly equal—about 24 mm.; its vertical diameter is about 23·5 mm. All three diameters are rather less in the female than in the male, but the size of the eyeball is fairly constant in the same sex. What are popularly described as large eyes owe their apparent increase in size to a greater prominence of the globe and to a wider fissure between the eyelids.

At birth the eyeball is nearly spherical and has a diameter of about 17·5 mm. By the age of puberty this has increased to 20 or 21 mm., after which it rapidly reaches its adult size.

The eyeball (Fig. 558) consists of three concentric tunics or coats, contained within which are three transparent refracting media. The three tunics are: (1) an outer fibrous coat, the sclero-cornea, consisting of an opaque posterior part, the **sclera**, and a transparent anterior portion, the **cornea**; (2) an intermediate vascular, pigmented, and partly muscular tunic, the tunica vasculosa oculi, comprising from behind forward the **chorioid**, the **ciliary body**, and the **iris**; (3) an internal nervous tunic, the **retina**. The three refracting media are named, from before backwards, the **aqueous humour**, the **crystalline lens**, and the **vitreous body.**

## SCLERA.

The **sclera**, sclerotic coat, or white of the eye, is a firm, opaque membrane, which forms something like the posterior five-sixths of the outer tunic. Thickest posteriorly (about 1 mm.), it thins at the equator to 0·4 mm.-0·5 mm., and again increases to 0·6 mm. near the sulcus scleræ. In the child it is thinner than in the adult, and presents a bluish appearance, caused by the pigment of the chorioid shining through it, while in old age it assumes a yellowish tinge. Its outer surface is covered by a layer of endothelium and is in contact with the capsule of Tenon—a lymph space, **the suprascleral lymphatic space**, only intervening. In front of the equator it is roughened by the attachment of the tendons of the ocular muscles, while its anterior part is covered by mucous membrane, the conjunctiva. Its deep surface presents a brownish colour, and is loosely attached to the chorioid, except at the optic entrance and in the neighbourhood of the sulcus scleræ. It is pierced behind by the optic nerve, the entrance for which is funnel-shaped, wide behind and narrow in front, and is situated 1 mm. below and 3 mm. to the nasal side of the posterior pole of the eyeball. The fibrous sheath of the nerve blends with the outer part of the sclera, while the nerve bundles pass through a series of orifices; this perforated portion is named the **lamina cribrosa scleræ.** Around the entrance of the optic nerve are some fifteen or twenty small apertures for the passage of the ciliary nerves and short ciliary arteries. The two long posterior ciliary arteries pierce it, one on either side, some little distance from the optic entrance; while a little behind the equator are four openings, two above and two below, for the exit of veins, called **venæ vorticosæ.** Near the sulcus scleræ it is perforated by the anterior ciliary arteries. Its inner surface is lined by flattened endothelial cells; and between it and the chorioid is an extensive lymph space, the **spatium perichorioideale,** which is traversed by the ciliary nerves and arteries just mentioned, and by an irregular meshwork of fine, pigmented, connective tissue, the **lamina fusca**, which loosely attaches the sclera to the chorioid. At the corneo-scleral junction the fibrous tissue of the sclera passes continuously into that of the cornea, and in the deeper part of this junction there is a circular canal, the sinus venosus scleræ, or **canal of Schlemm,** which communicates externally with the scleral veins, and internally, through numerous small openings, with the anterior chamber of the eyeball.

The sclera consists of bundles of white fibrous tissue, together with some fine elastic fibres, the bundles forming equatorial and meridional layers, which interlace with each other. Numerous spaces containing connective tissue cells and migratory cells exist between the fibres. Pigmented cells are plentiful in the lamina fusca, and a few are also found in the tissue of the sclera, near the optic entrance and in the region of the corneo-scleral junction. The sclera receives its blood-supply from the short posterior ciliary and anterior ciliary arteries, while its veins open into the venæ vorticosæ and anterior ciliary veins. The cell spaces play the part of lymphatics, and communicate with the perichorioidal and suprascleral lymph spaces. Its nerves are derived from the ciliary nerves, which, after losing their medullary sheath, pass between the fibrous bundles; their exact mode of ending is not accurately known.

## CORNEA.

The **cornea** forms the anterior sixth of the outer tunic and is transparent, in order to admit light into the interior of the eyeball; its index of refraction is from 1·33 to 1·35. Its anterior surface (facies anterior) is covered by a stratified epithelium, continuous with that which lines the conjunctiva; its posterior surface (facies posterior) is directed towards the anterior chamber of the eyeball and is in contact with the aqueous humour. Its degree of curvature varies in different individuals; it is always greater in youth than in old age, and is, as a rule, slightly greater in the vertical than in the horizontal plane. It diminishes also from its centre to its periphery, and is less on the nasal than on the temporal side of the anterior pole. The anterior surface of the cornea is almost, but not quite, circular, measuring 11 mm. vertically and 11·9 mm. transversely, while its posterior surface is circular and has a diameter of 13 mm. Its periphery is overlapped by the tissue of the sclera as the glass of a watch is overlapped by the metal rim, with, however, this essential difference, that the tissue of the cornea is directly continuous with that of the sclera.

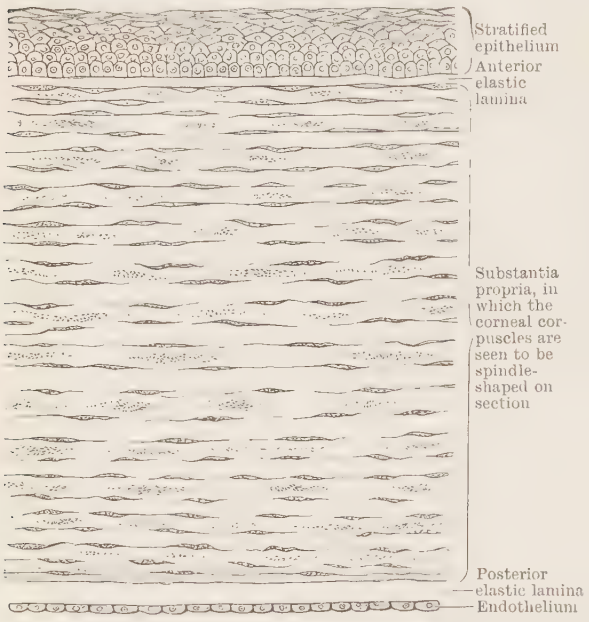

Fig. 559.—Vertical Section of Cornea (magnified).

The cornea consists, from before backwards, of the following strata, viz, (Fig. 559):—

1. A layer of stratified epithelium.
2. An anterior elastic lamina.
3. The substantia propria.
4. A posterior elastic lamina.
5. A layer of endothelium.

1. The **layer of stratified epithelium** (epithelium corneæ) is continuous with that which covers the free surface of the conjunctiva and consists of six or eight strata of nucleated cells. Deepest of all is a single layer of perpendicularly arranged columnar cells, the flattened and often-expanded bases of which rest on the anterior elastic lamina, while their opposite ends are rounded and contain the nuclei. Superficial to this layer are three or four strata of nucleated, polygonal cells, the majority of which exhibit finger-like processes which join with the corresponding processes of neighbouring cells. The more superficial layers assume the form of nucleated squames. The entire thickness of this stratified epithelium is about 45 $\mu$ at the centre and about 80 $\mu$ at the periphery of the cornea.

2. The **anterior elastic lamina** (lamina elastica anterior, Bowmani) is from 19-20 $\mu$ thick, and may be regarded merely as a differentiation of the outer part of the substantia propria from which it is with difficulty separated. It is not stained yellow by picrocarmine, thus differing from true elastic tissue, and its degree of development varies in different animals.

3. The **substantia propria** presents, in a fresh condition, a homogeneous appearance; but, with the assistance of reagents, it is seen to consist of modified connective tissue, with some few elastic fibres. An amorphous interstitial substance binds the fibres into bundles, and, in turn, cements the bundles into lamellæ, which are directly continuous with the fibrous tissue of the sclera. The fibres of any one lamella cross those of adjacent lamellæ almost at right angles, while the superimposed lamellæ are joined by sutural fibres and by amorphous substance. Between the lamellæ are found the **cell spaces** or **lacunæ** of the cornea—irregu-

larly stellate in shape, and communicating freely with each other by means of fine canaliculi. The corneal cells or corpuscles are contained in these lacunæ, without, however, completely filling them, the remainder of the cavities being occupied by lymph. These cells are nucleated, flattened, and star-like, and their branched processes join those of neighbouring cells in the canaliculi. Migratory or lymph cells are also found in cell spaces.

In old age a grayish opaque ring, 1½ to 2 mm. in breadth, is frequently seen near the periphery of the cornea; it is termed the **arcus senilis**, and results from a deposit of fat granules in the lamellæ and corneal corpuscles.

4. The **posterior elastic lamina** (lamina elastica posterior, Demoursi, Descemeti) is a clear, structureless membrane, covering the posterior aspect of the substantia propria and possessing a thickness of 6-8 $\mu$ at the centre and 10-12 $\mu$ at the periphery of the cornea. Less firmly attached than the anterior elastic lamina, it may be stripped off, when it will be found to roll up with its attached surface inwards. Between the ages of twenty and thirty small wart-like projections appear on its deep surface, near its periphery, and these increase in size and number as years advance, so that in old age the membrane may attain a thickness of 20 $\mu$. Towards the periphery of the cornea the lamina divides into three sets of fibres—anterior, middle, and posterior. The anterior fibres pass behind the canal of Schlemm into the sclera, the middle give attachment to the ciliary muscle, while the posterior are continued as radiating and anastomosing fibres into the substance of the iris, and constitute the **ligamentum pectinatum iridis.** A number of irregular spaces, the **spaces of Fontana**, or spatia anguli iridis, exist between the fibres of this pectinate ligament. Better developed in the horse and ox than in man, these spaces are lined by a prolongation of the corneal endothelium, and communicate internally with the anterior chamber and the lymph spaces of the iris, and externally with the canal of Schlemm.

5. The **layer of endothelium** (endothelium cameræ anterioris) consists of a single stratum of nucleated, flattened, polygonal cells, which present a fibrillar structure and are continued as a lining to the spaces of Fontana; this layer of endothelium is also reflected on to the anterior surface of the iris.

**Vascular and Nervous Supply of the Cornea.**—In the fœtus the cornea is traversed, almost as far as its centre, by capillaries; but in the adult it is devoid of blood-vessels, except near its margin. The capillaries of the conjunctiva and sclera pass into this marginal area for a distance of about 1 mm., where they terminate in loops. All the remainder of the cornea is nourished by the lymph which circulates in its cell spaces and canaliculi.

The **nerves** of the cornea, discovered by Schlemm, are derived from the ciliary nerves. Around its periphery they form a plexus, the plexus annularis, from which fibres pass into the cornea, where, after a distance of 1 or 2 mm., they lose their medullary sheaths and ramify in the substantia propria, forming what is termed the fundamental or stroma plexus. Perforating fibres (fibræ perforantes) extend from this plexus through the anterior elastic lamina and form a subepithelial plexus, from which fine filaments ramify between the epithelial cells as far as the superficial layers. From the annular and stroma plexuses fibrils pass to the substantia propria and come into close relation with the corneal corpuscles.

## VASCULAR AND PIGMENTED TUNIC.

The middle, vascular, and pigmented tunic (tunica vasculosa oculi) comprises, from behind forwards, the chorioid, the ciliary body, and the iris (Fig. 558).

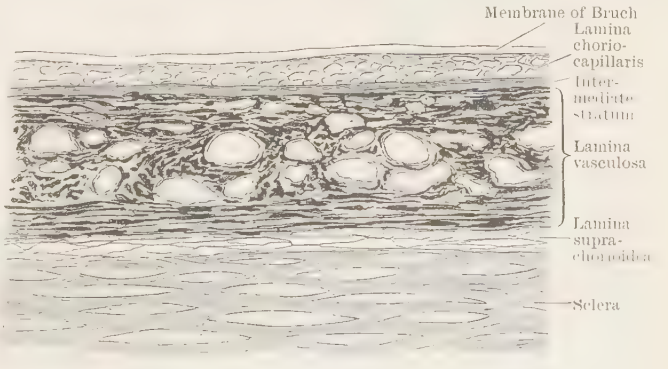

Fig. 560.—Vertical Section of Chorioid and Inner Part of Sclera.

The **chorioid** (chorioidea) intervenes between the sclera and the retina, reaching as far forwards as the ora serrata of the latter (p. 731). Dark brown or black in colour, it is pierced posteriorly by the optic nerve, and is here firmly attached

to the sclera. Thicker behind than in front, its outer surface is flocculent and is connected to the sclera by the ciliary vessels and nerves, and by the loose lamina fusca. Its inner surface is smooth and adheres to the outermost or pigmented layer of the retina.

The chorioid consists of blood-vessels and branched pigment cells embedded in a loose connective tissue, and presents from without inwards three layers, viz.: (*a*) the lamina suprachorioidea; (*b*) the proper tissue of the chorioid; and (*c*) a thin transparent membrane, the lamina basalis or membrane of Bruch (Fig. 560).

1. The **lamina supra-chorioidea** resembles the lamina fusca of the sclera, and consists of a series of fine non-vascular lamellæ, each containing a delicate network of elastic fibres, amongst which are stellate, pigmented cells, together with amœboid cells. The spaces between the laminæ are lined with endothelium, and together form the spatium perichorioideale, already referred to (p. 725).

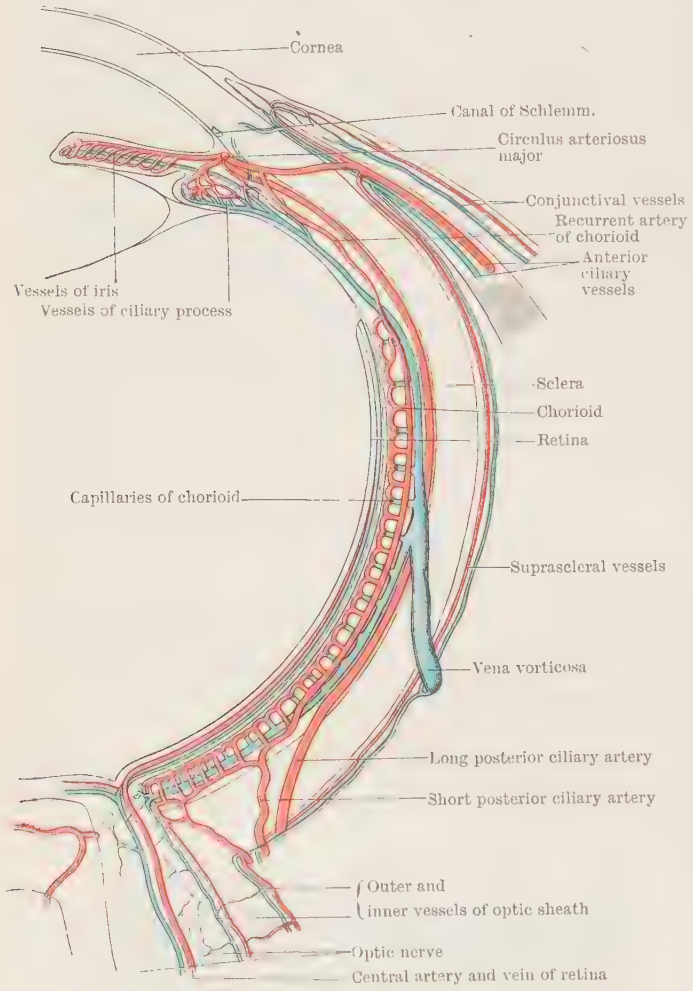

FIG. 561.—DIAGRAM OF THE CIRCULATION IN THE EYE (Leber).

The **proper tissue of the chorioid** consists of blood-vessels and numerous pigmented cells, supported by connective tissue and elastic fibres, together with some smooth muscular fibres. Its outer part contains the larger blood-vessels, and is named the **lamina vasculosa**, while its inner portion is composed of a network of fine capillaries, and is termed the **lamina choriocapillaris**; these two laminæ are joined by a thin **intermediate stratum**. The arteries of the chorioid are derived from the short posterior ciliary vessels, which pierce the sclera around the optic entrance and form a wide-meshed plexus in the lamina vasculosa. Their circular muscular coat is well developed, and longitudinal muscular fibres are also present in the larger branches. The veins, destitute of muscular tissue, are superficial to the arteries; they are surrounded by peri-vascular lymphatic sheaths and converge to form whorls, which open into the venæ vorticosæ. In the tissue between the blood-vessels are numerous stellate, flattened, and pigmented cells.

The **lamina chorio-capillaris**, or membrane of Ruysch, is composed essentially of small capillaries, which form an exceedingly close network, embedded in a finely granular or almost homogeneous tissue. The **intermediate stratum** between the malina vasculosa and lamina chorio-capillaris consists of a network of delicate

elastic fibres and contains almost no pigment cells; it is lined next the lamina chorio-capillaris by a continuous layer of endothelium.

The **lamina basalis**, or membrane of Bruch, is transparent and nearly structureless. Its outer surface presents a trellis-like network of fibres which unite it to the membrane of Ruysch, while its inner surface is smooth and is in contact with the pigmented layer of the retina.

**Tapetum.**—In many animals a brilliant iridescent appearance is seen on the postero-external part of the chorioid to which the name **tapetum** is applied. Absent in man, it may be due, as in the horse, to a markedly fibrous condition of the stratum intermedium (tapetum fibrosum), or as in the seal, to the presence of some five or six layers of flattened iridescent cells lying immediately outside the lamina chorio-capillaris (tapetum cellulosum).

The **ciliary body** (corpus ciliare) connects the chorioid to the circumference of the iris (Fig. 562), and presents the following three zones, viz.: (*a*) the orbiculus ciliaris, (*b*) the ciliary processes, and (*c*) the ciliary muscle.

The **orbiculus ciliaris** forms a zone of about 4 mm. in width immediately adjoining the chorioid, and exhibits numerous radially-arranged ridges.

The **ciliary processes** (processus ciliares), about seventy in number, form a circle of radial thickenings, each of a somewhat triangular shape. The base of the triangle is directed forwards towards the equator of the lens, while the apex is continuous behind with some three or four ridges of the orbiculus ciliaris. They vary in size, the largest having a length of 2-5 mm. The structure of the orbiculus ciliaris and ciliary processes is similar to that of the chorioid, but the capillaries are larger and more tortuous, and there is no lamina chorio-capillaris. The deep aspect of the ciliary processes is covered by two strata of columnar epithelium, the anterior layer of which is pigmented; these two strata form a direct continuation forwards of the retina and constitute the **pars ciliaris retinæ**. This epithelium is invaginated to form more or less tubular glands, which may take a share in the secretion of the aqueous humour.

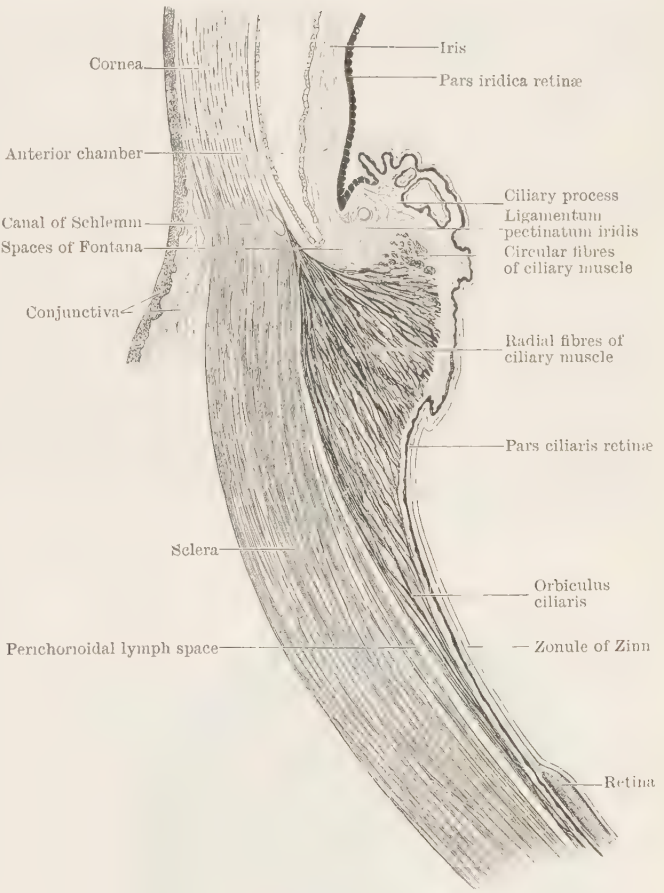

Fig. 562.—Section through Ciliary Region of Eyeball.

The **ciliary muscle** (m. ciliaris) is triangular on antero-posterior section, and consists of two sets of fibres—radial and circular (Fig. 562). The **radial fibres** (fibræ meridionales, Brückei) spring from the corneo-scleral junction behind the canal of Schlemm and from the ligamentum pectinatum iridis, and radiate backwards, to be attached to the ciliary processes and orbiculus ciliaris. When they contract the chorioid is drawn forwards and the lens becomes more convex, owing to the relaxation of its suspensory ligament (see p. 736). The **circular fibres** (fibræ

circulares, Mülleri) form a triangular zone behind the ligamentum pectinatum iridis, close to the periphery of the iris, and also extend backwards under the radial fibres. Considerable individual differences are found as to the degree of development of these two portions of the ciliary muscle. The radial fibres are always more numerous than the circular fibres, the latter being absent or rudimentary in myopic eyes, but well developed, as a rule, in hypermetropic eyes.

The **iris** forms a contractile diaphragm in front of the lens, and is pierced a little to the nasal side of its centre by an almost circular aperture, the **pupil** (pupilla), which, during life, is continually varying in size in order to regulate the amount of light admitted into the interior of the globe. It divides the space between the cornea and lens into two parts, which are filled by the aqueous humour, and named respectively the **anterior and posterior chambers** of the eyeball. Its peripheral border, or **margo ciliaris**, is directly continuous with the ciliary body, and, through the medium of the ligamentum pectinatum iridis, with the posterior elastic lamina of the cornea. Its free edge, or **margo pupillaris**, forms the circumference of the pupil, and rests upon, but is not attached to the anterior surface of the capsule of the lens.

The distinctive colour of the eye, in different individuals, depends on the arrangement of the pigment in the iris; in the blue eye this is limited to the posterior surface of the iris, but in the brown or black eye it is also scattered throughout its stroma. In the albino the pigment is entirely absent, and the red appearance of the eye in such a case is produced by the network of blood-vessels in the iris.

The pupil is closed, during the greater part of fœtal life, by a thin transparent vascular membrane, the **membrana pupillaris**, continuous with the pupillary margin of the iris. Its vessels, derived partly from the vessels of the iris and partly from those of the capsule of the lens, converge towards the middle of the membrane, near which they form loops so as to leave the central part non-vascular. About the seventh month the vessels begin to be obliterated from the centre towards the circumference, and this is followed by a thinning and absorption of the membrane, which becomes perforated by the aperture of the pupil. This perforation gradually enlarges, and at birth the membrane has entirely disappeared, although in exceptional cases it persists.

On the anterior surface (facies anterior) of the iris is a layer of flattened endothelium, placed on a basement membrane, and continuous with that which lines the spaces of Fontana and covers the back of the cornea. Depressions or crypts are here and there seen in which the endothelium and basement membrane are absent, and are, by some, regarded as stomata, through which the lymphatics of the iris communicate with the cavity of the anterior chamber. Its posterior surface (facies posterior) is covered by a basement membrane, on which are placed two layers of columnar, pigmented epithelium, continuous with the pars ciliaris retinæ and termed the **pars iridica retinæ**. The proper tissue of the iris, or **stroma iridis**, consists of delicate connective tissue and elastic fibres, with pigmented cells, blood-vessels, nerves, and non-striped muscle.

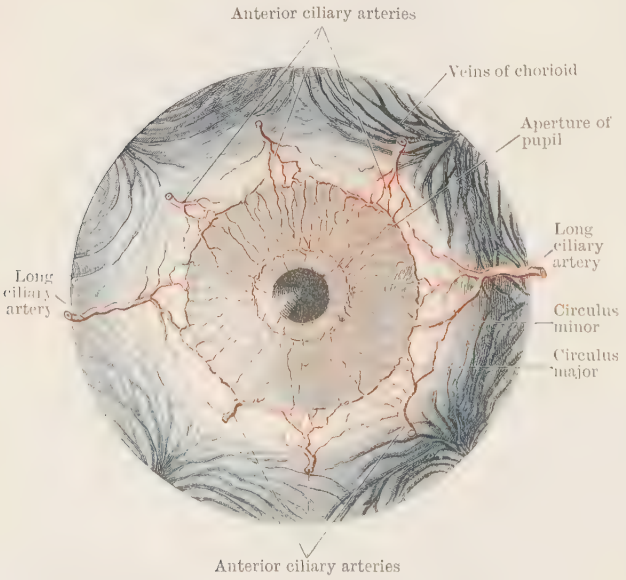

Fig. 563.—Blood-vessels of Iris and Anterior Part of Chorioid, viewed from the front (Arnold).

The **blood-vessels of the iris** (Fig. 563) are derived from the long and anterior

ciliary arteries. The long ciliary arteries, two in number, pierce the sclera on the inner and outer side of the optic nerve respectively, and extend forwards between the sclera and chorioid towards the ciliary margin of the iris. Here each divides into an upper and a lower branch, and the resulting four branches anastomose in the form of a circle, termed the **circulus arteriosus major**. This circle is joined by a varying number of anterior ciliary arteries derived from the lachrymal and muscular branches of the ophthalmic artery, and, after supplying the ciliary muscle, sends converging branches inwards towards the aperture of the pupil, around which a second circle, the **circulus arteriosus minor**, is formed. The **veins** proceed towards its ciliary margin, and communicate with the veins of the ciliary processes and with the canal of Schlemm. The convergence of the blood-vessels towards the aperture of the pupil gives to the anterior surface of the iris a striated appearance.

The **non-striped muscular fibres** are arranged in two sets: (*a*) circular, (*b*) radial. The **circular fibres** form a band around the pupillary aperture, by the contraction of which its size is lessened, and hence it is termed the **m. sphincter pupillæ**. The **radial fibres** extend outwards from the sphincter to the ciliary margin and constitute the **m. dilatator pupillæ**. Many anatomists regard the radial fibres, in man and most mammals, as being elastic and not muscular. In animals, where the radial fibres are muscular, the degree of their development varies considerably; they are feebly marked in the rabbit, but well developed in the bird, and still more so in the otter.

The **nerves of the chorioid and iris** are derived from the long and short ciliary nerves. The former, two or three in number, are branches of the nasal nerve; the latter, varying from eight to fourteen, are derived from the ciliary ganglion. Piercing the sclera around the optic entrance the nerves traverse the perichorioidal lymph space, where they form a plexus, rich in nerve-cells, from which filaments are supplied to the blood-vessels of the chorioid. In front of the ciliary muscle a second plexus, also rich in nerve-cells, is formed, which supplies the muscle itself, and sends filaments into the iris as far as its pupillary margin, for the supply of its muscular fibres and blood-vessels. The sphincter pupillæ is supplied by the third cranial nerve, whilst filaments from the sympathetic are distributed to the dilatator pupillæ.

## THE RETINA.

The **retina**, or nervous tunic of the eyeball, is a soft, delicate membrane, in which the fibres of the optic nerve are spread out. It consists of two strata, viz.: (*a*) an outer, pigmented layer (stratum pigmenti), attached to the chorioid; and (*b*) an inner nervous lamina, the retina proper, in contact with the hyaloid membrane of the vitreous body, but only attached to it at the optic entrance and in the region of the ciliary processes. Expanding from the entrance of the optic nerve the retina appears to end, a short distance behind the ciliary body, in a wavy border, the **ora serrata**. Here its nervous elements cease and the membrane becomes suddenly thinned, but a delicate continuation of it is prolonged over the posterior aspect of the ciliary body and iris. This continuation consists of the stratum pigmenti, together with a layer of columnar epithelium, and constitutes the **pars ciliaris retinæ** and **pars iridica retinæ** already referred to (pp. 729 and 730). The portion behind the ora serrata is termed the "physiological retina," or **pars optica retinæ**, and its thickness gradually diminishes from 0·4 mm., near the optic entrance, to 0·1 mm. at the ora serrata. Viewed from the front it presents, at the posterior pole of the eyeball, and therefore directly in the axis of the globe, a small yellowish spot, the **macula lutea**. Somewhat oval in shape, the greatest or transverse diameter of the macula measures from 2-3 mm.; its central part is depressed and named the **fovea centralis**. About 3 mm. to the nasal side of the posterior pole and about 1 mm. below its level is a whitish, circular disc, the **optic disc**, or porus opticus, which corresponds with the entrance of the optic nerve and has a diameter of about 1·5 mm. The circumference of the optic disc is slightly raised and is named the **colliculus nervi optici**, while its depressed central portion is termed the **optic cup**, or excavatio papillæ nervi optici. The optic disc consists merely of nerve-

fibres, the other layers of the retina being absent, and constitutes the "blind spot" of physiologists.

The nervous layer of the retina is transparent during life, but becomes opaque and of a grayish colour soon after death. If an animal be kept in the dark before the removal of its eyeball, the retina presents a purple tinge, due to the presence of a colouring matter named **rhodopsin** or **visual purple**, which, however, becomes rapidly bleached on exposure to sunlight. This colouring matter is absent from the macula lutea, and also over a narrow zone, 3-4 mm. in width, near the ora serrata.

**Structure of the Retina** (Figs. 564, 565, 566).—The nervous elements of the retina are supported by non-nervous or **sustentacular fibres**, and are arranged in seven layers, to which must be added the stratum pigmenti.

Our conception of the minute structure of the retina, as of all nervous tissues, has of late years been greatly advanced by the discoveries of Ramon y Cajal, on whose observations the following description is based (Fig. 565):—

The layers from within outwards, *i.e.* from vitreous body to chorioid, are:

1. Layer of nerve-fibres (stratum opticum).
2. Layer of nerve-cells (ganglionic layer).
3. Inner molecular or inner plexiform layer.
4. Inner nuclear layer or layer of inner granules.
5. Outer molecular or outer plexiform layer.
6. Outer nuclear layer or layer of outer granules.
7. Layer of rods and cones (bacillary layer).
8. Layer of pigmented epithelium (stratum pigmenti).

1. **Layer of nerve-fibres or stratum opticum.**—The fibres of this stratum are nearly all centripetal, and are mostly continuations of the non-medullated axons of the cells in the ganglionic layer. Some, however, are centrifugal and end in branched clubbed extremities in the inner molecular or inner nuclear layers.

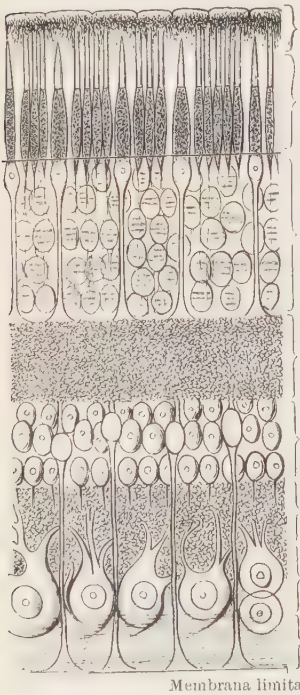

FIG. 564.—DIAGRAMMATIC SECTION OF THE HUMAN RETINA (modified from Schultze).

2. **Ganglionic or nerve-cell layer.**—The cells of this stratum vary in size, are oval or pyriform in shape, and form a single layer, except at the macula lutea, where several strata are present. Each cell contains a large nucleus, and gives off, from its inner aspect, an axon which is continued as a fibre of the nerve-fibre layer. From the outer surface of each cell numerous dendrites arise, which form arborisations in the inner molecular layer. The cells may be divided into unistratified, multistratified, and diffuse, according as their dendrites ramify in one or in several strata of the inner molecular layer, or extend throughout nearly its whole thickness.

3. **Inner molecular or inner plexiform layer.**—This is chiefly constituted by the interlacement of the dendritic arborisations of the cells of the ganglionic layer with those of the inner nuclear layer, and has been divided by Ramon y Cajal into five strata. It sometimes contains horizontal cells or spongioblasts, whose branched processes ramify in it.

4. **Inner nuclear layer or layer of inner granules.**—This is the most complicated of the retinal strata, and consists of numerous cells which may be divided into three groups, viz.: (*a*) bipolar cells, (*b*) horizontal cells, and (*c*) spongioblasts, or amacrine cells.

(*a*) The **bipolar cells**, by far the most numerous are fusiform and nucleated, and each gives off an external and an internal process. The internal processes terminate in flattened tufts at different levels in the inner molecular layer, while the external produce an abundant ramification in the external zone of the outer molecular layer. These bipolar cells are divided into rod bipolars, cone bipolars, and giant bipolars. The **rod bipolars** end peripherally in vertical arborisations around the button-like ends or spherules of the rod fibres, and, centrally, in branched extremities

which mostly become applied to the cells of the ganglionic layer. The **cone bipolars** end peripherally in flattened arborisations in the outer molecular layer in contact with

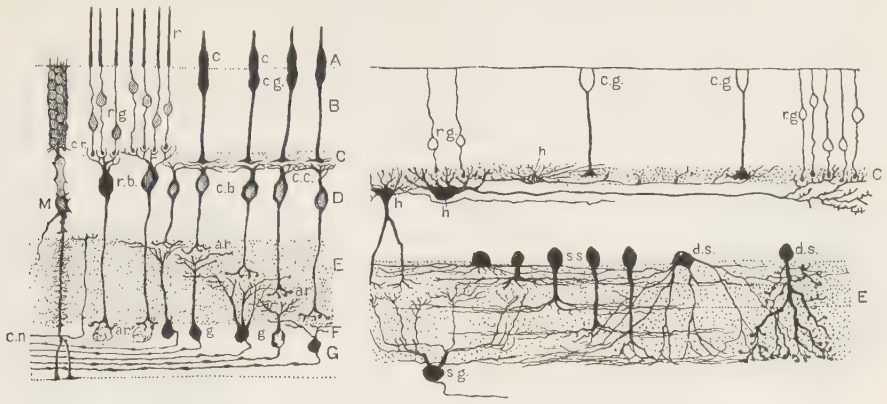

FIG. 565.—PERPENDICULAR SECTIONS OF MAMMALIAN RETINA (Cajal).

A, Layer of rods and cones; B, Outer nuclear layer; C, Outer molecular layer; D, Inner nuclear layer; E, Inner molecular layer; F, Ganglionic layer; G, Stratum opticum; *r*, rods; *c*, cones, *r.g*, rod granules; *c.g*, cone granules; *r.b*, rod bipolars; *c.b*, cone bipolars; *c.r*, contact of rod bipolars with the spherules of the rod fibres; *c.c*, contact of cone bipolars with the branches of the cone fibres; *ar*, internal arborisation of cone bipolars; *ar'*, internal arborisation of rod bipolars; *c.n*, centrifugal nerve fibre; *h*, horizontal cells; *s.s*, stratified spongioblasts; *d.s*, diffuse spongioblasts; *s.g*, stratified ganglion cell; M, Sustentacular fibre of Müller.

the ramifications of the foot-plates of the cone fibres, and, centrally, ramify in some one of the five strata of the inner molecular layer. The **giant bipolars** form, peripherally, an extensive horizontally arranged arborisation in the outer molecular layer; centrally, they ramify in one or other of the strata of the inner molecular layer.

(*b*) The **horizontal cells** are of two varieties: (1) small, flattened, star-like cells, lying immediately below the outer molecular layer, and sending a tuft of dendrites outwards towards the bases of the cone fibres, while their axons are directed horizontally for a variable distance; (2) large, irregular cells, lying internal to the above and ending in finger-like ramifications in the outer molecular layer. Their axons run horizontally for some distance, and end in extensive varicose arborisations under the spherules of the rod fibres.

(*c*) The **spongioblasts** are situated in the innermost part of the inner granular layer and have not yet been shown to possess axons. Their dendrites ramify in the inner molecular layer, it may be in one stratum (stratified spongioblasts) or in several strata (diffuse spongioblasts).

5. **Outer molecular or outer plexiform layer.**—This is constituted by the interlacement of the dendrites of the bipolar and horizontal cells, just described, with the spherules of the rod fibres and the ramifications of the foot-plates of the cone fibres. It is divided into two strata: (*a*) *external*, indicating the contact of the rod bipolars with the spherules of the rod fibres; (*b*) *internal*, the line of contact between the cone bipolars and the branches of the cone fibres.

6. **Outer nuclear layer or layer of outer granules.**—This is made up of clear granules somewhat resembling those of the inner nuclear layer, and are divisible into two kinds: (*a*) cone granules, (*b*) rod granules. The **cone granules** are the larger, and each contains an oval nucleus; they lie immediately inside the outer limiting membrane, through which they are continuous with the cones of the next layer. Each is prolonged internally as a straight fibre, which, on reaching the outer molecular layer, expands to form a foot-plate, from which several horizontal fibrils are given off. The **rod granules** are far more numerous than the cone granules, and each contains a small oval nucleus, which is transversely striated.

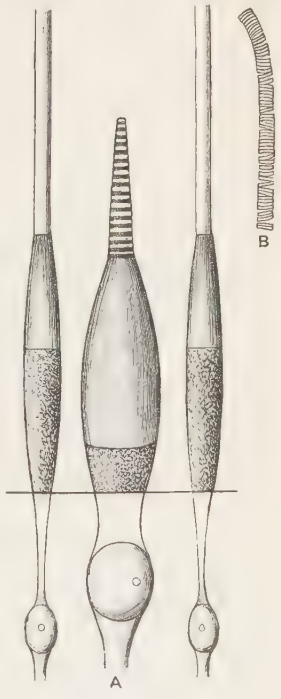

FIG. 566.

A, A cone and two rods from the human retina (modified from Max Schultze); B, Outer part of rod separated into discs.

Their outer processes are continuous, through the outer limiting membrane, with the rods of the next layer, while their inner processes pass into the outer molecular layer and end in free, unbranched spherules amongst the arborisations of the rod bipolars.

7. **Layer of rods and cones.**—This consists of two sets of structures, viz. **rods** and **cones**. Except at the macula lutea the rods are far more numerous than the cones and assume the form of elongated cylinders, while the cones are shorter than the rods and taper externally to fine points. Each rod and cone consists of two segments—inner and outer. The inner segment of the rod only slightly exceeds in diameter its outer segment, whereas the inner segment of the cone greatly exceeds its outer part. The inner segments of both rods and cones have an affinity for staining reagents, and consist of a basal homogeneous portion and an outer longitudinally striated part, the proportion of the latter to the former being greater in the cones than in the rods. The outer segments have not the same affinity for reagents, but tend to break transversely into numerous discs (Fig. 566, B). The colouring matter, rhodopsin, already referred to, is found only in the outer segments of the rods, the terminal parts of which extend into the layer of pigmented epithelium.

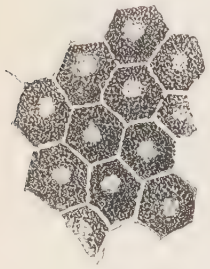

FIG. 567.—PIGMENTED EPITHELIUM OF HUMAN RETINA (viewed from the surface).

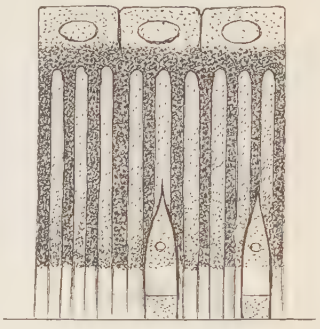

FIG. 568.—SECTION THROUGH OUTER LAYERS OF RETINA (semi-diagrammatic).

8. **Layer of pigmented epithelium** (stratum pigmenti).—This consists of a single stratum of cells which, on surface view, are hexagonal (Fig. 567), their outer flattened surfaces being firmly attached to the chorioid. When seen in profile the outer part of each cell contains a large oval nucleus and is devoid of pigment, while the inner portion is filled with pigment and extends as a series of thread-like processes amongst the outer segments of the rods and cones. When the eye is kept in the dark the pigment accumulates near the outer part of the cell, but when exposed to light it streams in between the rods and cones (Fig. 568).

It will be seen from the foregoing description that there is no direct continuity between the nervous elements which form the different layers of the retina. In the inner molecular layer there is merely an interlacement between the dendrites of the ganglionic layer and the arborisations of the cells of the inner granular layer, and a similar interlacement in the outer molecular layer between the rod and cone elements and the processes of the outer granules.

**Sustentacular fibres of the retina** (fibræ Mülleri).—These support the nervous structures and extend from within outwards through the thickness of the retina as far as the bases of the rods and cones (Fig. 565, M). They begin at the inner surface of the nerve-fibre layer in single or forked expanded bases, by the apposition of which a delicate membrane, the **membrana limitans interna**, is formed. In the ganglionic layer they give off a few lateral branches, and, on passing through the inner nuclear layer, supply lateral ramifications amongst the inner granules for their support; in this part of each fibre there is seen an oval nucleus. In the outer nuclear layer they break up into a network of fibrils which surround the rod and cone fibres, and end externally at the bases of the rods and cones in a delicate membrane, the **membrana limitans externa**.

**Structure of the macula lutea and fovea centralis.**—The yellow colour of the macula is due to the presence of pigment in the inner layers of the retina. At the circumference of the macula the nerve-fibre layer is greatly thinned and the rods are few in number; the ganglionic layer, on the other hand, is thickened and may contain from seven to nine strata of cells, while the outer granular layer is also thicker and its bipolar cells have an oblique direction. At the fovea centralis the retina is much thinned, since here its nerve-fibre and ganglionic layers are absent and its other strata greatly attenuated. The stratum pigmenti, on the other hand, is thicker and its pigmentation more pronounced. The cone nuclei are situated some distance internal to the outer limiting membrane, and thus the thin inner and outer granular layers are in apposition. There are no rods, and the cones, closely crowded together, are narrower and their outer segments more elongated than elsewhere, so that the line of their bases, indicated by the membrana limitans externa, presents a convexity directed forwards. The fovea centralis and macula lutea are spoken of by the physiologist as the "region of distinct vision."

**Structure of the ora serrata.**—Here the nervous layers of the retina suddenly cease; the layer of rods and cones first failing, to be immediately followed by the disappearance of the other nervous strata. In front of the ora serrata the retina is prolonged over the ciliary processes in the form of two layers of cells: (*a*) an inner layer of columnar epithelium, and (*b*) an outer, consisting of the stratum pigmenti, the two forming the pars ciliaris retinæ. The same two layers are prolonged over the back of the iris, where both are pigmented and form the pars iridica retinæ.

**Vessels of the retina** (Fig. 569). The retina is supplied by the **arteria centralis retinæ**, a branch of the ophthalmic artery, which pierces the sheath of the optic nerve about three-quarters of an inch behind the eyeball, and makes its appearance in the centre of the optic disc. Here it divides into an upper and a lower branch, and each of these again bifurcates into an internal or nasal, and an external or temporal, branch. The resulting four branches ramify towards the periphery of the retina, and are named the superior and inferior temporal and the superior and inferior nasal arteries. The temporal arteries pass outwards above and below the macula lutea, to which they give small branches;

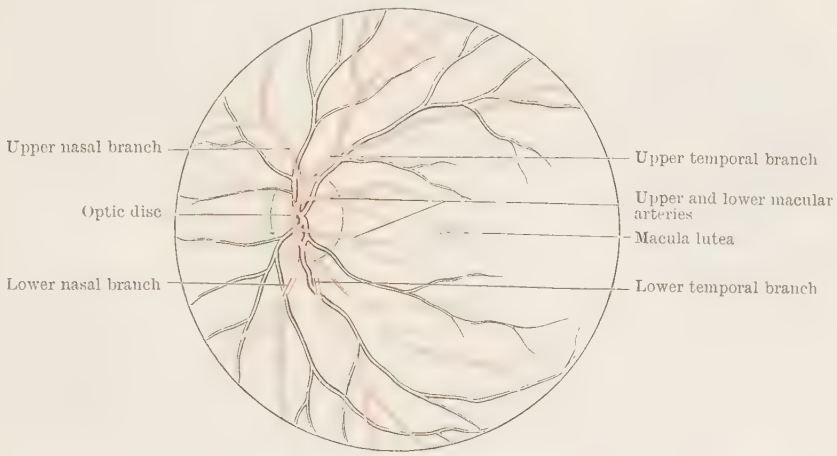

Fig. 569.—Blood-vessels of the Retina.

these do not, however, extend as far as the fovea centralis, which is devoid of blood-vessels. The macula also receives two small arteries (superior and inferior macular) directly from the porus opticus. The larger vessels run in the nerve-fibre layer near the membrana limitans interna and form two capillary networks—an inner, in the nerve-fibre layer, and an outer, in the inner nuclear layer. The inner network arises directly from the arteries and sends numerous small branches to the outer network, from which the veins take origin. The vessels do not penetrate deeper than the inner granular layer, nor do the arteries anastomose except through the capillary plexuses. The **veins** follow the course of the arteries; they have no muscular coats, but consist merely of a layer of endothelial cells, outside which is a perivascular lymphatic sheath, surrounded by delicate retiform tissue.

## REFRACTING MEDIA OF THE EYEBALL.

The **vitreous body** (corpus vitreum) is a transparent, jelly-like substance situated between the crystalline lens and the retina, and occupying the posterior four-fifths of the globe (Fig. 558). In front it presents a deep concavity, the **fossa patellaris**, for the reception of the posterior convexity of the lens. It is enclosed within a thin transparent membrane, the **membrana hyaloidea**, which is in contact with the membrana limitans interna of the retina and adherent to it at the optic entrance. The portion of the membrana hyaloidea in front of the ora serrata is thickened and strengthened by radial fibres, and is termed the **zonule of Zinn**, or zonula ciliaris. Situated behind the ciliary body the zonula is radially folded and presents a series of alternating furrows and elevations. The ciliary processes are received into, and are firmly adherent to, the furrows, with the result that, if removed, some of their pigment remains attached to the zonula. The elevations of the zonula are not attached to the interciliary depressions, but are separated by a series of lymph spaces (recessus cameræ posterioris); these may be regarded as diverticula of the

posterior chamber with which they communicate. As the zonula approaches the equator of the lens it splits into two chief layers, viz.: (*a*) a thin posterior lamina, which covers that portion of the membrana hyaloidea which lines the fossa patellaris; and (*b*) a thicker anterior layer, termed the **suspensory ligament** of the lens (Fig. 558), which blends with the front of the lens capsule a short distance from its equator. Scattered fibres of this ligament are also attached to the equator itself and to the regions immediately anterior and posterior to it. By this suspensory ligament the lens is retained in position, and its convexity varies inversely with the degree of tension of the ligament. The radial fibres of the ciliary muscle, by pulling forward the ciliary processes and the attached zonule of Zinn, relax the ligament, and thus allow the lens to become more convex. Behind the suspensory ligament a sacculated lymph space surrounds the equator of the lens; it is named the **canal of Petit**, and may easily be inflated on introducing a fine blow-pipe through the suspensory ligament (Fig. 570). In the fœtus a blood-vessel, termed the **arteria hyaloidea**, is continued from the arteria centralis retinæ forwards through the vitreous body for the supply of the capsule of the lens. Its position, in the adult, is represented by a lymph channel, termed the **canalis hyaloideus** of Stilling (Fig. 558), the presence of which may be demonstrated by shaking up the vitreous body in a solution of picrocarmine, when some of the pigment may be seen to extend along the canal (Anderson Stuart).

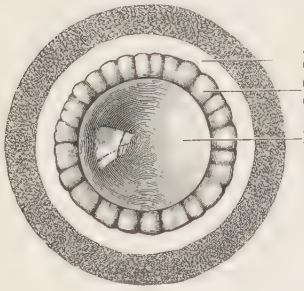

Fig. 570.—Canal of Petit distended and viewed from the Front (enlarged).

When the vitreous body is treated by a weak solution of chromic acid it presents a series of concentric, peripherally arranged striæ, together with numerous radial striæ converging towards its centre. Between these the more fluid part lies, and it frequently contains vacuolated amœboid cells scattered through it. The vitreous body consists of 98·4 per cent of water, having in solution about 1·4 per cent of sodium chloride and traces of extractives and albumen.

The **crystalline lens** (lens crystallina) lies in front of the vitreous body and behind the iris, and is a biconvex, transparent body (Fig. 558). It is enclosed in a thin, transparent, homogeneous capsule, the capsule of the lens (capsula lentis). The central points of its anterior and posterior surfaces are termed respectively its **anterior and posterior poles**, a line joining which is known as its **axis** (axis lentis); its peripheral circumference is named the **equator** (æquator lentis). Its axial measurement is 4 mm., and its transverse diameter from 9-10 mm. Its anterior surface (facies anterior lentis) is less curved than the posterior, and its central part corresponds with the aperture of the pupil and is directed towards the anterior chamber. Around the aperture of the pupil the pupillary margin of the iris rests upon the lens, but its peripheral part is separated from it by the aqueous humour of the posterior chamber. Its posterior surface (facies posterior lentis), more convex than the anterior, occupies the fossa patellaris of the vitreous body. The relations of its equator to the suspensory ligament and the canal of Petit have already been referred to. The superficial part of the lens possesses a refractive index of about 1·4, and its central part or nucleus one of about 1·45. The curvatures of its surfaces, especially that of the anterior, are constantly varying during life for the purpose of focusing rays from near or distant objects on the retina.

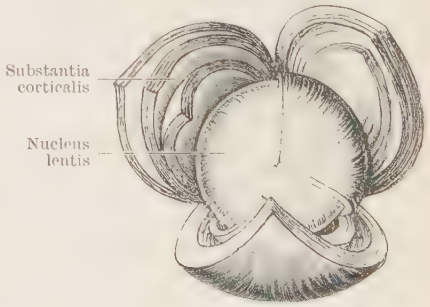

Fig. 571.—Lens hardened in Formalin and dissected to show its Concentric Laminæ (enlarged).

The lens substance (substantia lentis) consists of a soft outer part, the **substantia corticalis**, easily crushed between the finger and thumb, and of a dense central part,

the **nucleus lentis.** Faint lines (radii lentis) radiate from its anterior and posterior poles towards its equator. In the fœtus they are three in number, and form with each other angles of 120° (Fig. 572). From the anterior pole one ray ascends vertically and the other two diverge downwards, while from the posterior pole one ray descends vertically and the other two diverge upwards. In the adult the rays may be increased to six or more. They represent the free edges of a corresponding number of septa which dip into the substance of the lens, and along which the extremities of the different groups of lens fibres come into contact, and are attached by a clear, amorphous substance. The lens, when hardened, exhibits a series of concentrically arranged laminæ (Fig. 571), superimposed like the coats of an onion and attached to each other by a clear, amorphous substance. Each lamina is split along the radiating lines, and consists of a series of hexagonal, riband-like fibres, the fibræ lentis, which are adherent to each other by their margins; those of the deeper laminæ are smaller and serrated, but non-nucleated; while those of the superficial coats are larger and nucleated, but non-serrated. The fibres extend in a curved manner from the rays on the anterior surface to the rays on the posterior surface, but no fibre extends from pole to pole. Fibres which start at or near one pole end at or near the equator on the opposite surface, and *vice versa*, while the intervening fibres take up intermediate positions. Between the substantia lentis and the anterior part of the capsule there is a layer of nucleated columnar epithelial cells, the epithelium lentis. On being traced towards the equator its cells become gradually elongated and transformed into lens fibres, which, when fully formed, lose all trace of their nuclei, except in the more superficial laminæ. Each lens fibre represents, therefore, a greatly elongated columnar cell (Fig. 573).

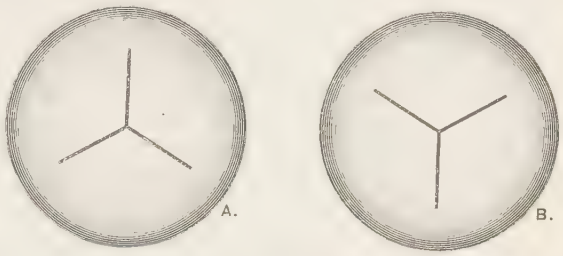

Fig. 572.—Diagrammatic Representation of the Radii Lentis of the Fœtal Lens.

A, Seen from the front; B, From behind.

Fig. 573.

Section through the Equator of the Lens.

Showing the gradual transition of the epithelium into lens fibres (after Babuchin).

In the fœtus the lens is soft, of a pinkish colour, and nearly spherical; while in old age it becomes more flattened than in the adult, and, losing its transparency, assumes a yellowish tint.

**Chambers of the Eye and Aqueous Humour** (Fig. 558).—As already stated (p. 730), the space between the cornea and the lens is divided by the iris into two unequal parts, viz. the anterior chamber in front and the posterior chamber behind. These are filled by the **aqueous humour,** and, in the adult, communicate freely through the aperture of the pupil, but in the fœtus are separated from each other by the pupillary membrane. The **anterior chamber** (camera oculi anterior) is bounded in front by the cornea, behind by the iris and lens, whilst peripherally it communicates with the spaces of Fontana. The **posterior chamber** (camera oculi posterior) is triangular on section, and is bounded in front by the iris, behind by the circumferential part of the lens and its suspensory ligament; the base of the triangle, situated externally, corresponds with the thick, anterior extremities of the ciliary processes. It communicates with the recessus cameræ posterior and canal of Petit. The aqueous humour has a refractive index of about 1·336, and consists of about 98 per cent of water, with 1·4 per cent of sodium chloride and traces of albumen.

## EYELIDS.

The **eyelids or palpebræ** are two movable cutaneous curtains situated in front of the eyeball, and named, from their position, upper and lower. The upper is the larger and more movable, being provided with a special elevator muscle, the m. levator palpebræ superioris. The interval between the lids is termed the **palpebral fissure** (rima palpebrarum), and measures transversely about 30 mm., but varies considerably in different individuals and in different races. When the eye is open the fissure is elliptical in shape, but when closed it assumes the form of a transverse slit, which lies on a level with the lower margin of the cornea. The two lids meet at the extremities of the fissure, and form the **outer** and **inner angles**, or **canthi**. Their free margins are flattened and are surmounted by eyelashes from the external

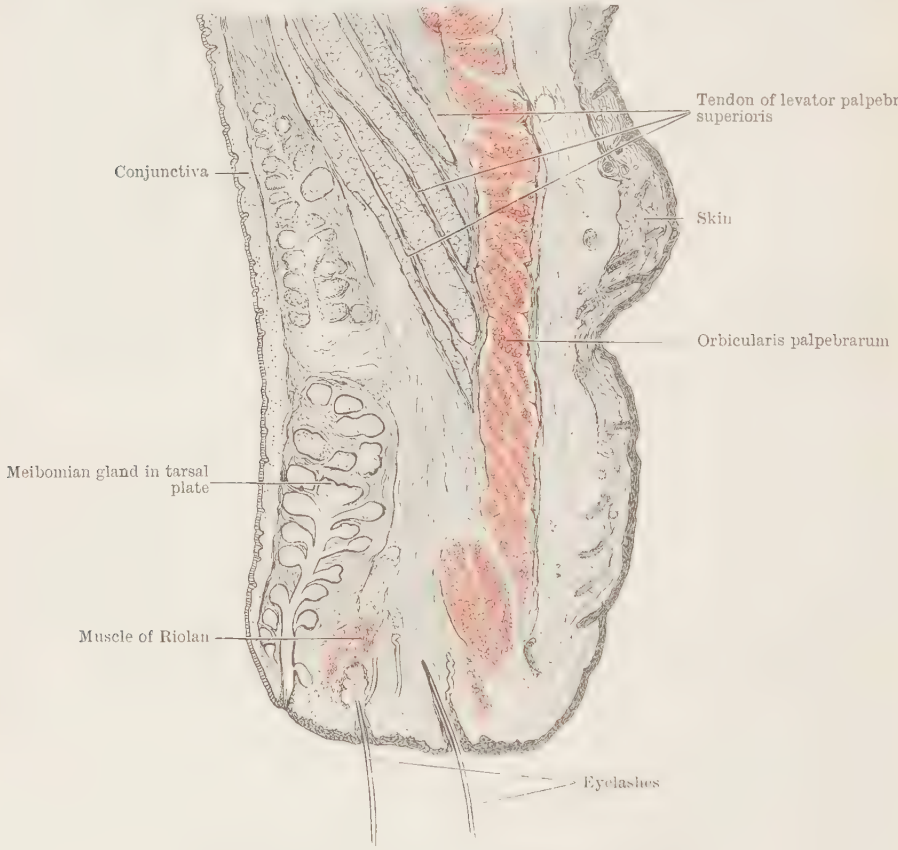

Fig. 574.—Vertical Section through Upper Eyelid.

canthus to a point about 5 mm. from the inner canthus—a point indicated by a small papilla, the **papilla lacrimalis**. Internal to this papilla the margins are rounded and destitute of eyelashes, and form the upper and lower boundaries of a triangular space, termed the **lacus lacrimalis**, which is occupied by a small pale-red body, the **caruncula lacrimalis**. This caruncula consists of a minute island of modified skin, and contains sweat glands, sebaceous glands, and fine hairs. Posteriorly the lids are lined by a mucous membrane, the conjunctiva, and are in contact with the eyeball, except near the inner canthus, where, between the eyeball and the caruncula lacrimalis, there intervenes a vertical fold of conjunctiva, the **plica semilunaris conjunctivæ**. This, which in many animals contains a plate of cartilage, is the representative of the membrana nictitans, or third eyelid of birds, etc.

In each lid there exists a framework of condensed fibrous tissue, which gives consistence and shape to the lid, and is termed the **tarsal plate or tarsus**. In front of the tarsus are the fibres of the orbicularis palpebrarum muscle and the

integument, while embedded in its posterior surface, and covered by the conjunctiva, are numerous modified sebaceous glands named the **tarsal or Meibomian glands.** The superior tarsal plate (tarsus superior) is larger than the inferior and of a half oval shape, with its greatest vertical diameter measuring about 10 or 11 mm. Its upper margin is thin and convex, and is continuous with the tendon of the levator palpebræ superioris muscle, while its lower edge is thick and straight. The inferior tarsal plate (tarsus inferior) is a thin, narrow strip, with a nearly uniform vertical diameter of about 5 mm. The extremities of the two plates are continuous with the **external and internal tarsal ligaments.** The external tarsal ligament is a narrow band attached to the malar bone; it divides, at the outer canthus, into upper and lower pieces which are fixed to the margins of the respective tarsal plates. The internal tarsal ligament is a strong band attached to the nasal process of the superior maxillary bone directly in front of the lachrymal groove; it divides at the inner canthus into two slips, one for either tarsal plate.

The eyelids are further strengthened by membranous expansions, termed the **superior** and **inferior palpebral ligaments**, which extend into them from the margin of the orbit. The superior ligament is continuous, along the upper margin of the orbit, with the pericranium and with the periosteal lining of the orbit, and blends below with the tendon of the levator palpebræ superioris. The inferior ligament is prolonged from the under edge of the inferior tarsal plate to the lower margin of the orbit, where it is continuous with the periosteum of the face and orbital floor. Externally the two palpebral ligaments fuse to form the external tarsal ligament, while internally they become thinned, and, separating from the internal tarsal ligament, are attached to the lachrymal bone behind the lachrymal sac. These two palpebral ligaments form a kind of septum or diaphragm, the **septum orbitale**, between the superficial and deep structures of the eyelids; this septum is perforated by the vessels and nerves, which extend from the orbital cavity to the face or scalp.

The skin covering the lids is thin and delicate, and is continuous, at their margins, with their conjunctival lining. It contains numerous small sweat glands and fine hairs, the latter being provided with sebaceous follicles. Branched pigment cells are present in the cutis, and pigment also exists in the deep layers of the epidermis. The subcutaneous tissue is loose and devoid of fat, and in it are found the fibres of the orbicularis palpebrarum muscle—a small separate bundle of which, termed the **muscle of Riolan**, occupies the margin of the lids behind the eyelashes. The **Meibomian glands**, or glandulæ tarsales, are elongated sebaceous glands with numerous lateral offshoots; they are embedded in the tarsal plates and filled with cubical epithelium. There are from twenty-five to thirty in the upper lid, and from twenty to twenty-five in the lower; they open by small ducts, about 1 mm. in length, along the lid margins behind the eyelashes; the ducts are lined by stratified epithelium placed on a basement membrane. Between the eyelashes and the muscle of Riolan are two or three rows of modified sweat glands, termed the **glands of Moll**; the blocking of a duct of one of these glands frequently gives rise to a stye.

H. Müller described a layer of non-striped muscle in each lid: in the upper extending from the tendon of the levator palpebræ superioris to the upper tarsal plate, and in the lower connecting the inferior tarsal plate with the inferior oblique muscle.

The tendon of the levator palpebræ superioris divides into three parts—an anterior, passing between the bundles of the orbicularis to the deep surface of the skin; a middle, attached to the superior tarsal plate; and a posterior, to the fornix conjunctivæ: there is no corresponding muscle in the lower lid. The eyelashes are curved, silky hairs which project from the free margins of the lids; in the upper lid they are longer and more numerous than in the lower, and are curved upwards, while those of the lower lid are bent downwards.

**Conjunctiva.**—This is the name applied to the mucous membrane which lines the back of the lids (**tunica conjunctiva palpebrarum**), and is continued on to the front of the eyeball (**tunica conjunctiva bulbi**). The line along which it is reflected from the lids on to the globe of the eye is termed the **fornix conjunctivæ.** The palpebral portion adheres intimately to the tarsal plate and presents numerous papillæ. It is covered by a layer of columnar epithelial cells, beneath the bases

of which are small flattened cells. Near the fornix a number of acino-tubular glands, much more plentiful in the upper than in the lower lid, open on its free surface. The conjunctiva bulbi is thinner than that lining the lids, and is loosely attached to the sclera by submucous tissue. The plica semilunaris conjunctivæ has already been referred to (p. 738). On the cornea the conjunctiva is represented merely by the stratified epithelium already described (p. 726).

**Vessels and Nerves.**—The chief **arteries** of the eyelids are the superior and inferior palpebral branches of the ophthalmic, which pierce the septum orbitale above and below the internal tarsal ligament, and run tortuously outwards in the corresponding lid near its free margin. On reaching the region of the outer canthus they anastomose with each other and with twigs from the lachrymal, superficial temporal, and transverse facial arteries, and in this way an arch is formed in each lid (upper and lower tarsal arches). Secondary smaller arches are found, one above the primary arch in the upper lid, and another below that of the lower lid, while the upper lid also receives branches from the supraorbital and frontal arteries. The **veins** are arranged in two sets: (*a*) subconjunctival or retrotarsal, opening into the muscular tributaries of the ophthalmic vein, and (*b*) pretarsal, into the angular and superficial temporal veins. The **lymphatics,** like the veins, form pre- and retrotarsal networks, which communicate with each other through the tarsal plates. The lymph is chiefly drained into the perauricular and parotid lymphatic glands, but partly, by vessels which accompany the facial vein, into the submaxillary lymphatic glands. The **sensory nerves** of the eyelids are supplied by the fifth cranial nerve—the upper lid chiefly by the supraorbital and supratrochlear branches of the ophthalmic; the lower, by the infraorbital branch of the superior maxillary. The region of the outer canthus receives some filaments from the lachrymal nerve, that of the inner from the infratrochlear. These sensory nerves form a marginal plexus behind the orbicularis palpebrarum muscle. The levator palpebræ muscle is supplied by the third cranial nerve and the non-striped fibres of the lids by the sympathetic.

## LACHRYMAL APPARATUS.

The **lachrymal apparatus** (apparatus lacrimalis) consists of: (1) the lachrymal gland, which secretes the tears; (2) the lachrymal canals, by which they are drained from the front of the globe; and (3) the lachrymal sac and nasal duct, which convey them into the nasal cavity.

The **lachrymal gland** is a flattened, oval body situated in the upper and outer part of the orbital cavity, and consists of two portions—orbital and palpebral—imperfectly separated from each other by the expansion of the tendon of the levator palpebræ superioris muscle. The **orbital** portion, or **glandula lacrimalis superior**, is firm and much larger than the palpebral part; it measures transversely about 20 mm., and sagittally from 12-14 mm. It occupies the fossa lacrimalis on the inner aspect of the external angular process of the frontal bone, and is fixed by fibrous bands to its periosteum, while its inferior surface is in contact with the levator palpebræ superioris and external recti muscles which intervene between it and the globe of the eye. The smaller, **palpebral portion**, or **glandula lacrimalis inferior**, consists of small, loosely aggregated lobules. It lies below and in front of the orbital portion, and projects into the posterior part of the upper eyelid, where its deep surface is in contact with the conjunctiva. The ducts which drain the orbital portion are from three to five in number; they pass between the lobules of the palpebral portion, and open at the upper and outer part of the fornix conjunctivæ. The ducts of the palpebral portion number from three to nine; some of them join those from the orbital part, while others open separately at the fornix conjunctivæ. The lachrymal gland has a structure similar to that of the parotid, and is supplied by the sympathetic and lachrymal nerves and by the lachrymal artery, while its veins are drained into the ophthalmic vein.

The **lachrymal canals** (ductus lacrimales) commence by minute orifices, termed the **puncta lacrimalia**, at the apices of the papillæ lacrimales already referred to (p. 738). The upper canal is the smaller of the two, and at first ascends for a short distance, and then runs inwards and slightly downwards; the lower descends for a short distance and then runs horizontally inwards. At the angle where they change their direction each is dilated into an ampulla (ampulla ductus lacrimalis). They occupy the margins of the lids, where these bound the lacus lacrimalis, and the two canals open close together into the outer and fore-part of the lachrymal sac, a little below its middle; sometimes they open separately into a pouch-like dilatation of the sac, termed the sinus of Maier. Each canal is lined by a

stratified epithelium placed on a tunica propria, outside which is a layer of striped muscular fibres derived from the tensor tarsi muscle. These muscular fibres are arranged somewhat spirally around the canals, but at the bases of the papillæ they are circular in direction and form a species of sphincter. On contraction they serve to empty the contents of the lachrymal canals into the lachrymal sac.

The **lachrymal sac** and **nasal duct** together form the passage by which the tears are conveyed from the lachrymal canals to the nose.

The **lachrymal sac** (saccus lacrimalis) is the upper expanded part of the passage, and measures from 12-15 mm. in length, about 7 mm. antero-posteriorly, and from 4-5 mm. transversely. It lies in the groove formed by the lachrymal bone and nasal process of the superior maxilla, and ends above in a rounded, blind extremity or fundus, while it narrows below into the nasal duct. Here a fold of mucous membrane, named the valve of Beraud, together with a laterally directed pouch, the sinus of Arlt, are sometimes present. Near its superior extremity it is crossed in front by the internal tarsal ligament, from the upper and lower edges of which the orbicularis palpebrarum takes origin, while behind it is the tensor tarsi muscle, or muscle of Horner.

The **nasal duct** (ductus naso-lacrimalis) averages about 18 mm. in length, and has a diameter of from 3-4 mm. Rather narrower near its middle than at its upper and lower extremities, it is directed downwards and slightly backwards, and opens into the inferior meatus of the nose at the junction of its anterior with its posterior three-fourths, *i.e.* a distance of 30-35 mm. from the posterior boundary of the nostril. Its lower orifice is somewhat variable in form and position, and is occasionally duplicated. It is frequently guarded by a fold of mucous membrane, termed the **valve** or **plica lacrimalis of Hasner**. Through this orifice the mucous lining of the duct is continuous with that of the nose. The mucous membrane of the duct is thrown into inconstant folds, several of which have been described as valves. Its epithelium is columnar and in part ciliated; opening into the lower part of the duct are numerous glands similar to those in the nasal mucous membrane. The nerves of the lachrymal canals and sac are derived from the infratrochlear branch of the nasal; their arteries from the inferior palpebral and nasal. The veins of the nasal duct are large and numerous, forming a sort of erectile tissue similar to that in the nose.

## Development of the Eye.

The retina and optic nerve are developed from a hollow outgrowth of the fore-brain, termed the **optic vesicle** (see pp. 478 and 595). This extends towards the side of the head, and its

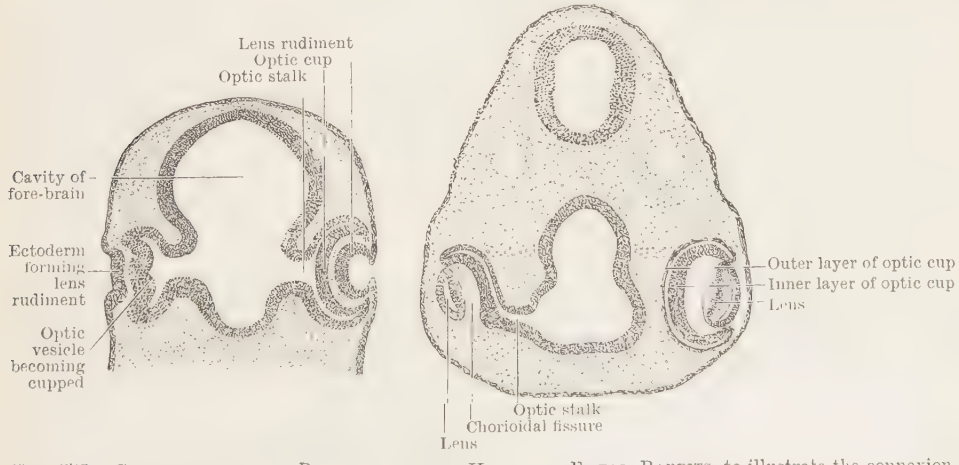

Fig. 575.—Sections through Portions of the Heads of Fœtal Rabbits, to illustrate the connexion of the optic cup with the fore-brain, and the invagination of the ectoderm to form the lens.

connexion with the brain is gradually elongated to form the **optic stalk**. The ectoderm overlying the optic vesicle becomes thickened, invaginated, and finally cut off as a hollow

island of cells, which is developed into the lens and is named the **lens vesicle**. This lens rudiment indents the outer and lower part of the optic vesicle, which now assumes the form of a cup (**optic cup**), lined by two layers of cells continuous with each other at the margin of the cup. The inner of these strata, thicker than the outer, is named the **retinal layer**, and becomes differentiated into the nervous and supporting elements of the retina; while the outer, named the **pigmentary layer**, forms its pigmented epithelium. The edge of the optic cup extends in front of the equator of the lens, and bounds the future aperture of the pupil. In front of the lens, and also opposite its equator, the retinal layer is thin, and represented only by a stratum of columnar cells which becomes closely applied to the pigmentary layer, the two forming the pars ciliaris and pars iridica retinæ. The indentation of the optic cup extends as a groove for some distance along the postero-inferior aspect of the optic stalk, forming what is termed the **chorioidal fissure** (Fig. 576). Through this fissure the mesoderm passes inwards between the lens and the retina to form the vitreous body, while the arteria centralis retinæ also becomes enclosed in it and so gains its future position in the centre of the optic nerve. The arteria centralis is prolonged forwards from the porus opticus through the vitreous body, as a cone of branches, as far as the back of the lens. By the fifth or sixth month all these branches have disappeared except one, the **arteria hyaloidea**, which persists until the last month of fœtal life, when it also atrophies, leaving only the **canalis hyaloideus** to indicate its position.

The lens rudiment, at first in contact with the ectoderm, from which it is derived, soon becomes separated from it by mesoderm, and then consists of a rounded vesicle lined by epithelium. The epithelium which lines the anterior part of the vesicle remains as a single layer of cells—the anterior lens epithelium of the adult. The cells lining the posterior part of the vesicle become elongated into lens fibres, and by the forward growth of these the cavity of the vesicle is obliterated. This elongation into lens fibres is greatest at the centre of the lens, while near the equator the fibres are shorter, and here the gradual transition between the anterior epithelium and the lens fibres is seen (Fig. 573). The lens becomes enveloped in a vascular tunic, which receives its vessels from the arteria centralis retinæ and from the vessels of the iris. The front part of this tunic forms the membrana pupillaris, and this, like the rest of the tunic, disappears before birth.

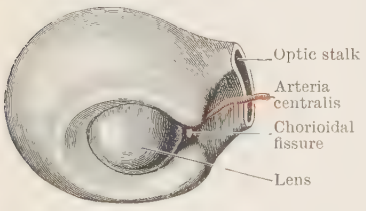

Fig. 576.—Optic Cup and Lens viewed from Behind and Below, to show formation of chorioidal fissure and enclosure of the arteria centralis retinæ (from model by Ziegler).

The hollow stalk of the optic cup becomes solid by the thickening of its walls and the obliteration of its cavity, and, acquiring nerve-fibres, becomes the optic nerve. These nerve-fibres are mostly centripetal, and are derived from the nerve-cells of the retina; but a few are centrifugal and have their origin in the brain. The further development of the retina resembles, in certain respects, that of the spinal cord.

Cameron states ("The Development of the Retina in Amphibia," *Journ. Anat. and Physiol.*, London, vol. xxxix.) that in the early stages of the development of the inner or retinal layer of the optic cup all the structures, described by His as being present in the spinal cord of the human embryo, are to be found, viz. (*a*) spongioblasts, (*b*) germinal cells, and (*c*) neuroblasts.

The spongioblasts undergo ramification and form a network or myelospongium, and also give rise to the inner and outer limiting membranes; the latter is next the original cavity of the optic vesicle, and therefore corresponds to the inner limiting membrane of the spinal cord. The spongioblasts also form the groundwork of the inner and outer molecular layers into which the processes of the neuroblasts grow and arborise.

The germinal cells are always situated beneath the external limiting membrane, and by their division give rise to the neuroblasts. The first-formed neuroblasts are larger than those of succeeding generations, and are found in the site of the future ganglionic layer. The germinal cells in the middle of the convexity of the retinal cup cease to divide at an early stage of development, and become directly transformed into the rod and cone cells from which the rods and cones develop as processes; hence these structures appear first over the middle of the convexity of the retina, and gradually extend towards the margin of the retinal cup.

The nuclei of the retinal neuroblasts undergo a progressive diminution in size—in some cases to one-fourth of that of their earlier stages. Cameron, after a careful study of the neuroblasts, not only in the retina, but in the wall of the cerebral vesicle and spinal cord, is of opinion that the neuroblastic nuclei are destitute of a protoplasmic investment, and that what has been described as a zone of "clear protoplasm" surrounding these nuclei during the process of karyokinesis is simply the achromatic nuclear substance set free by the disappearance of the nuclear membrane; and, further, that the processes which grow out from the neuroblasts in reality issue from the substance of the nuclei and thus cause the gradual diminution in size of the latter. "The processes of the retinal 'ganglion-cells' and of the cells of the inner nuclear layer first show

themselves as protrusions of the nuclear contents, while the rods and cones are at first also protrusions of the nuclei of the external nuclear layer. The rod and cone elements, when they first appear, do so as perfectly clear spherical globules consisting of nothing more than nuclear achromatin. The axis-cylinders of the optic nerve arise as processes of the nuclei in the ganglionic layer, and the great difficulty which is experienced in staining the individual fibres of the retinal nerve-fibre layer is due to the fact that they are composed of the achromatic nuclear substance of the ganglionic nuclei. The origin of the axis-cylinders from these nuclei supports the contention of those who insist on the fact that the axis-cylinder process of a nerve-cell can be traced right into the nucleus of that cell."

The molecular layers make their appearance as plexuses of myelospongium. The internal molecular layer is first developed at the centre of the retinal cup, and gradually extends towards the cup margin, and into it the processes from the nuclei on either side grow and ramify. The rod and cone fibres, and the outer processes of the internal nuclear layer, grow into and arborise within the external molecular layer.

The most interesting points with reference to the development of the nuclear layers are, (1) the extrusion of the various processes from the nuclei as already described, and (2) the free manner in which these nuclei multiply by *direct* division during the metamorphosis. It is interesting to note that the retinal nuclei are formed during the early stages by mitotic or indirect division of the germinal cells, while later they appear capable of multiplying by amitotic or direct division only.

The first evidences of the rods and cones are in the form of clear, absolutely achromatic globules, which lie between the nuclei of the external nuclear layer and the outer limiting membrane. Whenever these are protruded beyond this membrane they grow with great rapidity, and exert an influence on the retinal pigment cells, causing them to protrude their processes, the pigment of which they seem to digest and absorb, since they now stain deeply with iron-alum-hæmatoxylin. This gives us a clue to the mode by which the rhodopsin function of the rods in the adult is conducted, for these structures actually owe their growth and development to the ingestion of pigment from the pigment-cell processes.

The condensed mesoderm surrounding the optic cup becomes the sclera and chorioid. In the portion of the mesoderm which lies in front of the lens a cleft-like fissure appears, and divides it into a thick anterior and a thin posterior layer. The former becomes the substantia propria of the cornea; the latter, the stroma of the iris and anterior part of the vascular tunic of the lens. The fissure represents the future anterior chamber, and its lining cells form the layer of endothelium on the back of the cornea and front of the iris.

The **eyelids** arise as two integumentary folds above and below the cornea, each being covered on both its surfaces by the ectoderm. By the third month the folds meet and unite with each other at their edges, the eyelids being only permanently opened shortly before birth; in many animals they are not opened until after birth. The ectoderm forms the epithelium of the conjunctiva and the stratified epithelium of the cornea. It is also invaginated at the lid margins to form the hair follicles and the lining cells of the Meibomian glands and glands of Moll, and, at the fornix conjunctivæ, to form the lining of the alveoli and ducts of the lachrymal gland.

The **nasal duct, lachrymal sac, and canals** represent the remains of the furrow which extends from the inner angle of the eye to the nasal cavity between the superior maxillary and lateral nasal processes (p. 40). It is at first filled by a solid rod of cells, which becomes hollowed out to form the duct and canals.

## THE EAR.

The ear or organ of hearing (organon auditus, Fig. 577) consists of three portions —external, middle, and internal—the last constituting its essential part, as within it are distributed the peripheral terminations of the auditory nerve.

### EXTERNAL EAR.

The **external ear**[1] includes —(*a*) the pinna or auricula, attached to and projecting from the side of the head; and (*b*) the passage or external auditory meatus (meatus acusticus externus), leading inwards from the most depressed part of the pinna as far as the tympanic membrane or outer wall of the middle ear.

#### The Pinna.

The **pinna** or **auricula** (Fig. 578) presents two surfaces, outer and inner, the latter forming an angle (cephalo-auricular angle) of about 30°, with the side of the

[1] Although it is usual to speak of the external, middle, and internal ear, it would be more correct to use the terms external, middle, and internal *portions* of the ear.

head. The outer surface is irregularly concave, but presents several well-marked elevations and depressions. The deepest of the depressions is situated near its middle, and is named the **concha** (concha auriculæ). It is divided by an almost transverse ridge, the **crus helicis**, into an upper, smaller, and a lower, larger portion: the former is termed the **cymba conchæ**; the latter, which leads into the meatus, the **cavum conchæ**. Anteriorly, the crus helicis is continuous with the margin of the pinna or **helix**, which is folded over, in the greater part of its extent, like the rim of a hat, and is directed at first upwards, and then backwards and downwards, to become gradually lost a little below the middle of the pinna. Near the point where the helix begins to turn downwards a small tubercle, the **tuberculum superius** (Darwini), is often seen; it will be again referred to. In front of the descending part of the helix is a second elevation, the **antihelix**. Single below, it divides superiorly into two limbs, termed the **crura antihelicis**, between which is a triangular depression, the **fossa of the antihelix**, or **fossa triangularis**. The elongated furrow between the helix and antihelix is named the **fossa of the helix** or **scapha**. The concavity of the concha is overlapped in front by a tongue-like process, the **tragus**, and behind by a triangular projection, the **antitragus**; the notch, directed downwards and forwards between these two processes, is named the **incisura intertragica**. The tragus really consists of two tubercles, the upper of which constitutes the **tuberculum supratragicum** of His, and is separated from the helix by a groove, the **sulcus auris anterior**. The **lobule** (lobulus auriculæ) is situated below the incisura intertragica, and is the most dependent part of the pinna.

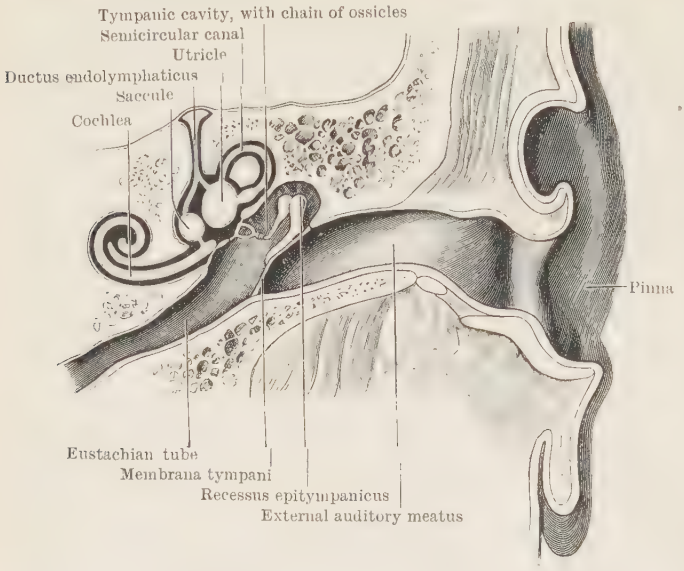

Fig. 577.—Diagrammatic View of the Organ of Hearing.

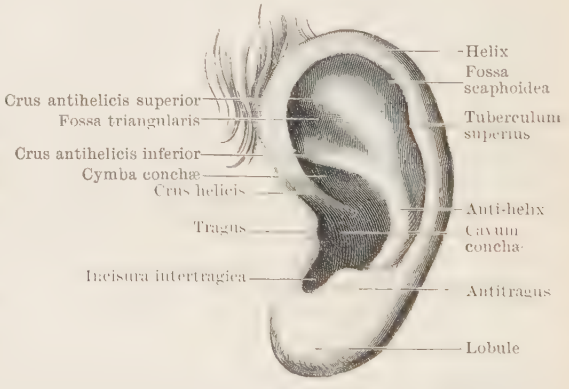

Fig. 578.—View of Outer Surface of Left Pinna (half natural size).

The inner or cranial surface is also irregular, and presents elevations corresponding to the depressions on its outer surface, *e.g.* **eminentia conchæ, eminentia triangularis**, etc.

The pinna is usually smaller and more finely modelled in the female than in the male, but presents great variations in size and shape in different individuals. In the newly-born child its length is about one-third of that of the adult, while it increases slightly in length and breadth in old age.

The relation of the width to the height is termed the auricular index, and is expressed as follows:—

$$\frac{\text{width of pinna} \times 100}{\text{length of pinna}} = \textbf{Auricular index.}$$

This index is less in white than in dark races.

The **cephalo-auricular angle** may be practically absent, as in those cases where the skin of the head passes directly on to the outer surface of the pinna, or it may be increased to nearly a right angle, so that the outer surface of the pinna looks directly forwards. The **tuberculum superius**, the significance of which was recognised by Darwin, is a somewhat triangular prominence which projects forwards when the helix is well rolled over, but backwards and upwards when the incurving of the helix has been arrested. More frequently present in men than in women, it is of developmental interest since it has been shown to be well marked at the sixth month of fœtal life, the entire pinna, at this stage, resembling in appearance that of the adult macaque.

The **lobule** may be small and sessile or considerably elongated; it may adhere to the skin of the cheek (*i.e.* webbed), or may tend to bifurcate at its lower extremity.

**Structure of the Pinna.**—The greater part of the pinna consists of a lamella of yellow fibro-cartilage, the **cartilago auriculæ**; the cartilage is, however, absent from the lobule, which is composed of fat and connective tissue. When laid bare, the cartilaginous lamella (Figs. 579, 580) presents, in an exaggerated condition, all the inequalities of the pinna, and is seen to be prolonged inwards, to form a considerable portion of the external auditory meatus. The cartilage of the helix projects anteriorly as a conical eminence, the **spina helicis**, whilst its inferior extremity extends downwards as a tail-like process, the **cauda helicis**, which is separated from the lower part of the antitragus by a fissure, termed the **fissura antitragohelicina**. The cartilage of the pinna is continuous with that of the meatus by a narrow **isthmus** (isthmus cartilaginis auris) measuring from 8-9 mm. in breadth. This isthmus corresponds externally with the deepest part of the incisura intertragica, and internally it forms the outer boundary of a deep fissure, the **incisura terminalis auris**, which separates the cartilage of the meatus from that of the concha. The upper edge of the tragus fits into an angle below the crus helicis.

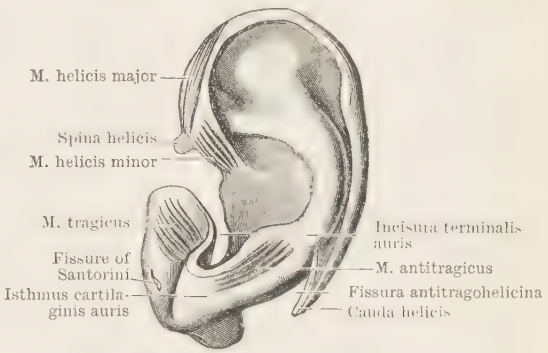

FIG. 579.—OUTER SURFACE OF CARTILAGE OF PINNA (one-half natural size).

If the incisura terminalis auris, together with the isthmus and the incisura intertragica, be taken as representing the boundary between the cartilage of the pinna and that of the meatus, it follows that the tragus really forms a part of the meatal cartilage.

On the cranial aspect of the cartilage (Fig. 580) the eminences produced by the concha and fossa triangularis are separated by a transverse furrow, the **sulcus antihelicis transversus**, corresponding with the crus antihelicis inferior; further, the eminentia conchæ is crossed horizontally by a groove, the **sulcus cruris helicis**, and almost vertically by a slight ridge, the **ponticulus**: the latter indicates the attachment of the M. auricularis posterior.

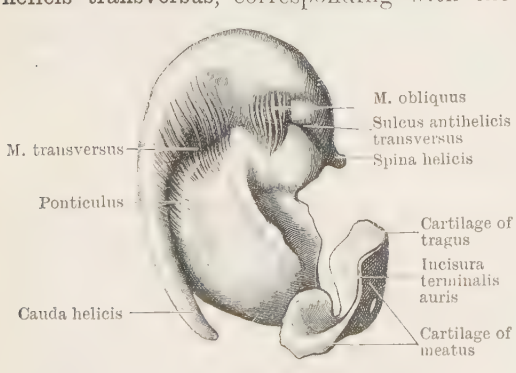

FIG. 580.—INNER SURFACE OF CARTILAGE OF PINNA (one-half natural size).

In addition to the fissures described, others, termed the **fissures of Santorini**, are found, usually one in the tragus and one or more in the cartilage of the meatus.

**Ligaments of the Pinna.**—The cartilage of the pinna is attached to the skull by two fibrous bands which form its extrinsic ligaments, viz.: an *anterior*, stretching from the zygoma to the spina helicis and tragus; and a *posterior*, passing from the eminentia conchæ and upper wall of the meatus to the mastoid

process. Small ligamentous bands pass between individual parts of the pinna, and form what are termed its intrinsic ligaments.

**Muscles of the Pinna** (Figs. 579, 580).—The muscles of the pinna are divided into two groups, *extrinsic* and *intrinsic*. The extrinsic muscles pass from the pinna to the skull or scalp, and are described in the section on Myology. The intrinsic muscles, on the other hand, are confined to the pinna and are six in number, four on its outer and two on its cranial aspect.

(*a*) *On the outer surface* (Fig. 579)—

1. **M. helicis major**, passes upwards from the spina helicis along the ascending part of the helix. 2. **M. helicis minor**, covers the crus helicis. 3. **M. tragicus**, quadrangular in shape, consists of fibres running vertically over the greater part of the tragus. Some of its fibres are prolonged upwards to the spina helicis and constitute the m. pyramidalis. 4. **M. antitragicus**, covers the antitragus and passes obliquely upwards and backwards as far as the antihelix and cauda helicis.

(*b*) *On the cranial surface* (Fig. 580)—

1. **M. transversus auriculæ**, consists of scattered fibres, which stretch from the eminentia conchæ to the convexity of the helix. 2. **M. obliquus auriculæ** (Tod), comprises a few fasciculi, which run obliquely or vertically across the furrow corresponding with the crus antihelicis inferior. A small muscle, the stylo-auricularis, sometimes extends from the root of the styloid process to the cartilage of the meatus.

**Skin of the Pinna.**—The skin covering the pinna is thin and smooth, and is prolonged inwards, in the form of a tube, as a lining to the external auditory meatus. It adheres firmly, on the outer surface of the pinna, to the subjacent perichondrium. Hairs are well developed on the tragus and antitragus, and also in the incisura intertragica, forming the **barbula hirci**, which guard the entrance to the concha. Soft downy hairs are found over the greater part of the pinna and point towards Darwin's tubercle. Sebaceous glands, present on both surfaces of the pinna, are most numerous in the concha and fossa triangularis. Sweat glands are found on both surfaces, but are much more numerous on the cranial aspect.

**Vessels of the Pinna.**—The **arteries** for the pinna are derived—(*a*) from the superficial temporal, which sends two or three branches to the outer surface; and (*b*) from the posterior auricular, which gives three or four branches to the cranial surface. From the latter two sets of twigs are prolonged to the outer surface, one turning round the free margin of the helix, and the other passing through small fissures in the cartilage. The **veins** from the outer surface open into the superficial temporal vein; those from the cranial surface chiefly join the posterior auricular vein, but some communicate with the mastoid emissary vein. The **lymphatics** take three directions, viz.: (*a*) forwards to the parotid lymphatic glands, and especially to the preauricular gland in front of the tragus; (*b*) downwards to the lymphatic glands which accompany the external jugular vein, and to the glands under the sternomastoid; and (*c*) backwards to the mastoid lymphatic glands.

**Nerves of the Pinna.**—The muscles of the pinna are supplied by the seventh cranial nerve. The skin receives its sensory nerves from—(*a*) the great auricular, which supplies nearly the whole of the cranial surface, and sends filaments in company with the branches of the posterior auricular artery to the outer surface; (*b*) the auriculo-temporal, which supplies the tragus and ascending part of the helix; (*c*) the small occipital, which sends a branch to the upper part of the cranial surface.

## External Auditory Meatus.

The **external auditory meatus** (meatus acusticus externus) (Figs. 580, 581) is the passage leading inwards from the concha as far as the membrana tympani. Its average length, measured from the bottom of the concha, is about one inch (24 mm.), but, if measured from the level of the tragus, nearly one inch and a half (35 mm.) On account of the obliquity of the membrana tympani its anterior and inferior walls are longer than the posterior and superior. The tube consists of two parts, viz.: (*a*) an external **fibro-cartilaginous portion**, the pars cartilaginea, having a length of about 8 mm.; and (*b*) an internal **osseous portion**, the pars ossea, measuring about 16 mm., and formed by a portion of the temporal bone. The entire meatus forms a somewhat S-shaped bend (Fig. 582), and may be divided into

three portions, viz.: (1) **pars externa**, directed inwards, forwards, and slightly upwards for about 7 mm.; (2) **pars media**, inclining inwards and backwards for about 5 mm.; (3) **pars interna**, the longest of the three, passing forwards, inwards, and slightly downwards. On transverse section the canal is seen to be elliptical, its greatest diameter having an inclination downwards and backwards. Widest at its outer extremity, it becomes somewhat narrower at the inner end of the pars cartilaginea; once more expanding in the outer part of the pars ossea, it is again constricted near the inner end of the latter, where its narrowest part, or **isthmus**, is found at a distance of about 19 mm. from the bottom of the concha. The inner extremity of the meatus is nearly circular and is closed by the membrana tympani.

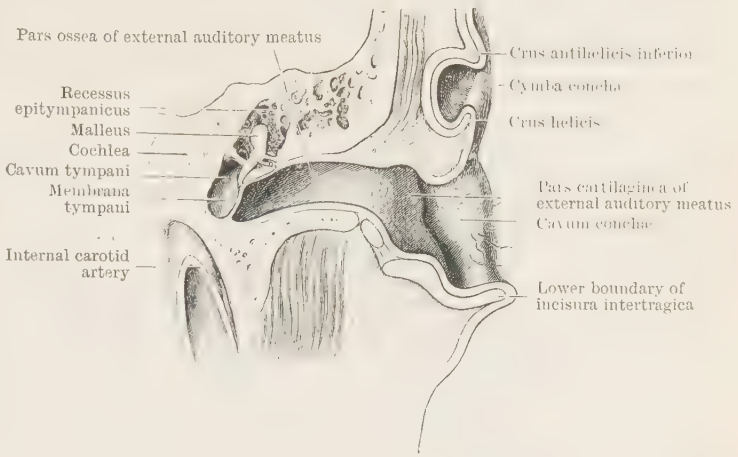

FIG. 581.—VERTICAL TRANSVERSE SECTION OF RIGHT EAR: ANTERIOR HALF OF SECTION, viewed from behind (natural size).

Bezold gives the diameters of the meatus as follows:—

| | Greatest. | Least. |
|---|---|---|
| At the commencement of the pars cartilaginea. . . | 9·08 mm. | 6·54 mm. |
| At the end „ „ „ . . . | 7·79 mm. | 5·99 mm. |
| At the commencement of the pars ossea . . . | 8·67 mm. | 6·07 mm. |
| At the end „ „ „ . . . | 8·13 mm. | 4·60 mm. |

The lumen of the pars cartilaginea is influenced by the movements of the lower jaw, being increased when the jaw is depressed. This can be easily verified by inserting a finger into the meatus, and then alternately opening and shutting the mouth.

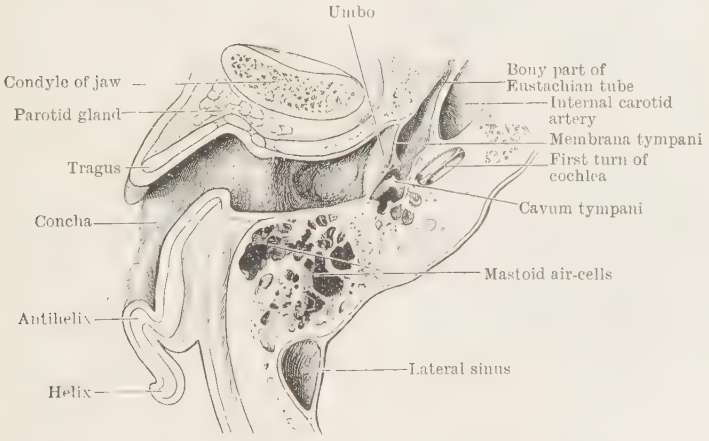

FIG. 582.—HORIZONTAL SECTION THROUGH RIGHT EAR; UPPER HALF OF SECTION seen from below (natural size).

The condyle of the jaw lies in front of the pars ossea, while between the jaw and the pars cartilaginea there intervenes a portion of the parotid gland. Below the meatus is the retro-mandibular part of the parotid gland. Behind the pars ossea, and separated from it by a thin plate of bone, are the mastoid air-cells.

**Structure of the Meatus.**—The cartilage of the meatus, directly continuous with that of the pinna, is folded on itself to form a groove, opening upwards and backwards, the margins of which are connected by fibrous tissue. The inner end of the cartilage is firmly fixed to the outer margin of the bony meatus, whilst its outer extremity is continuous with the cartilage of the tragus (*vide* p. 745). A couple of

fissures, the **fissures of Santorini**, exist in the anterior portion of the cartilage of the meatus, and are filled by fibrous tissue. In the outer part of the meatus the cartilage forms about three-fourths of its circumference; but, on passing inwards, the proportion of cartilage to fibrous tissue diminishes, with the result that near the inner end of the pars cartilaginea the cartilage forms merely a part of the anterior and lower boundaries of the canal.

The osseous portion (pars ossea) of the meatus is described on p. 117; but it may be well to state here that in the newly-born child it is represented only by an incomplete ring of bone, the **annulus tympanicus**, together with a small portion of the squamous temporal, which articulates with, and bridges over the interval between, the extremities of the ring superiorly. In the concavity of the annulus is a well-defined groove, the **sulcus tympanicus**, in which the circumference of the membrana tympani is fixed. On the inner aspect of the anterior part of the annulus, a little below its free extremity, a groove, the **sulcus malleolaris**, is directed downwards and forwards. It transmits the processus gracilis and anterior ligament of the malleus, the tympanic artery and the chorda tympani nerve. It is limited above by a well-marked ridge, the **crista spinarum** of Henle, which ends in front and behind in a spinous process (**spina tympanica anterior and posterior**). Below the sulcus malleolaris there is a second, less prominent ridge, the **crista tympanica** of Gruber, which subsequently unites with a process of the tegmen tympani, and so shuts off the canalis musculo-tubarius from the Glaserian fissure. A fibrous plate, the **tympanic fibrous plate** (Symington), intervenes between the annulus tympanicus and the inner end of the cartilage of the meatus, and into this plate the bony ring extends. The bony outgrowth does not, however, proceed uniformly throughout its circumference, but occurs most rapidly in the anterior and posterior parts of the ring. These outgrowths fuse about the end of the second year of life, so as to surround a foramen in the floor of the meatus (**foramen of Huschke**), which is usually closed by the fifth year, but persists until adult life in some 19 per cent of skulls (Bürkner).

The lumen of the meatus in the newly-born child is extremely small: its outer part is funnel-shaped; its inner a mere slit, bounded below by the tympanic fibrous plate and above by the obliquely-placed membrana tympani.

The **skin** which envelopes the pinna lines the entire meatus, and covers also the outer surface of the tympanic membrane. It is thick in the pars cartilaginea, and contains fine hairs and sebaceous glands, the latter extending inwards for some distance along the postero-superior wall of the pars ossea. The sweat glands are enlarged and of a brownish colour: they constitute the **glandulæ ceruminosæ** and secrete the ear wax or cerumen.

**Vascular and Nervous Supply of the Meatus.**—The meatus receives its blood-supply from the posterior auricular and superficial temporal arteries, and also from the deep auricular branch of the internal maxillary artery, the last distributing some minute branches to the membrana tympani. The **veins** open into the external jugular and internal maxillary veins, and also into the pterygoid plexus, while the **lymphatics** have a similar mode of termination to those of the pinna. **Sensory nerves** are supplied to the meatus by the auriculo-temporal branch of the fifth and by the auricular branch of the vagus.

## MIDDLE EAR OR TYMPANIC CAVITY.

The **tympanic cavity** (cavum tympani) is a small air chamber in the temporal bone, which intervenes between the membrana tympani and the outer wall of the internal ear or labyrinth (Figs. 581, 582). Lined by mucous membrane, it contains a chain of ossicles (ossicula auditus) which reaches from its outer to its inner wall, and by means of which the vibrations of the membrana tympani are transmitted across the cavity to the internal ear. Attached to the ossicles are several ligaments, together with a pair of small muscles, while certain nerves are either distributed to the cavity or pass through it.

The tympanic cavity consists of two portions: (1) The **tympanum proper**, or **atrium**, lying immediately to the inner aspect of the membrana tympani; and (2) the **recessus epitympanicus**, lying above the level of the membrane and containing the greater part of the incus and the upper half of the malleus. Including this recess, the vertical and antero-posterior diameters of the tympanic cavity are rather more than half an inch (15 mm.) The distance between its outer and inner walls is about 6 mm. above and 4 mm. below, while at its central part, owing to the bulging of the two walls towards the cavity, it measures only from $1\frac{1}{2}$ to 2 mm.

The tympanic cavity presents for examination a roof, a floor, and four walls, viz. anterior, posterior, external, and internal.

The **roof** (Fig. 583) (paries tegmentalis) is formed by a thin plate of bone, the **tegmen tympani**, constituting a portion of the upper surface of the petrous-temporal. It extends backwards so as to cover in the mastoid antrum, and forwards, to form

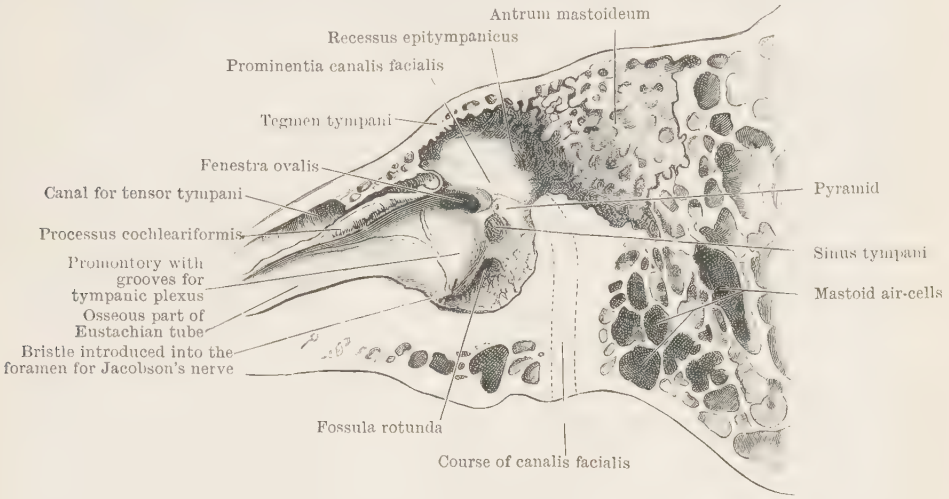

Fig. 583.—Section through Left Temporal Bone, showing inner wall of tympanic cavity, etc.

the roof of the canal for the tensor tympani muscle. It separates the tympanum and antrum from the cranial cavity, and may contain a few air-cells, whilst occasionally it is partly deficient. In the child its outer edge corresponds with the petro-squamous suture. The **floor** (fundus tympani seu paries jugularis) is narrower than the roof, and consists of a thin plate of bone which separates the cavity from the fossa jugularis; anteriorly, it extends upwards and becomes continuous with the posterior wall of the carotid canal. The inner orifice for Jacobson's nerve, or tympanic branch of the glosso-pharyngeal, is seen near the junction of the floor with the inner wall.

The **posterior wall** (paries mastoidea) presents, from above downwards: (1) A rounded or triangular opening, which extends backwards from the recessus epitympanicus and leads into the **mastoid antrum** (Fig. 583); the latter will be again referred to (p. 752). (2) A depression, the **fossa incudis** (Fig. 584), which lodges the extremity of the short process of the incus; this fossa is situated in the postero-inferior part of the recessus epitympanicus. (3) A minute conical bony projection, the **pyramid** or eminentia pyramidalis (Fig. 583), the summit of which is perforated by a round aperture for the passage of the tendon of the stapedius muscle. This aperture is continued downwards and backwards as a canal in front of the Fallopian aqueduct, and frequently opens, by a minute orifice, on the

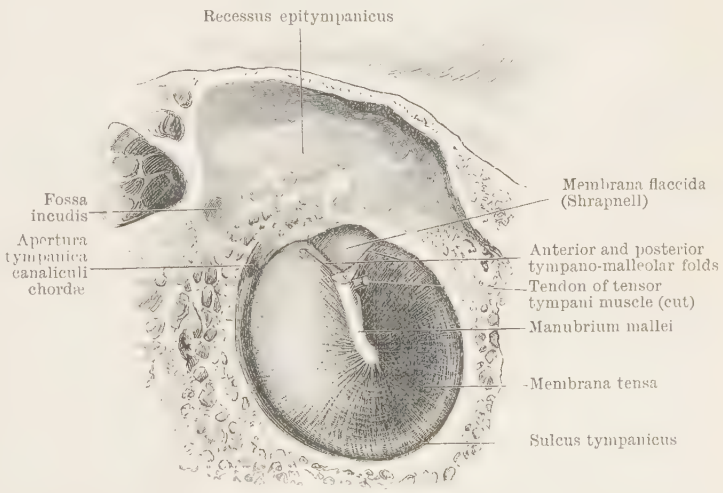

Fig. 584.—Left Membrana Tympani and Recessus Epitympanicus, viewed from within. The head and neck of the malleus have been removed to show the membrana flaccida and the tympano-malleolar folds. ×3.

base of the skull in front of the stylo-mastoid foramen. It communicates with the Fallopian aqueduct by one or two small foramina, through which the vessels and nerve pass to reach the stapedius muscle. A minute spicule of bone often extends from the pyramid to the promontory on the inner wall of the tympanum. (4) A small aperture, the **apertura tympanica canaliculi chordæ** (Fig. 584), which is situated immediately internal to the posterior edge of the membrana tympani, nearly on a level with the upper end of the manubrium mallei, and transmits the chorda tympani nerve. (5) A rounded eminence, the **prominentia styloidea**, is sometimes seen below the last; it is caused by the upward and forward prolongation of the styloid process.

The **anterior wall** (paries carotica) is narrowed in its transverse diameter by the approximation of the outer and inner boundaries of the cavity, and in its vertical diameter by the descent of the roof and ascent of the carotid canal. It presents (Fig. 583) two parallel canals, one above the other, separated by a thin lamella of bone, the **processus cochleariformis** (septum canalis musculo-tubarii). These run forwards on the outer wall of the carotid canal and open in the angle between the petrous and squamous parts of the temporal bone. The higher and smaller of the two is termed the **canal for the tensor tympani muscle** (semicanalis m. tensoris tympani), and lies immediately below the tegmen tympani. It has a diameter of about 2 mm., and extends on to the inner wall of the tympanic cavity above the anterior part of the fenestra ovalis. The lower and larger canal gradually increases in size from before backwards, and forms the **bony part of the Eustachian tube** (semicanalis tubæ auditivæ). It opens on the anterior wall of the tympanic cavity opposite the orifice leading into the mastoid antrum. Below the orifice of the Eustachian tube the anterior part of the tympanic cavity is separated from the ascending portion of the carotid canal by a thin plate of bone in which there are sometimes gaps or deficiencies. It is perforated by a small canal, the carotico-tympanic canal, which transmits the small, deep petrosal nerve from the sympathetic plexus of the carotid artery to the tympanic plexus. The Eustachian tube is described on p. 753.

The **outer wall** (paries membranacea) is formed almost entirely by the membrana tympani (Fig. 584), which closes the inner extremity of the external auditory meatus, and is fixed throughout the greater part of its circumference in a groove, the **sulcus tympanicus**. The bony ring containing this sulcus is deficient superiorly where it exhibits a distinct notch, the **notch of Rivinus**. On a level with the upper edge of the membrane, and in front of the ring of bone in which it is fixed, is the inner end of the **Glaserian fissure**, or remnant of the **fissura petro-tympanica**. This transmits the tympanic branch of the internal maxillary artery, and lodges the processus gracilis and anterior ligament of the malleus. Close to the inner extremity of the fissure is the **canal of Huguier**, or **iter chordæ anterius** through which the chorda tympani nerve leaves the tympanum.

**Membrana Tympani.**—This is an elliptical disc, its greatest diameter, 9 to 10 mm., being directed from above and behind, downwards and forwards, whilst its least diameter is from 8 to 9 mm. Its antero-inferior portion inclines markedly inwards, and thus the membrane is placed very obliquely, forming an angle of about 55° with the lower and anterior walls of the external auditory meatus; its antero-inferior part is, therefore, most distant from the outer orifice of the meatus. The membrane is said to be more oblique in cretins and deaf mutes, and more perpendicular in musicians.

The circumference of that portion of the membrane which is fixed in the sulcus tympanicus is considerably thickened, and is named the **annulus fibro-cartilagineus**. It is prolonged from the anterior and posterior extremities of the notch of Rivinus to the short process of the malleus in the form of two ligamentous bands, the **anterior** and **posterior malleolar folds** or **ligaments** (plica malleolaris anterior et posterior). The small triangular portion of the membrane (Fig. 584) situated above these folds is thin and lax, and constitutes the **pars flaccida** or membrane of Shrapnell; the main portion of the membrane is, on the other hand, tightly stretched and termed the **pars tensa**. A small orifice, sometimes seen in the pars flaccida, is probably either a pathological condition or has been artificially produced during manipulation. The handle of the malleus is firmly fixed to the inner

surface of the membrana tympani and draws its central portion inwards, rendering its outer aspect concave. The deepest part of this concavity corresponds with the lower extremity of the handle of the malleus, and is named the **umbo membranæ tympanæ** or **navel.**

The membrane tympani consists of three layers: (1) external, integumentary (stratum cutaneum); (2) middle, fibrous (membrana propria); (3) internal, mucous (stratum mucosum).

The **external layer** (stratum cutaneum) is continuous with the integumentary lining of the meatus, and consists of a thin layer of cutis covered by epidermis. The cutis is thickest near the circumference; the epidermis, on the other hand, is thickest near the centre of the membrane.

The **middle layer** (membrana propria) consists of two sets of fibres: (*a*) *external* or *radial* (stratum radiatum), situated immediately under the integument, and radiating from the handle of the malleus to the annulus fibro-cartilagineus; (*b*) *internal* or *circular* (stratum circulare), the fibres of which are numerous near the circumference, but scattered and few in number near the centre of the membrane (Fig. 584). Both radial and circular fibres are absent from the pars flaccida, which is constituted merely by the apposition of the cutaneous and mucous layers. Gruber pointed out that, in addition to the radial and circular fibres, there exists, next the stratum mucosum, a series of *dendritic* or *branched fibres,* which are best developed in the posterior part of the membrane.

The **internal layer** (stratum mucosum) is continuous with the general mucous lining of the tympanum. It is thicker over the upper part of the membrane than near its centre, and is covered by pavement epithelium.

**Otoscopic Examination of the Tympanic Membrane** (Fig. 585). The membrane, in the living, is of a "pearl-gray" colour, but may present a reddish or yellowish tinge, depending upon the condition of its mucous lining and on the condition of the cutaneous lining of the meatus; the posterior segment is usually clearer than the anterior. At the antero-superior part, close to its periphery, a whitish point appears as if projecting towards the meatus; this is the short process of the malleus. Passing downwards and backwards from this point to the umbo is a ridge caused by the handle of the malleus, the lower extremity of which appears rounded. Two ridges, corresponding with the tympano-malleolar folds, extend from the short process of the malleus, one forwards and upwards, the other backwards and upwards. Behind, and near the lower extremity of the handle of the malleus, is a reddish or yellowish spot, due to the promontory of the inner tympanic wall shining through. If the membrane be very transparent, the long process of the incus may be visible behind the upper part of the handle of the malleus, and reaching downwards as far as its middle. From the lower end of the handle of the malleus, the "cone of light" or "luminous triangle" extends downwards and forwards, its apex being directed towards the handle; this triangle varies in size in different people. A line prolonging the handle downwards divides the membrane into two parts, while another, drawn at right angles to this through the umbo, will subdivide it into four quadrants, viz. postero-superior, postero-inferior, antero-superior, and antero-inferior; this subdivision is useful in enabling the otologist to localise and describe accurately the seat of lesions in the membrane.

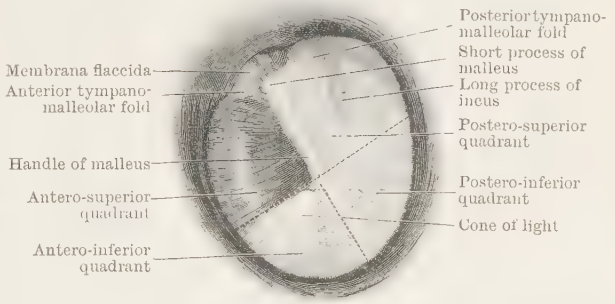

FIG. 585.—LEFT TYMPANIC MEMBRANE (as viewed from the external auditory meatus). ×3.

**Vascular and Nervous Supply of the Membrana Tympani.** The arteries are arranged in two sets, one on the cutaneous and another on the mucous surface. These anastomose by means of small branches which pierce the membrane, especially near its periphery. The first set is chiefly derived from the deep auricular branch of the internal maxillary, whilst those on the mucous surface are small and proceed from the tympanic branch of the internal maxillary, and from the stylo-mastoid branch of the posterior auricular. The **veins** from the cutaneous surface open into the external jugular; those from the inner surface partly into the venous plexus on the Eustachian tube, and partly into the lateral sinus and veins of the dura mater. The outer surface of the membrane receives its **nerves** from the auriculo-temporal branch of the fifth and from the auricular branch of the vagus; the inner surface, from the nerve of Jacobson (tympanic branch of the glosso-pharyngeal). The **lymphatics,** like the blood-vessels, are arranged in two

sets, cutaneous and mucous, which, however, communicate freely with each other. Kessel has described as lymphatics the spaces between the branches of Gruber's dendritic fibres.

The **inner wall** of the tympanic cavity (paries labyrinthica) is formed by the outer surface of the internal ear or labyrinth (Fig. 583). It presents—(1) a rounded eminence, the **promontory** (promontorium), which is caused by the first coil of the cochlea, and is grooved for the tympanic plexus of nerves. (2) An oval or somewhat reniform opening, the **fenestra ovalis seu vestibuli**, which is situated above and behind the promontory, with its long axis directed from before backwards. It measures 3 mm. in length and 1½ mm. from above downwards, and lies at the bottom of a funnel-shaped recess, the **fossula fenestræ vestibuli**. In the macerated bone it leads into the vestibule of the labyrinth, but is closed in the recent state by the foot of the stapes, surrounded by its **ligamentum annulare**. (3) An elevation, the **prominentia canalis facialis**, which is situated above the fenestra ovalis, in the recessus epitympanicus. This indicates the position of the upper part of the **aqueduct of Fallopius**, which contains the facial nerve and is continued backwards and downwards behind the tympanic cavity, to end at the stylo-mastoid foramen. (4) The **processus cochleariformis**, or septum canalis musculo-tubarii; this process extends backwards, above the anterior end of the fenestra ovalis, where it makes a sharp outward curve, and forms a pulley over which the tendon of the tensor tympani muscle plays. (5) A funnel-shaped recess, the **fossula fenestræ cochleæ**, which is situated behind and below the promontory, and almost hidden by its overhanging edge. It leads forwards, upwards, and inwards to an irregularly oval opening, termed the **fenestra rotunda seu cochleæ**, which in the macerated bone communicates with the cochlea, but in the recent state is closed by a membrane, the **membrana tympani secundaria**. This membrane appears angularly bent along a line joining its antero-inferior two-thirds with the postero-superior third. It consists of three layers: (*a*) *external*, continuous with the mucous lining of the tympanum and containing a network of capillaries; (*b*) *middle*, or substantia propria, the fibres of which radiate chiefly towards the periphery of the membrane —some branched, dendritic fibres are also present; (*c*) *internal*, continuous with the epithelial lining of the labyrinth. (6) Between the fenestra ovalis above and the fossula rotunda below is a small circular depression, the **sinus tympani**, which is perforated by one or two minute foramina for blood-vessels, and indicates the position of the ampullated extremity of the posterior semicircular canal.

### Mastoid Antrum and Mastoid Air-cells.

The **mastoid antrum** (antrum mastoideum seu tympanicum) is seen in the temporal bone at birth as a cavity, having a vertical measurement of 7-9 mm. and a transverse of 9-11 mm., and is nearly as large in the newly-born child as in the adult. Roofed in by the tegmen tympani, its floor and inner wall are formed by the petro-mastoid, while externally it is closed by the junction of the thin outer part of the squama with the pars mastoidea. It communicates with the epitympanic recess by a triangular or rounded opening, on the inner wall of which, immediately above and behind the canalis facialis, is a smooth, convex area of bone indicating the position of the ampullated extremities of the superior and external semicircular canals. At birth its outer wall has a thickness of only 1-2 mm., but by the ninth year this has increased to about 10 mm. Coincident with the growth of the mastoid process the mastoid air-cells are developed downwards and backwards as diverticula from the antrum, and present the greatest possible variations in different skulls. They may be large, comparatively few in number, and involve the whole process, in which case the compact bone which surrounds them is extremely thin, and the innermost cells are only separated by a transparent lamella from the lateral sinus—a lamella which, in some instances, is partly deficient. In other cases the cells may be small and numerous, only invading a portion of the process, the remainder consisting of diploëtic tissue. No definite conclusion can be come to as to their condition by external percussion or examination. A solid process is occasionally seen. The air-cells are not limited to the mastoid process, but extend forwards over the roof of the meatus, upwards towards the squama, and inwards towards the

temporo-occipital suture, whilst in a few cases they are seen to invade the pars jugularis of the occipital bone. They, together with the antrum, are lined by thin mucous membrane continuous with that of the tympanic cavity; the deep surface of the mucous membrane is firmly fixed to the periosteum, while its free surface is covered by a layer of flattened, non-ciliated epithelium.

## Eustachian Tube.

The **Eustachian tube** (tuba auditiva Eustachii) leads from the tympanic cavity to the naso-pharynx, and transmits air to the former, in order that the pressure on the inner and outer surfaces of the membrana tympani may be equalised; it may also serve to convey mucous secretion away from the tympanic cavity. Its outer extremity, the **ostium tympanicum tubæ auditivæ** (Fig. 583), opens into the anterior part of the tympanic cavity below the canal for the tensor tympani muscle. Directed downwards and inwards, the tube ends on the upper part of the naso-pharynx by a wide orifice, the **ostium pharyngeum tubæ auditivæ** (Fig. 555). It measures about an inch and a half (36 mm.) in length, and forms with the horizontal plane an angle of 30° to 40°, with the sagittal plane an angle of about 45°, and with the bony part of the external meatus one of 135° to 140°. It consists of two portions: (*a*) an antero-internal, fibro-cartilaginous part, the **pars cartilaginea tubæ auditivæ**, having a length of about one inch; and (*b*) a postero-external, osseous part, the **pars ossea tubæ auditivæ**, measuring half an inch in length. The two portions are not in the same plane, the cartilaginous part inclining downwards a little more than the osseous portion, and forming with it a wide angle. Its lumen is widest at the ostium pharyngeum, narrowest at the junction of the bony and cartilaginous portions, forming here the **isthmus**, and again expanding towards the tympanic cavity; hence it presents, on longitudinal section, somewhat the appearance of an hour-glass. The pars ossea occupies the angle between the squamous and petrous parts of the temporal bone, and is separated by the processus cochleariformis from the canal containing the tensor tympani muscle, whilst immediately to its inner side is the carotid canal. The pars cartilaginea consists partly of cartilage and partly of fibrous membrane. The cartilage (cartilago tubæ auditivæ) presents the form of an elongated triangular plate, of which the apex is firmly attached to the inner end of the pars ossea, while the base is free, and forms a projection on the upper and posterior aspects of the pharyngeal orifice. The upper edge of this cartilaginous plate is bent outwards in the form of a hook, and so produces a furrow open below and externally, the furrow being converted into a complete canal by the fibrous part of the tube. On transverse section (Fig. 586) the cartilage presents two laminæ continuous with each other superiorly: (*a*) *lamina medialis*, broad and thick; and (*b*) *lamina lateralis*, thin and hook-shaped. At the ostium pharyngeum the lamina medialis forms the entire inner wall of the tube, but it gradually diminishes in breadth on approaching the isthmus tubæ. Fissures are often seen in the cartilage; sometimes it is completely separated into several pieces, or accessory islands may be observed in the roof, floor, or membranous part.

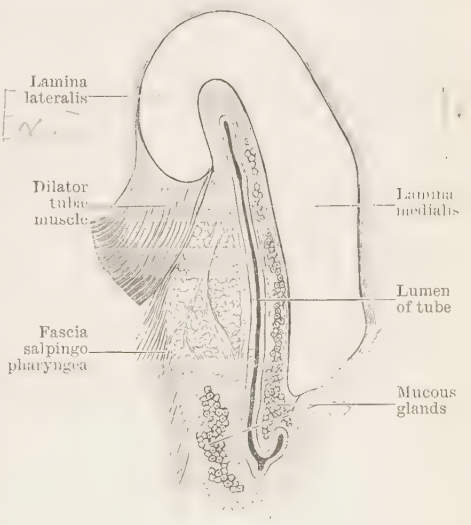

Fig. 586.—Transverse Section of the Cartilaginous Part of the Eustachian Tube.

The upper and inner aspects of the cartilage are firmly fixed to the base of the skull, where it lies in a groove, the **sulcus tubæ auditivæ**, situated between the great wing of the sphenoid and the petrous-temporal. Extending forwards on to the

root of the pterygoid process this sulcus ends at a projection, the **processus tubarius**, on the middle of the internal pterygoid plate. The tensor palati muscle lies to the outer side of the tube and receives some fibres of origin from its lamina lateralis; these fibres constitute the **dilator tubæ muscle** of Rüdinger. To the inner side of the cartilage are found the levator palati and the mucous membrane of the pharynx. The **membranous part** (lamina membranacea) consists of a strong fibrous membrane, stretching between the two edges of the cartilage, and so completing the under and outer parts of the canal. Thin above, it becomes thickened below and forms the **fascia salpingo-pharyngea** of Tröltsch, which gives origin to some of the fibres of the tensor palati muscle. Between this fascia and the mucous lining of the tube is a layer of adipose tissue.

The **pharyngeal orifice** of the Eustachian tube (ostium pharyngeum tubæ), triangular or oval in shape, is situated on the lateral wall of the naso-pharynx, the centre of the opening being on a level with the posterior end of the inferior turbinated bone. It is bounded above and behind by a pad or cushion produced by the inner end of the cartilage, which here abuts against the mucous membrane. The posterior part of this cushion is very prominent and forms the anterior boundary of the **fossa of Rosenmüller**. Prolonged downwards from it is an elevation of the mucous membrane, termed the **plica salpingo-pharyngea**, which covers the small salpingo-pharyngeus muscle. From the upper part of the cushion an indistinct fold, the **plica salpingo-palatina**, extends to the palate.

The mucous lining of the tube is continuous behind with that of the tympanic cavity, and in front with that of the naso-pharynx. It is thin in the pars ossea, contains few, if any, mucous glands, and is firmly fixed to the bony wall; whilst in the pars cartilaginea it is loose and thrown into longitudinal folds. Numerous mucous glands open into the tube near its pharyngeal orifice, and here also there exists a considerable amount of adenoid tissue, which constitutes the "tube-tonsil" of Gerlach. This adenoid tissue is continuous with that of the naso-pharynx, and, like it, is especially well developed in children. The lumen of the tube is lined with ciliated columnar epithelium.

The tube is opened, during deglutition, by the dilator tubæ and salpingo-pharyngeus muscles. The former springs superiorly from the cartilaginous hook of the tube, and blends inferiorly with the tensor palati. When the dilator tubæ contracts, the cartilaginous hook and membranous part of the tube are drawn outwards and forwards. Some anatomists are inclined to the view that the entire tensor palati acts chiefly as a dilator of the tube, and Rüdinger has named it the abductor tubæ. The salpingo-pharyngeus muscle draws downwards and backwards the inner cartilaginous plate, increasing the angle between it and the outer plate. Some difference of opinion exists as to the precise action of the levator palati; probably it assists in opening the tube.

The Eustachian tube receives its blood-supply from the ascending pharyngeal artery and from the middle meningeal and Vidian branches of the internal maxillary artery. Its veins form a network which opens into the pterygoid venous plexus. The sensory nerves of the tube are derived from the tympanic plexus and from the pharyngeal branches of the second division of the fifth cranial nerve.

The tube of the child differs considerably from that of the adult; its lumen is relatively wider, its direction more horizontal, and its pars ossea relatively shorter. Kunkel states that its pharyngeal orifice is below the level of the hard palate in the fœtus; at birth it is on the same level as the palate, whilst at the fourth year it is 3 to 4 mm., and in the adult 10 mm., above it. The pharyngeal orifice forms a narrow fissure, and its cartilage projects less towards the middle line.

### Tympanic Ossicles.

The **tympanic ossicles** (ossicula auditus) form an articulated column connecting the outer with the inner wall of the tympanic cavity, and are named, from without inwards, the malleus or hammer, the incus or anvil, and the stapes or stirrup. The first is attached to the inner surface of the membrana tympani; the last is fixed within the circumference of the oval fenestra.

The **malleus** (Fig. 587, B, D), the largest of the three ossicles, has a length of 8 to 9 mm., and consists of a head (capitulum mallei), a neck (collum mallei), and a

handle (manubrium mallei), together with two processes, viz. : (*a*) processus longus seu anterior, (*b*) processus brevis seu lateralis. The head and neck are situated in the epitympanic recess; the processus brevis and manubrium are fixed to the inner surface of the membrana tympani; whilst the processus longus is directed forwards towards the Glaserian fissure, to which, in the adult, it is connected by ligamentous

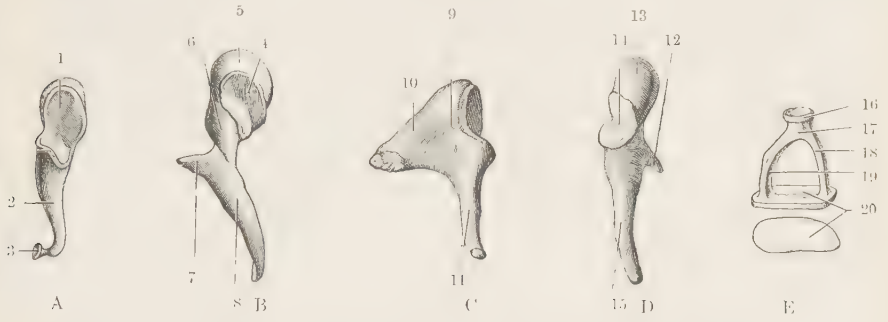

Fig. 587.—Tympanic Ossicles of Left Ear (enlarged about three times).

fibres. The **head**, somewhat rounded, is smooth and convex above and in front, and presents, on its posterior aspect, a facet for articulation with the body of the incus. This facet is directed obliquely downwards and inwards, and reaches slightly on to its mesial surface. More or less elliptical in form, it is constricted near the middle so as to resemble, somewhat, the figure 8; an oblique ridge, corresponding with the constriction, divides the facet into two parts—an upper and larger, directed back-

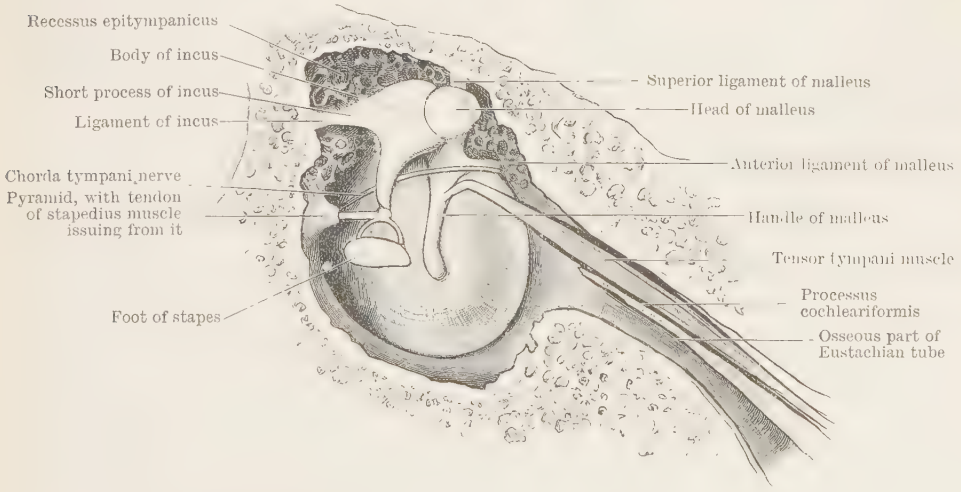

Fig. 588.—Left Membrana Tympani and Chain of Tympanic Ossicles (seen from inner aspect). × 3.

wards, and a lower and lesser, directed inwards. Opposite the lower part of the constriction the inferior edge of the facet is very prominent, and is continued upwards into the oblique ridge just referred to; it forms a tooth-like process, the **spur** or **cog-tooth** of the malleus. On the back of the head, below this spur, is an oblique crest, the **crista mallei**, to which is attached the external ligament of the malleus. The **neck** is the slightly constricted portion immediately below the head. Flattened from before backwards, its outer surface is directed towards the membrana flaccida,

whilst its inner is crossed by the chorda tympani nerve. The **handle** is directed downwards, inwards, and backwards from the neck, forming with the long axis of the head an angle, opening inwards, of 126° to 150°. Its upper part is flattened from before backwards, but towards the lower end it is twisted on itself, so that its surfaces look outwards and inwards; moreover, the lower end is slightly curved, the concavity being directed forwards and outwards. It is fixed, along its entire length, to the membrana propria of the tympanic membrane by its periosteum and by a layer of cartilage (Gruber). This latter intervenes between the handle and the membrane, and must be regarded as a residue of that stage of development when the entire malleus was cartilaginous. On the inner aspect of the handle, near its upper extremity, a slight projection for the attachment of the tendon of the tensor tympani muscle may be seen. The **long process** is a slender spicule springing from the fore-part of the neck and directed forwards towards the Glaserian fissure. In the fœtus it constitutes the longest process of the malleus and is directly continuous with Meckel's cartilage. In the adult it usually assumes the form of a small projection, since its anterior part is represented merely by fibrous tissue. The **short process** may be looked upon as the upper extremity of the handle projected outwards; it is fixed to the upper part of the membrana tympani by the cartilaginous layer already referred to, and to the extremities of the notch of Rivinus by the anterior and posterior malleolar folds.

The **incus** (Fig. 587, A, C) is best likened to a bicuspid tooth with widely divergent fangs. It consists of a body (corpus incudis), a long process (crus longum), and a short process (crus breve); the two processes form with each other an angle of 90° to 100°. The body and short process are situated in the epitympanic recess. The **body** presents a more or less saddle-shaped surface for articulation with the head of the malleus. This surface is directed forwards, and its lower part is hollowed out for the accommodation of the cog-tooth of the malleus. In front of this hollow it is prominent and spur-like. The **short process** is thick, triangular in shape, and projects horizontally backwards; its conical extremity, covered with cartilage, articulates with the fossa incudis in the postero-inferior part of the epitympanic recess. The **long process** projects, almost perpendicularly, downwards from the body into the tympanic cavity, where it lies parallel with, but $1\frac{1}{4}$ mm. behind and internal to, the handle of the malleus. Its lower end is bent inwards and narrowed to form a short neck, on the inner extremity of which is a small knob of bone, the **processus lenticularis**, for articulation with the head of the stapes. Until the sixth month of fœtal life this process exists as a separate ossicle, termed the **os orbiculare**.

The **stapes** (Fig. 587, E) presents a head (capitulum stapedis), a neck (collum stapedis), two crura (crus anterius et posterius), and a base or foot-plate (basis stapedis). The **head**, directed outwards, is concave externally for articulation with the processus lenticularis of the incus. The **neck** is the slightly constricted part immediately internal to the head, and from it the two crura spring; the tendon of the stapedius muscle is inserted into the posterior aspect of the neck. The anterior crus is shorter and less curved than the posterior. Diverging from each other, the crura are directed inwards and are attached—one near the anterior, the other near the posterior end of the foot-plate. The **foot-plate** almost completely fills the oval fenestra, and, like it, is somewhat oval or reniform, its anterior end being the more pointed. In the recent condition a membrane fills the arch formed by the crura and the foot-plate, the crura being grooved for its reception. In the child the crura of the stapes are less curved than in the adult, and the opening bounded by them and the foot-plate is nearly triangular.

**Articulations of the Tympanic Ossicles.**—The joint between the head of the malleus and the body of the incus (articulatio incudomalleolaris) is diarthrodial, and may be described as one of reciprocal reception. It is surrounded by a capsular ligament, from the inner surface of which a wedge-shaped meniscus projects into the joint cavity and incompletely divides it. The articulation of the processus lenticularis and the capitulum stapedis (articulatio incudostapedia) is of the nature of an enarthrosis and is surrounded by a capsular ligament. An interarticular cartilage has been described as occurring in this joint, while some observers deny the

presence of a synovial cavity and regard the articulation as a syndesmosis, the articular surfaces being held together merely by fibrous tissue.

**Ligaments binding the Ossicles to the Walls of the Tympanic Cavity** (lig. ossiculorum auditus).—The malleus is attached to the walls of the tympanum by three ligaments (Fig. 588), viz. anterior, superior, and external. The **anterior ligament** (lig. mallei anterius) consists of two portions: (*a*) the *band of Meckel*, which is attached to the base of the processus longus, and passes forwards through the Glaserian fissure to reach the spine of the sphenoid; it represents the remnant of a portion of Meckel's cartilage, and was formerly described as the laxator tympani muscle; (*b*) a firm bundle of fibres, the *lig. mallei anterius of Helmholtz*, which extends from the spina tympanica posterior at the anterior boundary of the notch of Rivinus to the anterior aspect of the malleus, above the base of the processus longus. The **superior ligament** (lig. mallei superius) extends, almost vertically, from the head of the malleus to the roof of the epitympanic recess. The **external ligament** (lig. mallei laterale) is short and fan-shaped; its fibres converge from the posterior half of the notch of Rivinus to the crista mallei. The posterior part of this ligament is strong and constitutes the *ligamentum mallei posticum of Helmholtz*. It forms, together with the ligamentum mallei anterius, the axis around which the malleus rotates, and the two constitute what Helmholtz has termed the "**axis-ligament**" of the malleus.

The posterior extremity of the crus breve of the incus is tipped with cartilage and fixed by means of a ligament, the **ligamentum incudis posterius** (Fig. 588), to the fossa incudis. Some observers describe this as a diarthrodial joint. A superior ligament, the **ligamentum incudis superius**, is sometimes present, but consists mainly of a fold of mucous membrane. The vestibular surface and the circumference of the foot of the stapes are covered by hyaline cartilage, and a similar layer lines the opening of the fenestra ovalis; that encircling the base of the stapes is joined to that which lines the fenestra by a dense ring of elastic fibres, named the **ligamentum annulare baseos stapedis**. The posterior fibres of this annular ligament are thicker and shorter than the anterior, and thus the anterior end of the foot-plate is free to make greater excursions, during the movements of the bone, than the posterior.

**Development of the Tympanic Ossicles.**—It is generally maintained that the malleus and incus are developed from the upper end of Meckel's cartilage, and that the stapes arises from the mesoblast in the region of the fenestra ovalis where it is developed around a small artery, the stapedial artery, which atrophies in man, but persists in many mammals. On the other hand, Gadow (*Phil. Trans.*, London, vol. clxxix.) says "the whole system of the one to four elements of the middle ear, which have all the same function, is to be looked upon as *one* organ, of *one* common origin, viz. a modification of the hyomandibula, the proximal paramere of the second visceral arch."

**Muscles of the Tympanic Cavity.**—These are two in number, viz. m. tensor tympani and m. stapedius.

The **m. tensor tympani** is the larger, and takes origin from the roof of the cartilaginous part of the Eustachian tube and from the adjacent part of the great wing of the sphenoid. It also receives some fibres from the bony canal in which it lies, and ends in a tendon which bends outwards, nearly at a right angle to the belly of the muscle, round the pulley-like, posterior extremity of the processus cochleariformis. Passing across the cavity of the tympanum this tendon is inserted into the inner edge and anterior surface of the manubrium mallei, near its upper end. When the muscle contracts it draws inwards the handle of the malleus, and so renders tense the membrana tympani; it probably also slightly rotates the malleus around its long axis. It receives its nerve from the motor division of the fifth cranial nerve through the otic ganglion.

The **m. stapedius** arises within the pyramid, and from the canal which prolongs the hollow of the pyramid downwards. Its tendon emerges from the apex of the pyramid and is inserted into the posterior surface of the neck of the stapes. On contraction it draws back the head of the stapes, and so tilts the anterior end of the foot-plate outwards towards the tympanic cavity and the posterior end inwards

towards the labyrinth, thus rendering tense the ligamentum annulare—the outward movement of the anterior end of the foot-plate being greater than the inward movement of its posterior end. The muscle is supplied by the facial nerve.

**Movements of the Tympanic Ossicles.**—The manubrium mallei follows all the movements of the membrana tympani, while the malleus and incus move together around an axis extending forwards through the short process of the incus and the anterior ligament of the malleus. When the membrana tympani moves inwards it carries with it the handle of the malleus, and the incus, moving inwards at the same time, forces the foot of the stapes towards the labyrinth. This inward movement is communicated to the fluid (perilymph) in the labyrinth, and causes an outward bulging of the secondary tympanic membrane, which closes the fenestra rotunda. These movements are reversed when the membrana tympani is relaxed, unless the outward movement of the membrane be excessive. In such a condition the incus does not follow the full outward movement of the malleus, but merely glides on this bone at the incudo-malleolar joint, and thus the forcible dragging of the foot of the stapes out of the fenestra ovalis is prevented. The cog-tooth arrangement, already described, on the head of the malleus and body of the incus, causes the incudo-malleolar joint to become locked during the inward movements of the handle of the malleus, the joint becoming unlocked during its outward movements.

**Mucous Lining of the Tympanic Cavity** (tunica mucosa tympanica).—This is continuous, through the Eustachian tube, with that of the naso-pharynx; it also extends backwards and lines the mastoid antrum and air-cells. Thin, transparent, and closely united with the subjacent periosteum, it covers the inner aspect of the membrana tympani and is reflected over the ossicles and their ligaments. It also supplies sheaths for the tendons of the tensor tympani and stapedius muscles, and forms the following **mucous folds**, viz.: (*a*) one from the roof of the epitympanic recess to the head of the malleus and body of the incus; (*b*) one enveloping the chorda tympani nerve and long process of the incus; (*c*) two extending from the short process of the malleus—one to the anterior, the other to the posterior margin of the notch of Rivinus. A recess, the **pouch of Prussak**, is situated between the membrana flaccida and the neck of the malleus. Communicating behind with the tympanic cavity, this pouch may serve as a reservoir to confine pus or other fluid, since its opening into the tympanum is above the level of its floor, a condition analogous to the opening from the antrum of Highmore into the nasal cavity. The fold of mucous membrane which extends downwards to envelop the chorda tympani nerve gives rise to two pouches, one in front of, and the other behind, the handle of the malleus; these are named the **anterior** and **posterior recesses of Troltsch**. The epithelium which lines the mucous membrane is flattened over the membrana tympani, promontory, and ossicles, but ciliated and columnar over the greater portion of the rest of the cavity.

The chorda tympani branch of the facial nerve passes from behind, upwards, and forwards through the tympanic cavity. Its course is described on p. 687.

**Vessels and Nerves of the Tympanic Cavity.**—The arteries which supply the tympanic cavity are: (1) The tympanic artery, a branch of internal maxillary, which reaches the cavity by way of the Glaserian fissure. (2) The stylo-mastoid branch of posterior auricular, which passes through the stylo-mastoid foramen and aqueduct of Fallopius; it supplies branches to the mastoid antrum and air-cells, to the stapedius muscle, to the floor and inner wall of the tympanic cavity, and forms an anastomotic circle, around the membrana tympani, with the tympanic artery. (3) The middle meningeal artery sends a branch to the tensor tympani muscle, and, after entering the skull, gives off its petrosal artery, which is conducted to the tympanum along the hiatus Fallopii; some twigs from the posterior division of the middle meningeal reach the antrum and epitympanic recess through the petro-squamous fissure. (4) The internal carotid artery, in its passage through the canal in the temporal bone, gives off one or two tympanic twigs, while (5) a branch from the ascending pharyngeal accompanies the nerve of Jacobson. The **veins** drain their contents into the pterygoid plexus, the middle meningeal vein, and superior petrosal sinus. The **nerves** which supply the muscles of the tympanic cavity have already been referred to (pp. 757, 758). The mucous membrane receives its nerves from the tympanic plexus, which is described on p. 690.

**Early Condition of Tympanic Cavity.**—During the greater part of intrauterine existence the tympanic cavity is almost completely filled by a soft, reddish, jelly-like embryonic tissue. The narrow, slit-like space is lined by epithelium, which is ciliated over the promontory, but squamous elsewhere. Towards the end of fœtal life the gelatinous tissue becomes thinned and the cavity correspondingly enlarged. At birth it is filled with fluid which becomes absorbed, coincident with the passage of air from the naso-pharynx through the Eustachian tube.

## INTERNAL EAR.

The innermost, and, at the same time, the essential part of the organ of hearing is situated in the substance of the petrous-temporal bone, and consists of two sets of structures, viz.: (1) a series of cavities hollowed out of the bone and constituting the **bony labyrinth** (labyrinthus osseus); these cavities are continuous with each

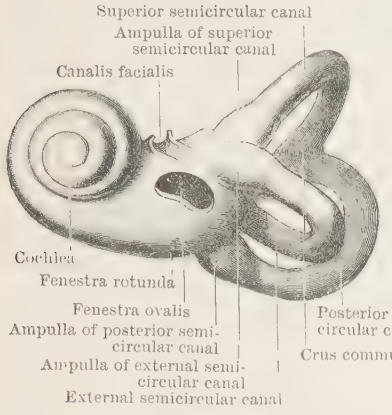

FIG. 589.—LEFT BONY LABYRINTH (viewed from the outer aspect).

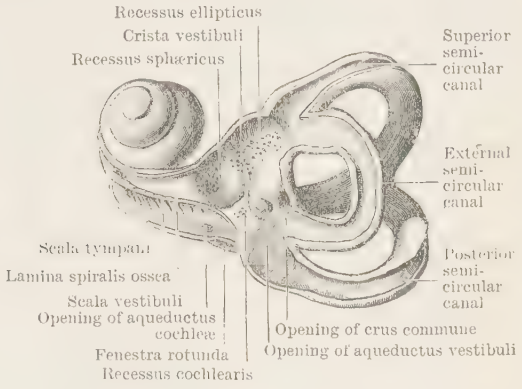

FIG. 590.—INTERIOR OF LEFT BONY LABYRINTH (viewed from outer aspect).

other, and are named from before backwards the **cochlea**, **vestibule**, and **semicircular canals** (Figs. 589, 590); (2) a complex arrangement of membranous channels (Fig. 592), situated within, but not nearly filling, the bony labyrinth and forming the **membranous labyrinth** (labyrinthus membranaceus). These channels are named the **ductus cochlearis**, **utricle, saccule**, and **membranous semicircular canals**; the utricle and saccule are lodged within the bony vestibule.

## OSSEOUS LABYRINTH.

**Vestibule.**—The vestibule forms the central portion of the osseous labyrinth, and communicates behind with the semicircular canals and in front with the cochlea. It is somewhat ovoid in shape, its long axis being directed forwards and outwards. It measures about 6 mm. antero-posteriorly, 4-5 mm. from roof to floor, and about 3 mm. from without inwards. Its outer wall is directed towards the tympanic cavity, and in it is seen the fenestra ovalis, which, in the recent state, is closed by the foot of the stapes. Its inner wall corresponds with the bottom of the internal auditory meatus, and presents, at its antero-inferior part, a rounded depression, the **recessus sphæricus**, which lodges the saccule. This recess is perforated by some twelve or fifteen small foramina, which constitute the **macula cribrosa media**, and transmit the filaments of the auditory nerve for the supply of the saccule. The recessus sphæricus is limited above and behind by an oblique ridge, the **crista vestibuli**, the anterior extremity of which is triangular in shape and named the **pyramid** (pyramis vestibuli). Posteriorly this crista divides into two limbs, between which is a small depression, the **recessus cochlearis** of Reichert, perforated by some eight small foramina, which give passage to the nervous filaments for the supply of the posterior extremity of the ductus cochlearis. Above and behind the crista vestibuli, in the roof and inner wall of the vestibule, is an oval depression, the **recessus ellipticus**, which lodges the utricle. The pyramid and adjacent part of the recessus ellipticus are perforated by some 25-30 small apertures, which constitute the **macula cribrosa superior seu major**. The foramina in the pyramid transmit the nerves to the utricle; those in the recessus, the nerves to the ampullary ends of the superior and external semicircular canals. Behind and below the recessus ellipticus is a furrow, gradually deepening to form a canal, the **aqueductus vestibuli**, which passes backwards through the petrous bone, and opens, as a slit-like fissure, about midway between the internal auditory meatus and the groove for the lateral sinus. This

aqueduct measures 8-10 mm. in length, and gives passage to the ductus endolymphaticus and a small vein. The posterior part of the vestibule receives the five rounded apertures of the bony semicircular canals; its anterior part leads, by an elliptical opening, into the scala vestibuli of the cochlea. This opening is bounded inferiorly by a thin osseous lamella, the **lamina spiralis ossea**, which springs from the floor of the vestibule immediately to the outer side of the recessus sphæricus, and forms, in the cochlea, the bony part of the septum between the scala tympani below and the scala vestibuli above. From the anterior part of the floor of the vestibule a narrow cleft, the **fissura vestibuli**, extends forwards into the bony canal of the cochlea. It is bounded internally by the lamina spiralis ossea just referred to, and externally by a second, smaller lamina, the **lamina spiralis secundaria**, which projects inwards from the outer wall of the cochlea. These two lamina are continuous with each other around the posterior extremity of the fissure.

**Semicircular Canals** (canales semicirculares ossei).—The semicircular canals (Figs. 589, 590), three in number, are situated above and behind the vestibule. They are distinguished from each other by their position, and are named superior, posterior, and external. They open into the vestibule by five apertures, since the inner extremity of the superior and the upper extremity of the posterior join to form a common canal or crus commune. Differing slightly in length, each forms about two-thirds of a circle, one extremity of which is dilated and termed the ampulla (ampulla ossea). Somewhat compressed laterally, their greatest internal diameter is from 1 to 1·5 mm., whilst the diameter of the ampulla is about 2 mm.

The **superior semicircular canal** (canalis semicircularis superior), 15-20 mm. in length, is vertical and placed transversely to the long axis of the petrous bone. Its convexity is directed upwards, and its position is indicated on the anterior surface of the petrous-temporal by an eminence. Its ampullated end (ampulla ossea superior) is anterior and external, and opens into the vestibule immediately above that of the external canal. Its opposite extremity joins the non-ampullated end of the posterior canal to form the **crus commune**, which is about 4 mm. in length, and opens into the upper and inner part of the vestibule. The **posterior semicircular canal** (canalis semicircularis posterior) is the longest of the three and measures from 18-22 mm. Its ampullary end (ampulla ossea posterior) is placed inferiorly, and opens into the lower and back part of the vestibule, where may be seen some six or eight small apertures, forming the **macula cribrosa inferior**, for the transmission of the nerves to this ampulla. Its upper extremity ends in the crus commune. The **external canal** (canalis semicircularis lateralis) is the shortest. It measures from 12 to 15 mm., and arches nearly horizontally outwards. Of its two extremities the external is ampullated (ampulla ossea lateralis), and opens into the vestibule immediately above the fenestra ovalis and in close relationship to the ampullary end of the superior canal.

Although the three canals are generally regarded as opening into the vestibule by five orifices, some observers incline to the view that the ampullary ends of the superior and external canals form a common orifice, and that, consequently, there are only four openings for the three canals. Crum Brown (*Journ. Anat. and Physiol.*, London, vol. viii.) pointed out "that the exterior canal of one ear is very nearly in the same plane as that of the other; while the superior canal of one ear is nearly parallel to the posterior canal of the other."

**Cochlea.**[1]—When freed from its surroundings the cochlea assumes the form of a short cone (Fig. 591); the central part of its **base** (basis cochleæ) corresponds with the bottom of the internal auditory meatus, whilst its apex or **cupola** is directed forwards and outwards, and comes into close relation with the canal for the tensor tympani muscle. It measures about 9 mm. across the base and about 5 mm. from base to apex, and consists of a spirally arranged tube, which forms from $2\frac{1}{2}$ to $2\frac{3}{4}$ coils around a central pillar termed the **modiolus**. The length of the tube is from 28 to 30 mm., and its diameter, near the base of the cochlea, 2 mm. Its coils are distinguished by the terms basal, central, and apical; the first, or basal coil, gives rise to the promontory on the inner wall of the tympanum.

[1] In the following description the cochlea is supposed to be placed on its base.

The modiolus is about 3 mm. in height, and diminishes rapidly in diameter from base to apex, while its tapered extremity fails to reach the cupola by a distance of 1 mm. Its **base** (basis modioli) corresponds with the **area cochleæ** on the fundus of the internal auditory meatus, and exhibits the **tractus spiralis foraminosus**, which transmits the nerves for the basal and central coils of the cochlea and the **foramen centrale**, which gives passage to the nerves for the apical coil. The foramina of the tractus spiralis foraminosus traverse the modiolus, at first parallel to its long axis, but, after a varying distance, they bend outwards to reach the attached edge of the lamina spiralis ossea, where they become expanded and form by their apposition a spiral canal, the **canalis spiralis modioli of Rosenthal**, which lodges the **ganglion of Corti**, or **ganglion spirale cochleæ**. From this spiral canal numerous small foramina, for the transmission of vessels and nerves, pass outwards to the free edge of the lamina spiralis. The **lamina spiralis ossea**, a thin, flat shelf of bone, winds round the modiolus like the thread of a screw, and, projecting about half-way into the cochlear tube, incompletely divides it into two passages, of which the upper is named the **scala vestibuli**; the lower, the **scala tympani**. The lamina spiralis ossea commences at the floor of the vestibule, near the fenestra rotunda, and ends close to the apex of the cochlea in a sickle-shaped process, the **hamulus**, which assists to form an

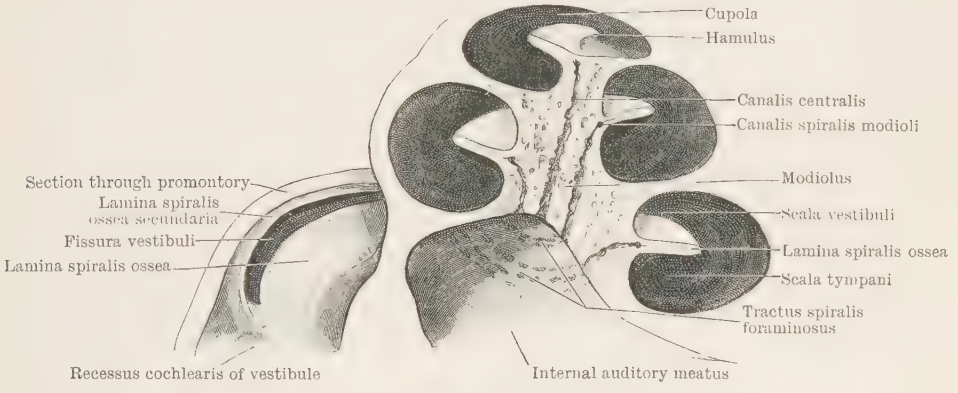

FIG. 591.—SECTION OF BONY COCHLEA.

aperture named the **helicotrema**. In the basil coil the upper surface of the spiral lamina forms almost a right angle with the modiolus, but the angle becomes more and more acute on ascending the tube. In the lower half of the basil coil a second smaller bony plate, the **lamina spiralis secundaria**, projects inwards from the outer wall of the cochlea towards the lamina spiralis ossea, without, however, reaching it. If viewed from the vestibule the slit-like fissura vestibuli, already referred to (p. 760), is seen between the two osseous spiral laminæ. A membrane, the **membrana basilaris**, stretches from the free edge of the lamina spiralis ossea to the outer wall of the cochlea, and completes the septum between the scala vestibuli and scala tympani, but the two scalæ communicate with each other through the opening of the helicotrema at the apex of the cochlea. The scala tympani begins at the fenestra rotunda, through which, in the macerated bone, it communicates with the tympanic cavity; in the recent condition the fenestra is closed by the secondary tympanic membrane (*vide* p. 752). At the commencement of the scala tympani a crest, termed the **crista semilunaris**, stretches from the attached margin of the lamina spiralis ossea towards the orifice of the fenestra rotunda. Close to this crest is seen the inner orifice of the **aqueductus cochleæ**, a canal measuring from 10 to 12 mm. in length, and opening on the under aspect of the petrous bone internal to the fossa jugularis. Through it there is established a communication between the scala tympani and the subarachnoid space, and through it, also, a small vein passes to join the inferior petrosal sinus. The scala vestibuli, the higher of the two passages, begins in the vestibule; its diameter in the basal coil is less than that of the scala tympani, but in the upper coils it exceeds that of the latter.

**Internal Auditory Meatus.**—It is convenient, at this stage, to study the

fundus of the internal auditory meatus, which has been referred to as forming the inner wall of the vestibule and the base of the modiolus. It is divided by a transverse ridge, the **crista transversa**, into two parts—an upper or **fossula superior** and a lower or **fossula inferior**. The anterior part of the fossula superior is termed the **area facialis** and exhibits a single large opening, the commencement of the aqueduct of Fallopius, for the transmission of the facial nerve. Its posterior part is named the **area vestibularis superior**, and is perforated by the nerves for utricle and ampullæ of the superior and external semicircular canals. The anterior part of the fossula inferior is termed the **area cochleæ**, and consists of the **canalis centralis** and the surrounding **tractus spiralis foraminosus**, for the passage of the nerves to the cochlea. Behind the area cochleæ, and separated from it by a ridge, is the **area vestibularis inferior**, which transmits the nerves to the saccule, whilst at the posterior part of the fossula inferior is seen a single foramen, the **foramen singulare**, which gives passage to the nerves for the ampulla of the posterior semicircular canal.

## MEMBRANOUS LABYRINTH.

The **membranous labyrinth** (labyrinthus membranaceus) assumes, more or less closely (Fig. 592), the form of the bony labyrinth in which it is situated, but does not nearly fill it. It contains a fluid termed **endolymph**, while the interval between it and the bony labyrinth is named the **perilymphatic space**, and is occupied by a fluid termed **perilymph**. The perilymphatic space in the vestibule measures about 3 mm. from without inwards, and about 3·5 mm. from before backwards. It is continuous behind with the perilymphatic space of the semicircular canals, and opens in front into the scala vestibuli. At the apex of the cochlea it is continuous through the helicotrema with the scala tympani, which is shut off from the tympanum by the secondary tympanic membrane. It is also prolonged into the aqueductus cochleæ, at the extremity of which it communicates with the subarachnoid space. The membranous semicircular canals and the membranous canal of the cochlea follow the course of their bony tubes and lie along the inner aspect of their outer walls. The bony vestibule, on the other hand, contains two chief membranous structures, the **utricle** and **saccule**. The former receives the extremities of the membranous semicircular canals, whilst the latter communicates with the membranous canal of the cochlea. Moreover, the cavities of the utricle and saccule are indirectly connected, and thus all parts of the membranous labyrinth communicate with each other, and the contained endolymph is free to move from one portion to another. The vestibule, also, contains the ductus endolymphaticus and the commencement of the ductus cochlearis.

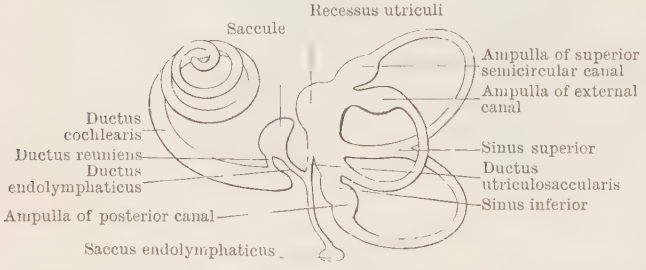

FIG. 592.—DIAGRAMMATIC REPRESENTATION OF THE DIFFERENT PARTS ON THE MEMBRANOUS LABYRINTH.

The **utricle** (utriculus), the larger of the two sacs (Fig. 592), occupies the postero-superior portion of the bony vestibule. Its highest part, or **recessus utriculi**, lies in the recessus ellipticus and receives the ampullæ of the superior and external membranous semicircular canals. Its central part receives on its lateral aspect the non-ampullated end of the external canal, and is prolonged upwards and backwards as the **sinus superior**, into which the crus commune of the superior and posterior membranous canals open. The ampulla of the posterior membranous canal opens into its lower and inner part, or **sinus inferior**. The floor and anterior wall of the recessus utriculi are thickened to form the **macula acustica utriculi**, to which are distributed the utricular fibres of the auditory nerve. Whitish in colour, and of an oval or nearly rhombic shape, this macula measures 3 mm. in length and 2·3 mm. in its greatest breadth.

The **saccule** (sacculus) occupies the recessus sphæricus, in the lower and fore-part of the vestibule (Fig. 590). Smaller than the utricle, it is of an oval shape and measures 3 mm. in its longest, and about 2 mm. in its shortest diameter. It presents anteriorly an oval, whitish thickening, the **macula acustica sacculi**. This has a breadth of about 1·5 mm., and to it are distributed the saccular fibres of the auditory nerve. The superior extremity of the saccule is directed upwards and backwards, and forms the **sinus utricularis sacculi**, which abuts against, but does not fuse with, the wall of the utricle. From the lower part of the saccule a short canal, the **ductus reuniens** of Hensen, opens into the ductus cochlearis, a short distance in front of its vestibular or blind extremity. A second small channel, the **ductus endolymphaticus**, is continued from the posterior part of the saccule, and, passing between the utricle and the inner wall of the vestibule, is joined by a small canal, the **ductus utriculosaccularis**, which arises from the inner aspect of the utricle. It then enters and traverses the aqueductus vestibuli and ends, under the dura mater on the posterior surface of the petrous bone, in a dilated blind extremity, termed the recessus Cotugnii, or **saccus endolymphaticus**: this, according to Rüdinger, is perforated by minute foramina, through which the endolymph may pass into the meningeal lymphatics.

The vestibule also contains the blind extremity (cæcum vestibulare) of the ductus cochlearis, which lies immediately below the saccule in the recessus cochlearis of Reichert; from here it passes forwards into the spiral tube of the cochlea.

The walls of the utricle and saccule are composed of connective tissue which blends, along their attached surfaces, with the periosteal lining of the vestibule. It is modified internally to form a homogeneous membrana propria, which is covered by a layer of pavement epithelium and is thickened at the maculæ acusticæ. Towards the periphery of the maculæ the epithelium is cubical, while on them it is columnar.

The **structure of the maculæ** in the utricle and saccule is practically the same; two kinds of cells are found, viz. (*a*) supporting cells, and (*b*) hair cells. The **supporting cells** are somewhat fusiform, each containing, near its middle, a nucleus. Their branched, deep extremities are attached to the membrana propria; their free ends lie between the hair cells and form a thin inner limiting cuticle. The **hair cells** are flask-shaped and do not reach the membrana propria, but end in rounded extremities which lie between the supporting cells. Each contains, at its deepest part, a large nucleus, the rest of the cell being granular and pigmented. From the free end of each there projects a stiff, hair-like process, which, on the application of reagents, splits into several finer filaments. The nerve-fibres pierce the membrana propria, and end in arborisations around the deep extremities of the hair cells. A collection of small, rhombic crystals of carbonate of lime, termed **otoconia**, adheres to each of the maculæ.

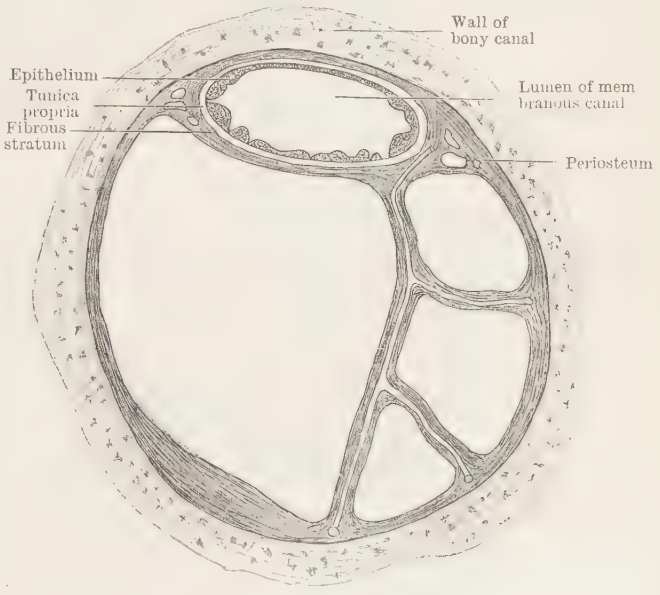

Fig. 593.—Transverse Section of Human Semicircular Canal (Rüdinger).

The **membranous semicircular canals** (ductus semicirculares) are elliptical on transverse section (Fig. 593), and are attached to the greater circumference of the bony tubes. The peripheral portion of the ellipse is fixed to the periosteal lining of the bony canal, whilst the opposite part is free, except that it is connected by irregular bands, the **ligamenta labyrinthi canaliculorum**, which pass through the perilymphatic space to the bony wall. Like the bony canals, each of the membranous canals is dilated at one extremity into an ampulla (ampulla membranacea), which is especially developed towards the concave aspect of the tube. While the membranous ampullæ nearly fill the corresponding portions of the bony tubes, the calibre of the remaining parts of the membranous canals is only equal to about one-fourth of that of the osseous canals.

Each membranous canal consists of three layers, viz.: (*a*) an outer **fibrous stratum** which contains blood-vessels, together with some pigment, and fixes the tube to the bony wall; (*b*) an intermediate, transparent **tunica propria**, presenting a number of papilliform elevations which project towards the lumen. The fibrous layer and tunica propria are thinnest along the attached surface of the tube, and in this region also the papilliform elevations are absent; (*c*) an internal **epithelial layer**, composed of pavement cells. In the ampullæ the tunica propria is much thickened, and projects into the cavity as a transverse elevation, termed the **septum transversum**, which, when seen from above, is somewhat fiddle-shaped; its most prominent part is covered by auditory epithelium forming the **crista acustica**, at each end of which is a half-moon-shaped border of small columnar cells, the **planum semilunatum**. The cells covering the crista acustica consist of **supporting cells** and **hair cells**, and are similar in their arrangement to those in the maculæ of the utricle and saccule. The hairs of the hair cells are, however, considerably longer, and project as far as the middle of the ampullary lumen. In fresh specimens they appear to end free, but in hardened preparations are seen to terminate in a soft, clear, dome-like structure, the **cupola terminalis**, which is striated, the striæ converging towards its concavity. The nerves form arborisations around the bases of the hair cells.

The **membranous cochlea** (ductus cochlearis or scala media) commences in the

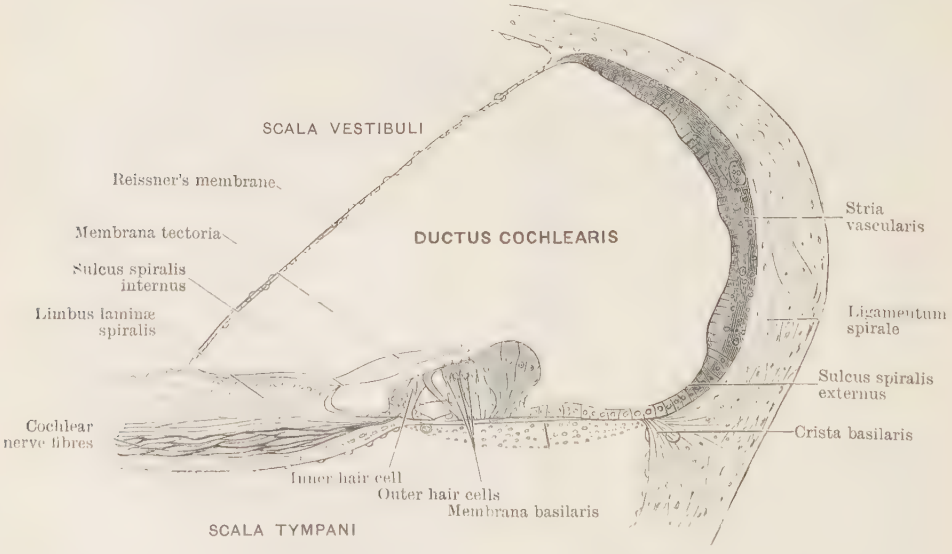

Fig. 594.—Section across the Ductus Cochlearis (Retzius).

recessus cochlearis of the vestibule by a blind extremity (cæcum vestibulare), close to which it receives the ductus reuniens of Hensen (*vide* p. 763). It forms a spirally arranged canal inside the bony cochlea, and ends at the apex of the latter in a second blind extremity, the **lagena**, or cæcum cupulare, which is fixed to the cupola and partly bounds the helicotrema. As already stated (*vide* p. 761), the membrana basilaris extends from the free edge of the lamina spiralis ossea to the outer

wall of the cochlea. A second, more delicate membrane, the **membrane of Reissner**, or membrana vestibularis, stretches from the thickened periosteum covering the upper surface of the lamina spiralis ossea to the outer cochlear wall, some little distance above the external attachment of the membrana basilaris. A canal is thus enclosed between the underlying scala tympani and the overlying scala vestibuli, and constitutes the membranous cochlea or **ductus cochlearis**. Triangular on transverse section, it possesses a roof, an outer wall, and a floor, and is lined throughout with epithelium and filled with endolymph. On its floor the epithelium is greatly modified, and here are found the endings of the cochlear division of the auditory nerve.

The **roof** or **vestibular wall** of the ductus cochlearis is formed by the membrane of Reissner, which consists of a delicate, nearly homogeneous membrane, covered on its two surfaces by a layer of epithelium. Its entire thickness is about 3 $\mu$.

The **outer wall** of the ductus cochlearis (Fig. 595) consists of the periosteal lining of the bony cochlea, which, however, is much thickened and greatly modified to form what is termed the **ligamentum spirale cochleæ**. Occupying the whole outer wall, this ligament projects inwards inferiorly as a triangular prominence, the **crista basilaris**, to which the outer edge of the membrana basilaris is attached. The fibres of the membrane radiate into the ligament in the form of a series of bundles analogous to the ligamentum pectinatum iridis. In the upper part of the ligamentum spirale the periosteum is of a reddish yellow colour, and contains, immediately under its epithelial lining, numerous small blood-vessels and capillary loops, forming the **stria vascularis**. The lower limit of this stria is bounded by a prominence, the **prominentia spiralis**, in which is seen a vessel, the **vas prominens**, and between this prominence and the crista basilaris is a concavity, the **sulcus spiralis externus**. The height of the outer wall diminishes towards the apex of the cochlea.

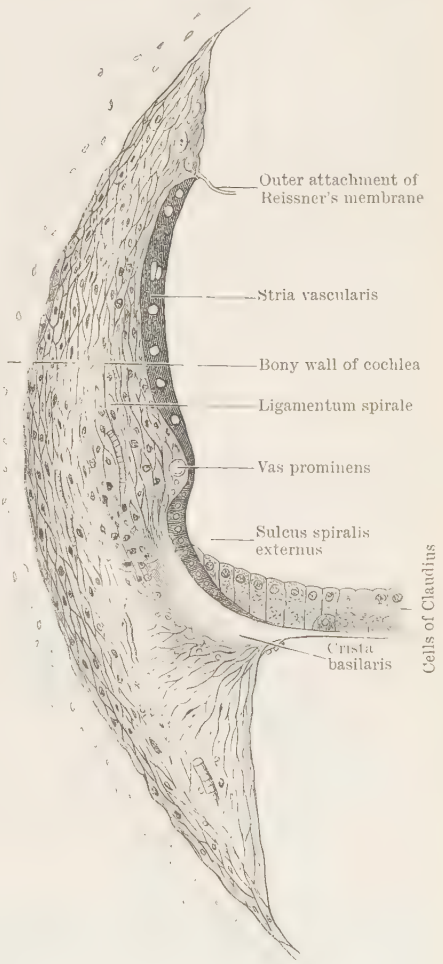

Fig. 595.—Transverse Section through Outer Wall of Ductus Cochlearis (Schwalbe).

The **floor** or **tympanal wall** of the ductus cochlearis is formed by the periosteum covering that portion of the lamina spiralis ossea which is situated to the outer side of Reissner's membrane, and by the **membrana basilaris**, which stretches from the free edge of the lamina spiralis ossea to the crista basilaris. On the inner part of the membrana basilaris the complicated structure termed the **organ of Corti** is situated. The lamina spiralis ossea consists of two plates of bone, between which are placed the canals for the branches of the cochlear nerve. On the upper plate the periosteum is thickened and modified to form the **limbus laminæ spiralis**, the outer extremity of which forms a C-shaped concavity, the **sulcus spiralis internus**. The portions of the limbus which project outwards, above and below this concavity, are termed respectively the **labium vestibulare** and **labium tympanicum**. The latter is perforated by some 4000 small apertures, the **foramina nervosa**, or habenula perforata, for the transmission of the cochlear nerves. Externally it becomes continuous with the

membrana basilaris. The upper surface of the labium vestibulare presents a number of furrows crossing each other nearly at right angles, and intersecting a series of elevations which, at the free margin of the labium, form a row of tooth-like structures, some 7000 in number, the **auditory teeth of Huschke**. Covering the limbus is a layer of apparently squamous epithelium; the deeper protoplasmic portions of the cells, however, with their contained nuclei, fill up the intervals between the elevations and auditory teeth. This layer of epithelium is continuous with that covering the under surface of Reissner's membrane and with that which lines the sulcus spiralis internus.

**Membrana Basilaris.**—The inner part of this membrane is thin, and supports the organ of Corti; it is named the **zona arcuata**, and reaches as far as the foot-plate of the outer rod of Corti. Its outer part, extending from the foot-plate of the outer rod of Corti to the crista basilaris, is thicker and distinctly striated, and is termed the **zona pectinata**. The substantia propria of the membrane is almost homogeneous, but exhibits, in its deeper part, numerous fibres. These fibres are most distinct in the zona pectinata, and number, according to Retzius, about 24,000. Covering the under surface of the membrana basilaris is a layer of connective tissue, which contains, in its inner part, small blood-vessels, one of which, larger than the rest, lies below the tunnel of Corti and is named the vas spirale. The width of the membrana basilaris increases from 210 $\mu$ in the basil coil to 360 $\mu$ in the apical coil.

**Organ of Corti** (Fig. 596).—Placed upon the inner portion of the membrana basilaris, the organ of Corti consists of an epithelial eminence which extends along the entire length of the ductus cochlearis, and comprises the following structures, viz.: (1) Corti's rods or pillars, (2) hair cells (inner and outer), (3) supporting cells of Deiters, (4) the cells of Hensen and Claudius, (5) the lamina reticularis, and (6) a cuticular membrane, the membrana tectoria.

The **rods of Corti** form two rows, **inner** and **outer**, of stiff, pillar-like structures, and each rod presents a base or foot-plate, an intermediate elongated portion, and an upper end or head. The bases of the two rows are planted on the membrana basilaris some little distance apart. The intermediate portions incline towards each other and the heads

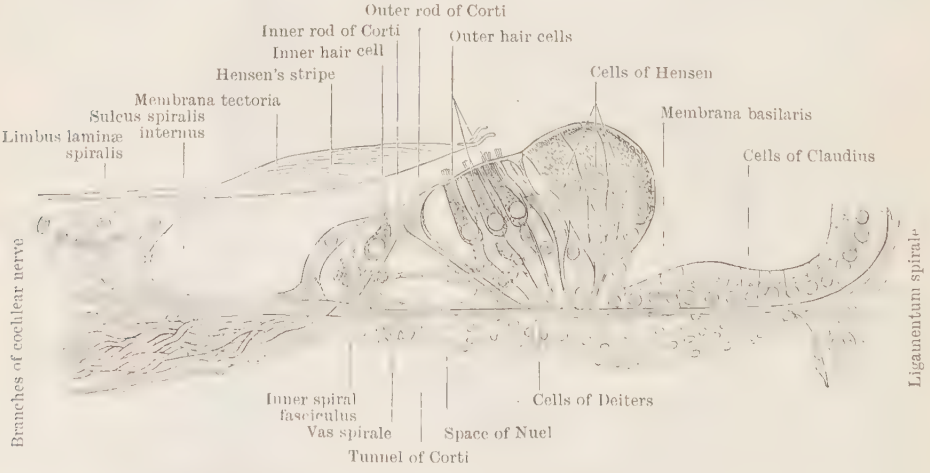

FIG. 596.—TRANSVERSE SECTION OF CORTI'S ORGAN FROM THE CENTRAL COIL OF COCHLEA (Retzius).

come into contact, so that, between the two rows above and the membrana basilaris below, there is enclosed a triangular tunnel, the **tunnel of Corti**; this tunnel increases both in height and width on passing towards the apex of the cochlea. The **inner rods** number nearly 6000, and the head of each resembles somewhat the upper end of the ulna, presenting a deep concavity, externally, for the reception of a corresponding convexity on the head of the outer rod. The part of the head which overhangs this concavity is prolonged outwards, under the name of the **head-plate**, and overlaps the head of the outer rod. The expanded bases of the inner rods are situated on the innermost portion of the membrana basilaris, immediately to the outer side of the foramina nervosa of the labium tympanicum. The intermediate parts of the inner rods are sinuously curved, and form, with the

membrana basilaris, an angle of about 60°. The **outer rods** number about 4000, and are longer than the inner, especially in the upper part of the cochlea. They are more inclined towards the membrana basilaris, and form with it an angle of about 40°. The head of each is convex internally, to fit the concavity on the head of the inner rod, and is prolonged outwards as a plate, the **phalangeal process**, which becomes connected with the lamina reticularis. In the head is an oval body which has an affinity for certain reagents. The main part of each rod consists of a nearly homogeneous material, which is finely striated. At the bases of the rods, on the side next the tunnel, is a nucleated mass of protoplasm which reaches as far as the heads of the rods, and covers also the greater part of the tunnel floor. This may be regarded as the undifferentiated part of the cell from which the rod was developed. Slit-like intervals, for the transmission of nerves, exist between the intermediate portions of adjacent rods.

**Hair Cells.**—These, like Corti's rods, form two sets, **inner** and **outer**. The former consists of a single row lying immediately internal to the inner rods—the latter of three, or, it may be, four rows placed to the outer side of the external rods. The **inner hair cells** are about 3500 in number, and have a greater diameter than the inner rods, and so each is supported by more than one rod. Somewhat oval in shape, their free extremities are surmounted by about twenty fine hair-like processes, arranged in the form of a crescent, with its concavity directed inwards. The deep end of the cell is rounded, and contains a large nucleus. It reaches only about half-way down the rod, and in contact with it are the arborisations of the nerve terminations. To the inner side of this row of hair cells are two or three rows of elongated columnar cells, which act as supporting cells, and are continuous with the low columnar cells lining the sulcus spiralis internus. The **outer hair cells** number about 12,000, and form three rows in the basal coil and four rows in the upper two coils, although in the higher coils the rows are not so regularly arranged. Their rounded free extremities support some twenty hairlets arranged in the form of a crescent, opening inwards. Their deep extremities reach about half-way to the membrana basilaris, and are in contact with the nerve arborisations.

Alternating with the rows of the outer hair cells are the rows of **Deiters' supporting cells**, the lower extremities of which are expanded on the membrana basilaris, whilst their upper ends are tapered; the nucleus is placed near the middle of each cell, and, in addition, each cell contains a bright, thread-like structure called the **supporting fibre**. This fibre is attached by a club-shaped base to the membrana basilaris, and expands, at the free end of the cell, to form a **phalangeal process** of the membrana reticularis.

The **cells of Hensen**, or outer supporting cells, consist of about half a dozen rows, immediately outside Deiters' cells, and form a well-marked elevation on the floor of the ductus cochlearis. Their deep extremities are narrow and attached to the membrana basilaris, while their free ends are expanded; each cell contains a distinct nucleus and some pigment granules. The columnar cells, situated externally to the cells of Hensen, cover the outer part of the zona pectinata, and are named the **cells of Claudius**. A space, the **space of Nuel**, exists between the outer rods of Corti and the neighbouring row of hair cells. It communicates internally with Corti's tunnel, and extends outwards between the outer hair cells as far as Hensen's cells.

The **lamina reticularis** is a thin cuticular structure which lies over Corti's organ, and extends from the heads of the outer rods as far as Hensen's cells, where it ends in a row of quadrilateral areas which form its outer border. On looking at it from above it is seen to consist of two or three rows of structures, named **phalanges**, which are elongated cuticular plates resembling in shape the digital phalanges. The innermost row is formed by the phalangeal processes of the heads of the outer row of Corti's rods; the succeeding row, or rows, represent the expanded upper ends of Deiters' supporting cells. The number of rows of phalanges, therefore, varies with the number of rows of outer hair cells and the alternating cells of Deiters. The phalanges separate the free ends of the hair cells from each other, since these are seen to occupy the somewhat circular apertures between their constricted middle portions.

The **membrana tectoria** (Fig. 596) is an elastic membrane overlying the sulcus spiralis internus and the organ of Corti. Attached, by its inner end, to the limbus laminæ spiralis, near the lower edge of Reissner's membrane, it reaches outwards as far as the outer row of hair cells. Its inner portion is thin and overlies the auditory teeth of Huschke. Its outer part is, at first, much thickened, but becomes attenuated near its external border, which, according to Retzius, is attached to the outer row of Deiters' cells. Its lower edge presents a firm, homogeneous border, and opposite the inner row of hair cells contains a clear, spirally arranged band, named **Hensen's stripe**. Probably the membrana tectoria acts as a damper comparable to the otoconia in the utricle and saccule.

**Auditory Nerve** (Fig. 597).—The auditory nerve consists of two main parts, the **ramus vestibularis** and the **ramus cochlearis**; as the former traverses the internal auditory meatus it presents a gangliform swelling, the **ganglion of Scarpa**. The

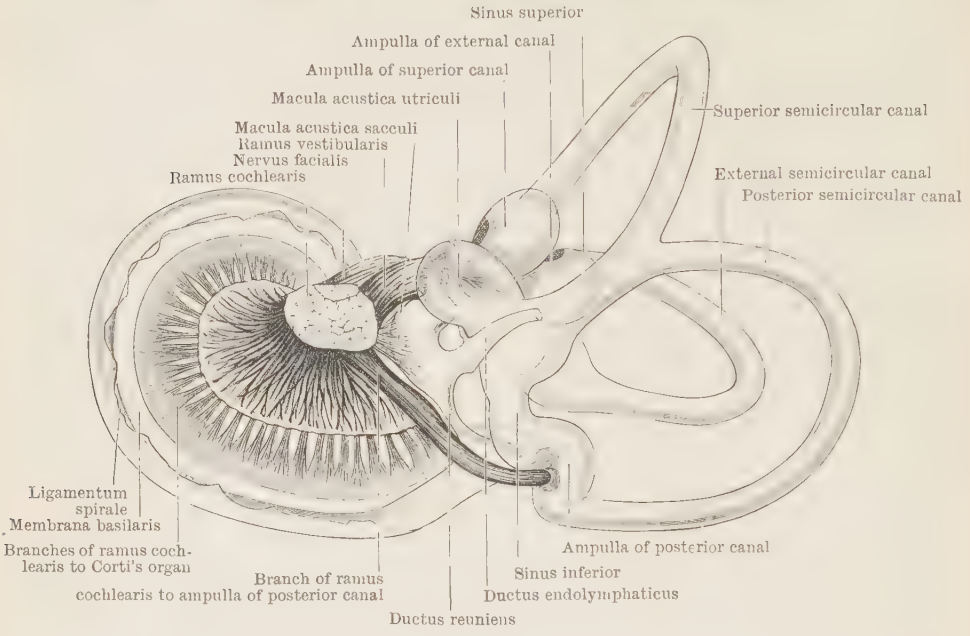

FIG. 597.—MEMBRANOUS LABYRINTH OF A FIVE MONTHS' FŒTUS, viewed from its postero-mesial aspect (Retzius).

ramus vestibularis divides into three branches, the filaments of which pass through the foramina in the area vestibularis superior, and are distributed to the macula acustica utriculi and the ampullæ of the superior and external semicircular canals. The ramus cochlearis gives off a branch to the macula acustica sacculi and another to the ampulla of the posterior semicircular canal. The former exhibits a gangliform swelling beyond which its filaments pass through the foramina in the area vestibularis inferior; the latter is transmitted through the foramen singulare, and in this part of its course the nerve possesses two gangliform enlargements. The remainder of the ramus cochlearis is distributed to the hair cells of Corti's organ, the branches for the basal and middle coils entering the foramina in the tractus spiralis foraminosus, those for the apical coil passing up through the canalis centralis of the modiolus. Extending upwards, in the bony canals of the modiolus, the nerve-fibres radiate outwards between the lamellæ of the lamina spiralis ossea. Contained in the spiral canal of the modiolus, near the attached margin of the lamina, is a ganglion which winds spirally round the modiolus, and is named the **ganglion spirale** or ganglion of Corti (Fig. 598). It consists of bipolar nerve-cells, and each nerve fibre, probably, has its continuity interrupted by one of these cells. Beyond the ganglion spirale the nerve-fibres extend outwards, at first in bundles, and then in a more or less continuous sheet, from the outer edge of which they are again collected into bundles, which pass through the foramina nervosa of the labium tympanicum. Beyond this they appear as naked axis-cylinders, and, turning in a spiral manner (**inner** or **first spiral fasciculus**), send fibrillæ towards the

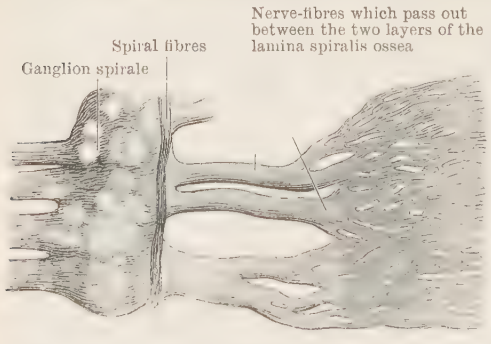

FIG. 598.—PART OF COCHLEAR NERVE, highly magnified (Henle).

inner row of hair cells. Other fibrils pass outwards between the inner rods and form a **second spiral fasciculus** in Corti's tunnel, from which fibrils extend outwards across the tunnel, and, passing between the outer rods, enter Nuel's space. They form a spiral fasciculus on the inner aspect of each row of Deiters' cells, and from these fasciculi fibrillæ pass towards the bases of the outer hair cells.

Schwalbe divides the auditory nerve into three portions, viz. : (1) **ramus utriculo-ampullaris,** corresponding with the ramus vestibularis already described ; (2) **ramus sacculo-ampullaris,** for the saccule and posterior ampulla ; and (3) **ramus cochlearis,** for the ductus cochlearis.

**Vessels of the Internal Ear.**—The **auditory artery,** a branch of the basilar, enters the internal auditory meatus and divides into vestibular and cochlear branches. The vestibular branch supplies the soft tissues in the vestibule and semicircular canals, each canal receiving two arteries, which, starting from opposite extremities of the canal, anastomose on the summit of the arch. The cochlear branch divides into numerous twigs, which enter the foramina in the tractus spiralis foraminosus, and run outwards in the lamina spiralis ossea to reach the soft structures ; the largest of these arteries runs in the canalis centralis. The stylo-mastoid artery also supplies some minute branches to the cochlea. Siebenmann describes the auditory artery as dividing into three branches, viz. : (1) anterior vestibular, (2) cochlear proper, and (3) vestibulo-cochlear. The **veins** from the cochlea and vestibule unite at the bottom of the meatus with the veins from the semicircular canals to form the **internal auditory vein,** which may either open into the posterior part of the inferior petrosal sinus or into the lateral sinus. Small veins also pass through the aqueductus cochleæ and aqueductus vestibuli, the former opening into the inferior petrosal sinus or into the internal jugular vein, the latter into the superior petrosal sinus.

## Development of Labyrinth.

The epithelial lining of the labyrinth is derived from an invagination of the cephalic ectoderm, termed the **auditory pit,** which appears opposite the hind brain immediately above the first visceral cleft. The mouth of the pit is closed by the growing together of its margins, and it then assumes the form of a hollow vesicle, the **otic vesicle,** lined by epithelium ; the vesicle sinks into the subjacent mesoderm, and is met by the auditory nerve growing out from the neural crest. The vesicle soon becomes pear-shaped ; its upper tapering part is named the **recessus labyrinthi,** and forms the future ductus endolymphaticus. About the fifth week, the lower part of the vesicle is prolonged forwards as a tubular elongation, the future ductus cochlearis. This is at first straight, but soon becomes curved on itself, so that at the twelfth week all three coils are differentiated. From the upper part of the vesicle the semicircular canals are developed, and appear as hollow, disc-like evaginations, the central parts of the two walls of which coalesce and disappear, leaving only the peripheral rings or canals. The three canals are free about the beginning of the second month, and are developed in the following order, viz. : superior, posterior, and external. The intermediate part of the otic vesicle represents the vestibule, and is divided by a constriction into an anterior part, the saccule, communicating with the ductus cochlearis, and a posterior portion, the utricle, receiving the extremities of the semicircular canals. The constriction extends for some distance into

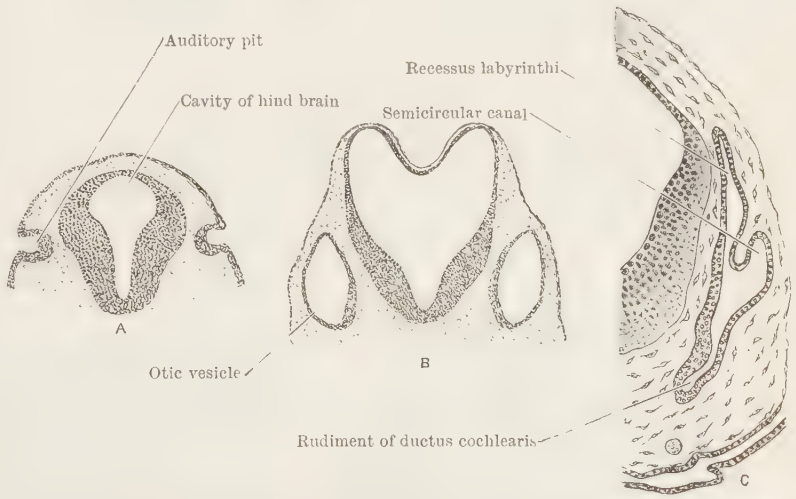

Fig. 599.—Sections through the Region of the Hind Brain of Fœtal Rabbits (to illustrate the development of the labyrinthine epithelium).

In A the ectoderm is invaginated to form the auditory pit ; in B the auditory pit is closed and detached from the ectoderm, forming the otic vesicle ; while C shows a further stage in the development of the vesicle.

the ductus endolymphaticus, and thus the utricle and saccule are only indirectly connected by a Y-shaped tube. Another constriction makes its appearance between the saccule and the ductus cochlearis near its commencement, and forms the **canalis reuniens** of Hensen. The epithelial lining is at first columnar, but becomes cubical throughout the whole labyrinth, except opposite the terminations of the auditory nerve, where it forms the columnar epithelium of the maculæ of the utricle and saccule, of the cristæ ampullæ, and of the organ of Corti. On the floor of the ductus cochlearis two ridges appear, of which the inner forms the limbus laminæ spiralis, whilst the cells of the outer become modified to form the rods of Corti, the hair cells, and the supporting cells of Deiters and Hensen.

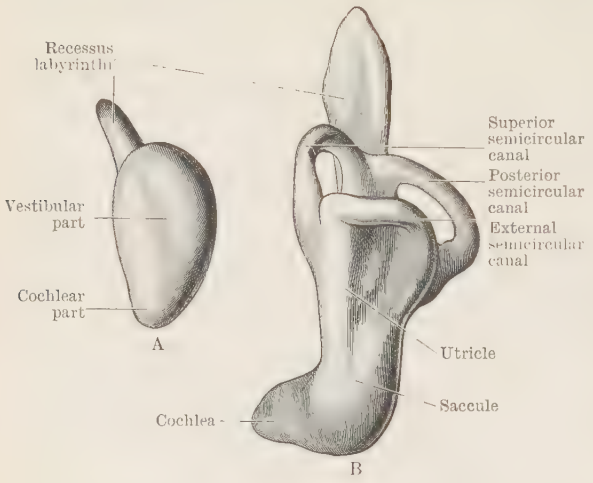

FIG. 600.

A, Left labyrinth of a human embryo of about four weeks; B, Left labyrinth of a human embryo of about five weeks (from W. His, jun.)

The mesoderm surrounding the otic vesicle is differentiated into: (1) a fibrous layer, the wall of the membranous labyrinth; (2) a cartilaginous external capsule, the future petrous bone; and (3) an intervening layer of gelatinous tissue, which is ultimately absorbed to form the perilymphatic space between the bony and membranous labyrinths.

## ORGANS OF TASTE.

The peripheral organs of the sense of taste (organon gustus) consist of groups of modified epithelial cells, termed the **taste buds**, which are found on certain parts of the tongue and its immediate neighbourhood.

Taste buds are present in large numbers around the circumference of the papillæ vallatæ, while some are also found on their opposing walls (Fig. 601). They

FIG. 601.

A, Section through a papilla vallata of human tongue. B, Section through a part of the papilla foliata of a rabbit.

1. Papilla. 2. Vallum 3. Taste buds. 4. Papillæ. 5. Taste buds. 6. Duct of serous gland.

are very numerous over the fimbriæ linguæ, which correspond with the papillæ foliatæ of the tongue of the rabbit, and are also found over the posterior part and sides of the tongue, either on the papillæ fungiformes or throughout the stratified epithelium. They exist, also, on the buccal surface of the soft palate and on the posterior aspect of the epiglottis.

**Structure of Taste Buds** (Fig. 602).—They are oval or flask-shaped, and occupy nests in the stratified epithelium of the regions mentioned. The deep extremity of each is somewhat expanded and rests upon the corium; the free end is perforated by a minute pore, termed the **gustatory pore**. They consist of modified epithelial cells, which are grouped under the two varieties of—(*a*) supporting cells,

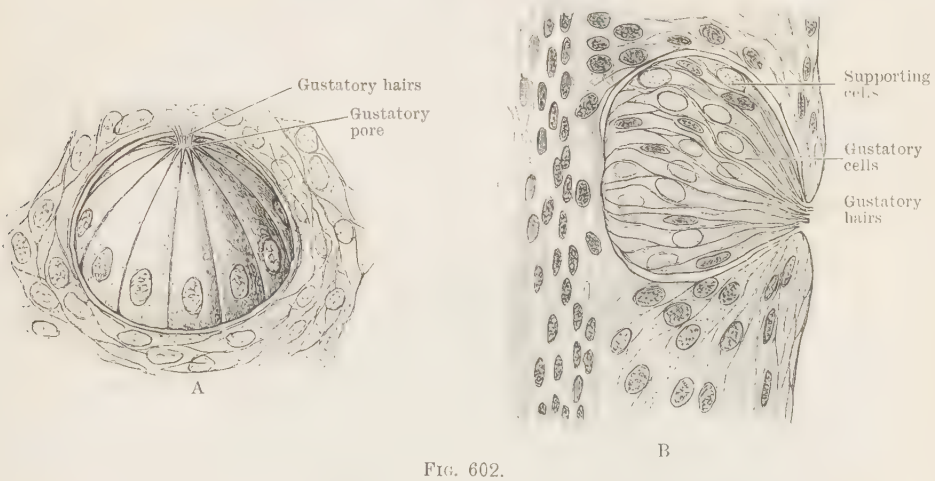

FIG. 602.

A, Three-quarter surface view of taste bud from the papilla foliata of a rabbit (highly magnified).

B, Vertical section of taste bud from the papilla foliata of a rabbit (highly magnified).

and (*b*) gustatory cells (Fig. 603). The **supporting cells** are elongated, nucleated spindles, and are mostly arranged like cask staves to form the outer envelope of the bud. Some are, however, found in the interior of the bud, amongst the **gustatory cells**. The latter occupy the centre of the bud, and present a nucleated cell-body, which is prolonged into a peripheral and a central process. The peripheral process is rod-like and almost hyaline, and terminates at the gustatory pore in a hair-like filament, **gustatory hair**. The central process passes inwards towards the deep extremity of the bud, where it ends free, either in a single varicose filament or by becoming bifurcated or branched.

FIG. 603.—ISOLATED CELLS FROM TASTE BUD OF RABBIT (Engelmann).

*a*, Supporting cells. *b*, Gustatory cells

**Nerves of Taste.**—The nerve which supplies the taste buds over the anterior part of the tongue is probably the chorda tympani, which, although a branch of the facial nerve, is generally regarded as being continuous with the pars intermedia of Wrisberg; that for the posterior part is the glosso-pharyngeal. The internal laryngeal branch of the vagus nerve supplies the epiglottis, together with a small area of the tongue immediately in front of it. The nerve fibrils, having lost their medullary sheaths, ramify partly between the gustatory cells and partly amongst the cells of the bud capsule. It was formerly thought that the nerve-fibrils were directly continuous with the central ends of the gustatory cells, but this view is no longer entertained.

The ducts of Ebner's glands open into the bottom of the valleys surrounding the papillæ vallatæ, and the serous-like secretion of these glands probably washes the free hair-like extremities of the gustatory cells, and so renders them ready to be stimulated by successive substances. It should be added that there is a close association between the senses of smell and taste. This can be best appreciated by considering the defective taste perceptions resulting from inflammatory conditions of the nasal mucous membrane, or the common practice of holding the nose in order to minimise the taste of nauseous drugs.

# THE SKIN OR INTEGUMENT.

## ORGANS OF TOUCH.

### The Skin.

The **skin** (integumentum commune) covers the body, and is continuous, at the orifices on its surface, with the mucous lining of its alimentary and other canals. It contains the peripheral terminations of the sensory nerves, and serves as an organ of protection to the deeper tissues. It is the chief factor in the regulation of the body temperature, and by means of the sweat and sebaceous glands, which open on its free surface, constitutes an important excretory structure. Its superficial layers are modified to form appendages in the shape of hairs and nails.

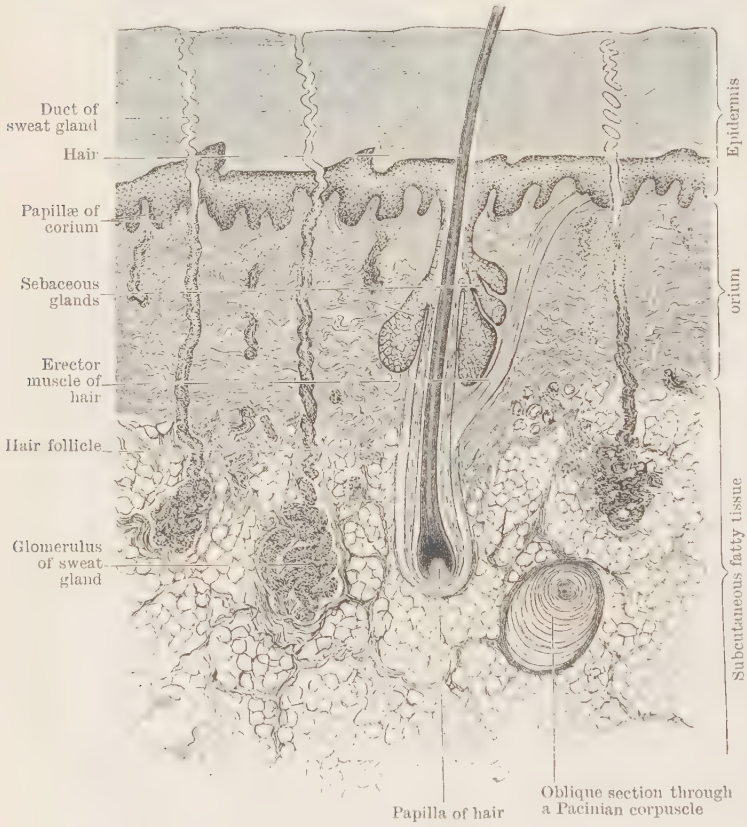

Fig. 604.—Vertical Section of the Skin (schematic).

The superficial area of the skin averages about one and a half square metres, whilst its thickness varies from 0·5 to 4 mm., being greatest on the palms of the hands and soles of the feet, and on the back of the neck and shoulders, and least on the eyelids and penis. It is very elastic and resistant, and its colour, determined partly by its own pigment and partly by that of the blood, is deeper on exposed parts and in the regions of the genitals, axillæ, and mammary areolæ, than elsewhere. The colour also varies with race and age, the different races of the world being roughly classified, according to the colour of their skin, into the three groups of white, yellow, and black. Pinkish in colour in childhood, the skin assumes a yellowish tinge in old age, while in certain diseases (*e.g.* icterus and melasma Addisonii) it undergoes marked alteration.

The surface of the skin is perforated by the hair follicles and by the ducts of the sweat and sebaceous glands, and on the palms, soles, and flexor aspect of the digits it presents numerous permanent ridges (cristæ cutis) which correspond with rows of underlying papillæ. Over the terminal phalanges these ridges form distinctive patterns, which are retained from youth to old age, and are utilised for purposes of identification. Folds of the skin (retinacula cutis) are seen in the neighbourhood of the joints, and it can be thrown into wrinkles by the contraction of the subcutaneous muscles, where these exist. Over the greater part of the body it is freely

movable; but on the scalp and outer surface of the pinna, as well as on the palms and soles, it is bound down to the subjacent tissues.

The skin consists of two strata, viz.: a deep, termed the dermis or corium, and a superficial, named the epidermis (Fig. 604).

The **corium** gives elasticity and sensibility to the skin, and consists essentially of a felted interlacement of connective tissue and elastic fibres. In its deeper part, or **stratum reticulare**, the fibrous bundles are coarse and form an open network, in the meshes of which are vessels, nerves, pellets of fat, hair follicles, and glands. This reticular stratum passes, as a rule, without any line of demarcation, into the panniculus adiposus or subcutaneous fatty tissue, but in some parts it rests upon a layer of striped or unstriped muscular fibres—the latter in the case of the scrotum. In the superficial layer, or **stratum papillare**, of the corium, the connective tissue-bundles are finer and form a close network. Projecting from its free surface are numerous finger-like, single, or branched elevations, termed **papillæ** (Fig. 605), the free ends of which are received into corresponding depressions on the under surface of the epidermis. These papillæ vary in size, being small on the eyelids, but large on the palms and soles, where they may attain a length of 225 $\mu$, and produce the permanent curved ridges already alluded to. Each ridge usually contains two rows of papillæ, between which the ducts of the sweat glands pass to reach the surface. The papillæ consist of fine connective tissue and elastic fibres, mostly arranged parallel to the long axis of the papilla. The majority contain capillary loops, but some the terminations of nerves. The superficial surface of the corium is covered by a thin, homogeneous basement membrane.

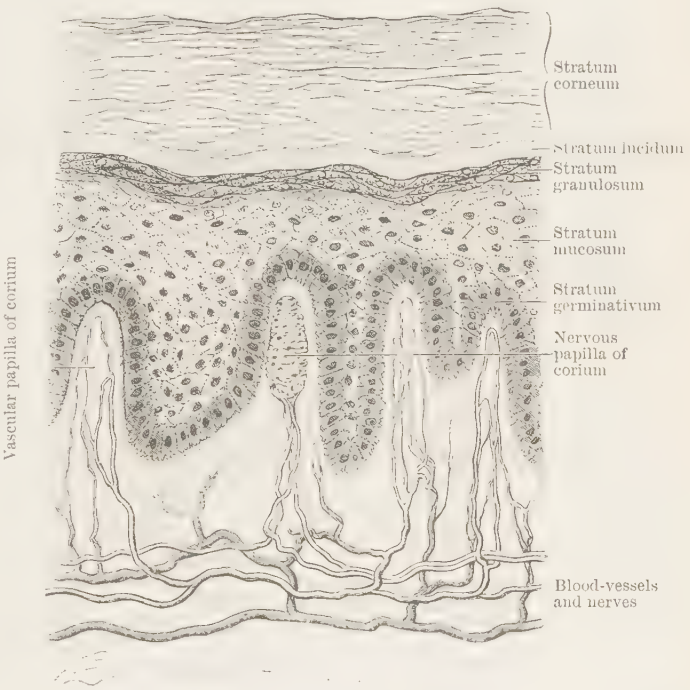

Fig. 605.—Vertical Section of Epidermis and Papillæ of Corium (highly magnified).

The **epidermis** covers the corium; it is non-vascular and consists of stratified epithelium. Its superficial layers are modified to form the **stratum corneum**, or **horny layer** of the skin, which may be separated by maceration or blistering from the deeper, softer portion, or **stratum mucosum** (Malpighi). The epidermis consists from within outwards of the following five strata (Fig. 605):—

1. The **basilar layer**, or **stratum germinativum**, which comprises a single stratum of nucleated columnar cells planted by denticulated extremities on the basement membrane of the corium.

2. The **stratum mucosum**, which consists of six or eight layers of polygonal, nucleated "prickle" or "finger" cells, the processes of which join those of adjacent cells. Between the cells of this layer are minute channels, in which leucocytes or pigment granules may be seen. The cells of the stratum mucosum are characterised by the presence of numerous epidermic fibrils, which are coloured violet by hæmatoxylin and red by carmine. These fibrils are unaffected by boiling, but swell up under the action of acids and alkalies, and form the filaments of union

between adjacent cells. On account of their presence, L. Ranvier (*Compt. rend.*, Paris, Jan. 1899, tome cxxviii.) has named this layer the **stratum filamentosum**. The dark colour of the negro's skin is caused by the presence of numerous pigment granules in the deeper layers of this stratum; the pigment—of which *melanin* forms an important constituent—is absent from the more superficial layers of the epidermis.

3. The **stratum granulosum**, which comprises two or three layers of horizontally arranged, flattened cells, scattered around the nuclei of which are elliptical or spherical granules of *eleidin*, a substance staining deeply with carmine, and probably representing an intermediate stage between the protoplasm of the deeper cells and the keratin of the superficial layers.

4. The **stratum lucidum**, which is an apparently homogeneous layer, but is in reality made up of several strata of flattened or irregular squames, some of which may contain eleidin granules.

5. The **stratum corneum**, which comprises several layers of flattened non-nucleated squames, the more superficial of which are from time to time removed by friction, and may be seen partly detached on the surface. Ranvier named these partly detached squames the **stratum disjunctum**. The deeper cells contain granules of a fatty material which has the consistency and plasticity of beeswax, and stains with osmic acid. The peripheral parts of the cells consist of **keratin**, a highly resistant substance which is unaffected by mineral acids, and is indigestible in pepsin-hydrochloric acid. Macleod (*Proceedings of the Anatomical Society of Great Britain and Ireland*, May, 1902) found that after digestion of the stratum corneum in the latter fluid the cells "presented the appearance of a fine network, like a honeycomb, the contents of which had completely gone. The periphery of the cell alone resisted the action of the pepsin and had become keratinised."

L. Ranvier (*op. cit.*) has pointed out that the **stratum lucidum** is really double, and has named the deeper of its two layers the **stratum intermedium**; this he describes as consisting of two or three layers of clear cells with atrophied nuclei, while in the cell-walls the epidermic fibrils "are rolled up like the threads of a cocoon."

**Regeneration of the epidermis** is generally regarded as taking place by cell proliferation in the stratum germinativum, the young cells gradually passing through the polyhedral and granular stages, and ultimately becoming the horny squames of the stratum corneum. Professor Thomson of Oxford considers that, although this view meets all the requirements in white races, a difficulty is met with if it is applied to coloured races, where most pigment is found in the deeper cells of the stratum mucosum, while the superficial layers are free from colour. If the deeper cells advance to the surface, it is only reasonable to suppose that they would carry their pigment with them. This theory, therefore, necessitates a satisfactory explanation of the disappearance of the pigment from the superficial layers. He suggests that possibly the growth of the epidermis is analogous to the growth of the cork cambium of plants, the stratum mucosum corresponding to the green cells, and the stratum corneum to the corky layer of the cambium. If such be the case—and he insists that there is much evidence in support of it—the deeper cells would advance inwards towards the corium, and the superficial cells would grow outwards towards the surface. Under this view the active layers would be the stratum granulosum and stratum lucidum, and by it many of the difficulties would be explained, including the mysterious disappearance of the pigment from the superficial layers; it would also afford a reasonable explanation of how it happens that, in old age, a negro's hair becomes white, while his skin retains its blackness.

**Vessels and Nerves of the Skin.**—The **arteries** form a plexus in the subcutaneous tissue from which branches extend into the corium, where they supply the hair follicles and glands, and form a second plexus under the papillæ, to which small loops are given. The **veins** and **lymphatics** commence in the papillæ, and, after forming a subpapillary plexus, open into their respective subcutaneous vessels.

The **nerves** of the skin vary in number in different parts of the body, being extremely numerous where the sense of touch is acute, *e.g.* on the palmar aspect of the terminal phalanges, while in the skin of the back, where the sensibility is less, they are fewer in number. They form a plexus in the corium, and either terminate amongst the cells of the epidermis, or in special end organs named **tactile corpuscles**. Those ending in the epidermis form a rich subepithelial plexus, from which delicate fibrils pass between the cells of the rete mucosum, where they become beaded, and end in rounded swellings on flattened discs—the **tactile discs** of Ranvier.

The **special end organs** are of three chief varieties (Fig. 606): (*a*) **Corpuscula bulboidea** (Krausii), found on the lips, glans penis, etc., and consisting of a connective tissue capsule enclosing a core of elongated and polygonal cells, amongst which the axis-cylinder of the nerve fibril becomes branched and its ramifications end in clubbed extremities. (*b*) **Corpuscula lamellosa** (Vateri and Pacini). These are small, oval bodies, with a long diameter of 2 to 3 mm., and are found in the subcutaneous tissue attached to the nerve trunks. They are very numerous on the digital nerves, but are present in many other situations, *e.g.* in the mesentery. Each possesses a sheath, consisting of a number of concentrically arranged connective tissue lamellæ, covered by endothelium continuous with the perineurium. The central part of each corpuscle consists of a soft, almost homogeneous core. The nerve-fibre passes along the centre of the stalk of the corpuscle, and, reaching the core, loses its medullary sheath, whilst its axis-cylinder passes into the core and becomes branched near its distal extremity, the branches ending in bulbous enlargements. (*c*) **Corpuscula tactus** (Meissneri). These are very numerous on the flexor aspect of the hands and feet, and especially so in the skin over the terminal phalanges; but they also exist in other parts of the body. They occupy certain of the papillæ of the corium, and are oval in shape, their long diameter in the hand being from 110 $\mu$ to 160 $\mu$. They consist of a connective tissue capsule, which sends imperfect septa into the interior of the corpuscle. One or two nerve-fibres perforate the capsule, either directly or after taking a spiral course around it; and losing, as a general rule, their medullary sheath, their axis-cylinders break up into fibrils, which end in globular or discoid enlargements.

FIG. 606.—TACTILE CORPUSCLES.

A, End bulb (Krause).
B, Corpuscle of Pacini } (after Ranvier).
C, Corpuscle of Meissner }

Ruffini has described a special variety of terminal corpuscle in the human finger. They are termed **Ruffini's endings**, and are situated either at the junction of the corium and subcutaneous tissue, or are embedded in the latter. Of an oval shape, they consist of a connective capsule within which the axis-cylinder divides into varicose filaments, and these terminate in small knobs.

## APPENDAGES OF THE SKIN.

The appendages of the skin comprise the nails, the hairs, the sebaceous, and the sudoriparous or sweat glands.

**Nails.**—The nails or ungues (Figs. 607, 608) are epidermal structures, and, in man, represent the hoofs and claws of the lower animals. The **root** of the nail, or radix unguis, is hidden from view and embedded in a fold of skin; the **body** (corpus unguis), or uncovered part, rests on the corium and ends in a **free edge** (margo liber). The greater part of the lateral margins is overlapped by a duplicature of skin, termed the **nail-wall** or **vallum unguis**. The nails are pink in colour, with the exception of a small semilunar area near the root, which is more opaque than the rest, and is named the **lunula**. The lunulæ diminish in size from the thumb towards the little finger, while the thickness of the nail diminishes towards its root and lateral margins. The corium under the nail is highly vascular and sensitive, and presents, especially under the anterior part of the body, numerous longitudinally arranged papillæ. The part of the corium under the body is termed the **nail bed**; that under the root, the **nail matrix**. The deep part of the nail consists of

the stratum germinativum and stratum mucosum, while its superficial horny portion is constituted by a greatly thickened stratum lucidum, and consists of nucleated, keratinised squames. The stratum corneum is represented by the thin cuticular fold overlapping the lunula, and termed the **eponychium**, while the stratum granulosum can only be traced as far forwards as the nail root.

Fig. 607.—Transverse Section of a Nail.

**Hairs.**—Hairs (pili) are well developed on the scalp, pubes, and margins of the eyelids, in the axilla, the vestibule of the nose, and at the entrance to the concha, and also on the face of the male. Those on the genitals and face appear about puberty. Rudimentary over the greater part of the body, they are entirely absent on the flexor surfaces of the hands and feet, over the dorsal aspect of the terminal

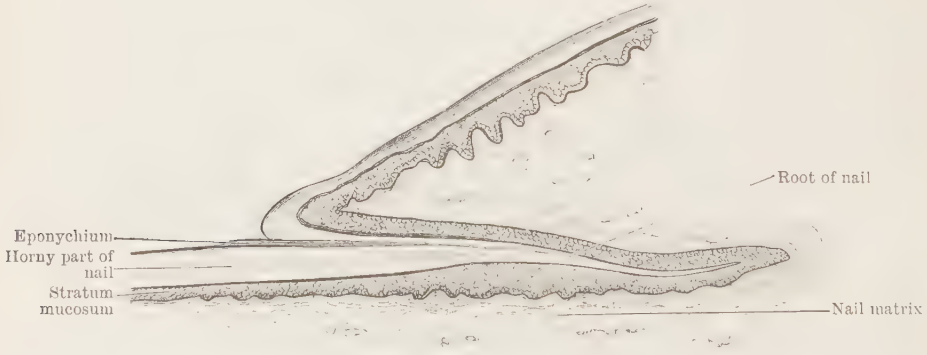

Fig. 608.—Longitudinal Section through Root of Nail.

phalanges, the glans penis, the inner surface of the prepuce, and inner aspect of the labia. Marked variations, individual and racial, exist as to the colour of the hair, and also as to the manner of its growth; hence the terms straight, curly, woolly, etc. are used to designate it. Straight hairs are coarser than curly ones, and have, moreover, a circular or oval outline on transverse section, curly hairs being flat and riband-like.

The **root of the hair** (radix pili) is embedded in a depression of the skin, termed the **hair follicle** (Fig. 604); while the free portion is named the **stem** or **shaft**, and consists from without inwards of three parts, viz. cuticle, cortex, and medulla. The *cuticle* is formed by a layer of imbricated scales which overlap one another from below upwards. The *cortex* consists of longitudinally arranged fibres made up of elongated, closely applied, fusiform cells, which contain pigment and sometimes air spaces, the latter especially in white hairs. The *medulla*, absent from the fine hairs of the body generally and from the hairs of young children, forms a central core, which appears black by transmitted, and white by reflected light, and is composed of polyhedral nucleated cells containing pigment, fat granules, and air spaces.

The **hair follicle** (folliculus pili) consists of an oblique or curved—the latter in

curly hairs—invagination of the epidermis and corium, which in the case of large hairs extends into the subcutaneous tissue (Fig. 604); some little distance below its orifice the ducts of the sebaceous glands open into it. The portion of the follicle derived from the corium (dermic coat) consists of a fibrous sheath of external longitudinal and internal circular connective tissue fibres, the latter being lined by a hyaline layer directly continuous with the basement membrane of the corium. The parts of the follicle derived from the epidermis are named the **inner** and **outer root sheaths.** Below the orifices of the sebaceous gland ducts the outer root sheath is formed by the stratum germinativum and stratum mucosum, while above them all the epidermal strata contribute to it. The inner root sheath surrounds the cuticle of the hair, and consists from without inwards of— (*a*) *Henle's layer*, a single stratum of nucleated, cubical cells; (*b*) *Huxley's layer*, a single or double layer of polyhedral nucleated cells; and (*c*) *a delicate cuticle*, consisting of a single layer of flattened

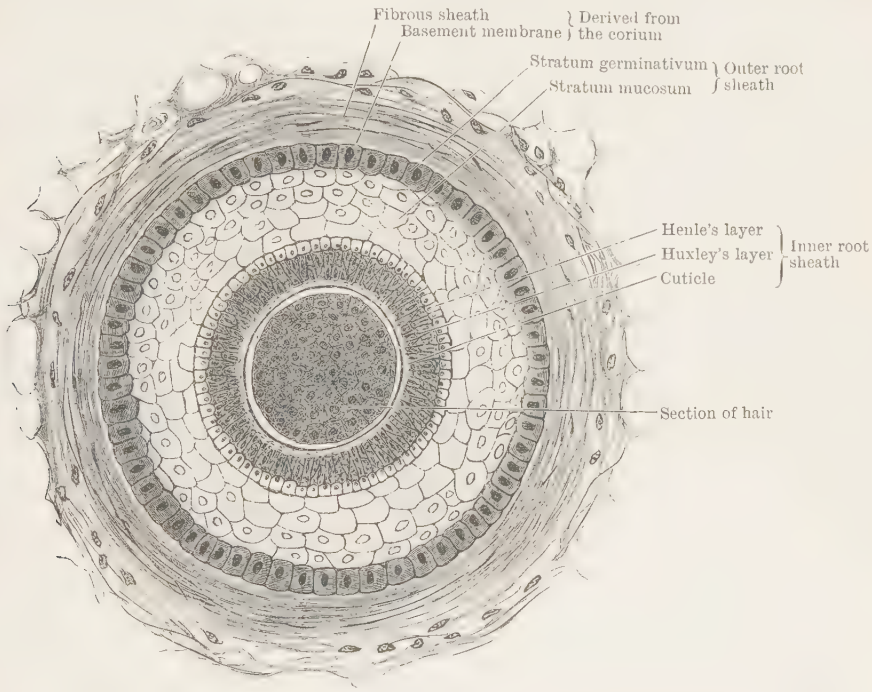

Fig. 609.—Transverse Section of Hair Follicle with contained Hair (highly magnified).

imbricated cells, with atrophied nuclei. The bottom of the hair follicle is indented by a vascular **papilla** (papilla pili), derived from the corium and capped by the bulb (bulbus pili) or expanded part of the hair root. The cells of the bulb are continuous with those of the outer root sheath, and form the different parts of the hair, as well as its inner root sheath. The vessels form capillary loops in the papilla of the hair, and send twigs into the outer layer of its fibrous sheath; the inner and outer root sheaths and the different parts of the hair are non-vascular. The nerves terminate in longitudinal and annular fibrils below the level of the sebaceous glands and outside the hyaline layer of the follicle.

**Sebaceous glands** (glandulæ sebaceæ) exist wherever there are hairs, and their ducts open into the superficial part of the hair follicles (Fig. 604); the number of glands associated with each follicle varies from one to four. On the labia minora and mammary areolæ they open on the surface of the skin independently of hair follicles, and in the latter situation undergo great enlargement during pregnancy. The deep extremity of each gland expands into a cluster of oval or flask-shaped **alveoli**, which are surrounded by a basement membrane, and filled with polyhedral cells containing oil droplets. By the breaking down of the superficial cells, their oily contents are liberated as the *sebum cutaneum* and discharged into the hair follicle, whilst the deeper cells undergo proliferation. The size of the gland bears

no proportion to that of the hairs, since they are very large in the minute hair follicles of the fœtus and newly born child, and also in the follicles of the rudimentary hairs of the nose and certain parts of the face.

Bundles of non-striped muscular fibre are associated with the hair follicles, and are named the **mm. arrectores pilorum**. Attached to the deep part of the hair follicle, and forming with it an acute angle, they pass outwards close to the sebaceous glands, to end in the papillary layer of the corium. Situated on the side of the hair towards which it slopes, they, on contraction, diminish the obliquity of the hair follicle and render the hair more erect, and, at the same time, compress the sebaceous glands and expel their contents. The condition of "goose-skin" is caused by the contraction of these slender muscles.

Thomson suggests that the condition of curly hair is produced by the contraction of these small muscles. Straight hair is thick and rounded; curly hair is flat and ribbon-like. When the erector muscle contracts, the thick rounded hair resists the tendency of the muscle to bend it, while the flat hair, not sufficiently strong to resist the strain of the muscle, becomes bent, and this is probably the explanation why the follicle assumes the curved form characteristic of the scalp of a bushman. The sebaceous gland lies in the concavity of the bend between the follicle and the muscle, and forms a mass of greater resistance, around which the follicle may be curved by the contraction of the muscle. The cells at the root of the hair accommodate themselves to the curved follicle, and, becoming more horny as they advance to the surface, retain the form of the follicle in which they are moulded.

The **sudoriparous** or **sweat glands** (glandulæ sudoriferæ) are relatively few in number on the back of the trunk, but are very plentiful on the palms and soles, where they open on the summits of the curved ridges. Each consists of an elongated tube, the deeper portion of which forms its secretory part, and is coiled in the subcutaneous tissue or deep part of the corium in the form of an ovoid or spherical ball, termed the **glomerulus** or **corpus glandulæ sudoriferæ** (Fig. 604). The superficial part of the tube, or **ductus sudoriferus**, extends through the corium and epidermis, and opens on the surface by a funnel-shaped orifice, the **porus sudoriferus**; where the epidermis is thick the duct is spirally coiled. The **glomeruli**, as a rule, vary in diameter from 0·1 to 0·5 mm., but in the axillæ they are much larger, and may measure from 1 to 4 mm. Each is surrounded by a capillary network and by a capsule of connective tissue, inside which is a homogeneous basement membrane. The lumen of the tube is lined by a layer of nucleated, granular, and striated, columnar, or prismatic epithelium, between the deep extremities of which and the basement membrane is a layer of non-striped muscular fibres, the long axis of which is more or less parallel with that of the tube. The excretory ducts are devoid of muscular fibres, and consist of a basement membrane lined by two or three layers of polyhedral cells, which are covered, next the lumen of the tube, by a thin cuticle.

The **glands of Moll** (glandulæ ciliares), opening at the margins of the eyelids, and the **glandulæ ceruminosæ** of the external auditory meatus, are modified sudoriparous glands; the former are, however, not coiled up to form glomeruli, while the cell protoplasm of the latter contains yellowish pigment, and their gland ducts, in the fœtus, open into hair follicles.

### Development of the Skin and its Appendages.

**Skin.**—The vascular and sensitive corium is developed from the mesoderm, the cells of which, immediately underlying the ectoderm, have, by the second month of fœtal life, become aggregated together and flattened parallel to the surface of the embryo. By the third month they are seen to form two layers, the superficial of which becomes the corium, and the deeper the subcutaneous tissue; the papillæ of the corium make their appearance in the fourth month. The epidermis, nails, hairs, sweat and sebaceous glands are all of ectodermal origin.

The epidermis at first consists of a single layer of cells, but by the end of the second month it is duplicated, and then exhibits a superficial layer of irregular cells and a deeper layer of more or less cubical cells. By the third month three strata are seen: (*a*) a deep layer, consisting of a single stratum of cubical cells—the future stratum germinativum; (*b*) a middle layer, comprising two or three strata of irregular cells—the future stratum

mucosum; and (*c*) an outer layer, a double stratum of large cells. This outer layer appears to be homologous with a thin membrane, termed the *epitrichium*, first described as covering the embryo of the sloth and overlying its hairs, but since shown to be present in birds and mammals. Over the hairy parts of the body it disappears about the sixth month; but over the free edge and root of the nails, and on the palms and soles, it develops into several layers of cells, which, in these parts, probably persist to form the thick stratum corneum. The part which persists over the root of the nail is termed the *eponychium*, and covers the proximal part of the lunula (*vide* p. 776). The stratum lucidum is differentiated from the cells of the epitrichium, and, where the latter is lost, possibly forms the superficial layer of the epidermis as it does the horny part of the nails.

**Nails.**—The first rudiment of the nails is seen about the beginning of the third month of embryonic life, and consists of a thickening of the epitrichium over the extremity of the digits. Owing to the growth of the palmar aspect of the digits, the nail rudiment comes to be placed dorsally, and, at its proximal edge, an ingrowth of the stratum mucosum occurs to form its root, while the future nail becomes limited behind and laterally by a groove. The superficial cells of the stratum mucosum become keratinised to form a thick stratum lucidum, the future nail proper, over the greater part of which the epitrichium disappears. The latter persists in the adult as the perionyx across the root of the nail, and, until fifth month, also forms a thick mass over the extremity of the nail, and is continued into the stratum corneum over the end of the digit. The future distal edge of the nail, at this stage, is continuous with the stratum lucidum in front of it; but this continuity is lost, and by the seventh month the nail presents a free border. The nails grow in length, and are renewed, in case of removal, by a proliferation of the cells of the stratum mucosum at the root of the nail, while an increase in their thickness takes place from the part of the same stratum which underlies the lunula.

**Hairs.**—The hair rudiments appear about the third month of embryonic life as solid downgrowths of the stratum mucosum, which pass obliquely into the subjacent corium. The deep end of this column of cells becomes expanded to form the hair bulb, and rests on a papilla derived from the corium, the epidermis immediately overlying which becomes differentiated into the hair and its inner root sheath, while the peripheral cells form its outer root sheath. The surrounding corium becomes condensed to form the fibrous sheath of the hair follicle, the hyaline layer of which is continuous with the basement membrane covering the corium. The hair gradually elongates, and, reaching the neck of the follicle, its extremity lies at first under the epitrichium, but becomes free on the disappearance of the latter. This takes place about the fifth month, and the first crop of hairs constitutes the *lanugo*, which is well developed by the seventh month. The lanugo consists of very delicate hairs, some of which are shed before, the remainder shortly after birth—the last to drop out being those of the eyelashes and scalp—and are replaced by stronger hairs. Shedding and renewal of the hairs take place during life, the renewal being, of course, absent in the case of baldness. Prior to the shedding of a hair active growth and proliferation of the cells of the hair bulb cease, and the papilla becomes atrophied, while the hair root, gradually approaching the surface, at last drops out. New hairs arise from epidermic buds, which extend downwards from the follicle, and their development is identical with that of the original hairs.

**Sebaceous Glands.**—These appear about the fifth month as solid outgrowths from the sides of the hair follicles, and consist of epidermal offshoots continued from the cells of the outer root sheath. Their deep ends become enlarged and lobulated, to form the secreting part of the gland, while the narrow neck connecting this with the follicle forms its duct. The sebaceous secretion, together with the cast-off epidermal cells, is collected on the surface of the body during the last months of intrauterine life, and forms a layer of varying thickness, termed the *vernix caseosa* or *smegma embryonum*.

**Sweat Glands.**—These, like the hairs, arise as solid downgrowths of the stratum mucosum. They descend, however, perpendicularly, instead of obliquely, and are of a yellowish colour; they appear on the palms and soles early in the fifth month, but much later over the hairy parts of the body. The downgrowths extend through the corium, and, on reaching the subcutaneous tissue, become coiled up to form the secreting part of the gland. The lumen of the gland does not open on the surface until the seventh month.

# THE VASCULAR SYSTEM.

By Alfred H. Young and Arthur Robinson.

The vascular system consists of a series of tubular vessels, with more or less distinct walls, which run through all parts of the body. Some contain blood, others are filled with a colourless fluid called lymph; hence the distinction between the blood-vascular system and the lymph-vascular system. The two systems differ, not only as regards their contents, but also in their relations to the tissues amongst which they lie; for whilst the vessels of the former system, with the possible exception of the splenic vessels, are closed, those of the latter communicate freely with intercellular spaces and serous sacs.

The **blood-vascular system** is tubular throughout; the tubes or vessels possess distinct walls; they vary in size and in the structure of their walls, but all contain blood, which is conveyed through them to and from the tissue elements of the body. The blood is propelled along the vessels chiefly by a central propulsive organ—the **heart**. The outgoing vessels from the heart, along which blood is transmitted to the tissues, are termed **arteries**; the vessels which return blood from the tissues to the heart are known as **veins**; whilst the smallest tubes—those which connect the arteries and veins together, constituting at once the terminations of the arteries and the commencements of the veins—are called **capillaries**.

Blood capillaries are very small (hair-like) vessels with exceedingly thin walls, which permit of the easy passage outwards of the nutritive plasma from the blood to the tissues, and, in the opposite direction, of some of the products of tissue changes and of modified food material from the alimentary canal.

Arteries and veins are simply conducting passages; structurally they differ from capillaries in the greater complexity of their walls. They vary greatly in size, but are always larger than capillaries. The calibres of the arteries and veins increase progressively from the periphery up to the heart, where the vessels reach their greatest size. With the increase in calibre there is a corresponding increase in the thickness and complexity of their walls.

**Structure of Blood Capillaries.**—Capillaries measure from $\frac{1}{3000}$ to $\frac{1}{2000}$ of an inch in diameter, and about $\frac{1}{25}$ to $\frac{1}{20}$ of an inch in length. Their walls are simple, and, in the smallest capillaries, consist principally of elongated elastic endothelial cells, with sinuous edges, pointed extremities, and oval nuclei. The cells are cemented to one another along their margins by intercellular cement, which readily stains with nitrate of silver. Here and there the cement substance appears to accumulate, forming minute spots indicative of the less perfect apposition of the edges of the cells. These spots, when small, form the so-called **stigmata**; when larger they are known as **stomata**.

The larger capillaries are invested by a connective tissue sheath consisting of branched cells which are united together and to the endothelial cells of the capillary wall. This sheath is termed the **adventitia capillaris.**

Capillaries are arranged in networks, the nature and character of which differ in different tissues. The small arteries which end in them are known as **capillary arterioles**, and the venous radicles which commence from them are appropriately termed **capillary veins.**

**Structure of arteries and veins.**—The delicate elastic endothelial membrane forming the wall of the simplest capillaries extends as a continuous lining throughout the whole of the blood-vascular system. The constituent cells are fusiform, narrow, and pointed in the arteries, whilst in the veins they are somewhat shorter and broader.

The most essential structural difference between capillaries and the arteries and veins which they unite together, is to be found in the presence, in both of the latter, of involuntary muscular fibres interposed between the endothelial lining and the outer connective tissue sheath. In small vessels, *e.g.* capillary arterioles, the muscle cells are few in number and more or less scattered. In larger vessels the walls become stronger and thicker, muscular fibres increase and form a continuous layer, whilst yellow elastic and ordinary white connective tissue are added in varying proportions. The walls of the vessels thus become more complex, and numerous strata may be distinguished; these, however, are for convenience regarded as forming three layers, which are known as the inner, middle, and outer coats, superadded to which is the investing common sheath.

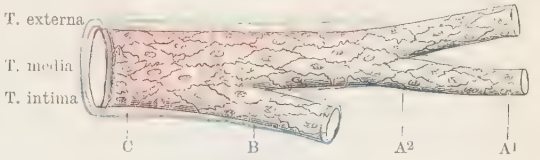

FIG. 610.—STRUCTURE OF BLOOD-VESSELS (diagrammatic).

$A^1$, Capillary—with simple endothelial walls. $A^2$, Larger capillary—with connective tissue sheath, "adventitia capillaris." B, Capillary arteriole—showing muscle cells of middle coat, few and scattered. C. Artery—muscular elements of the tunica media forming a continuous layer.

**Structure of Arteries.**—The walls of arteries are stronger and thicker than those of veins of corresponding size, the inner and middle coats being particularly rich in elastic and muscular elements.

**Inner coat** (tunica intima).—The simple endothelial layer of the arterioles is strengthened by the addition of yellow elastic tissue, the fibres of which are arranged in such a manner as to simulate a fenestrated membrane. In arteries of medium size the elastic lamina is separated from the endothelium by a layer of connective tissue consisting of branched cells and numerous fibrils. In the larger arteries the sub-endothelial connective tissue is considerably increased, and delicate elastic fibres appear which connect it with the more externally situated fenestrated elastic layer.

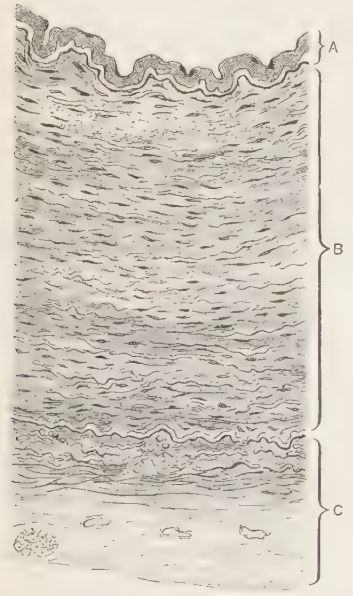

FIG. 611.—TRANSVERSE SECTION THROUGH THE WALL OF A LARGE ARTERY.

A, Tunica intima. B, Tunica media. C, Tunica externa.

The **middle coat** (tunica media) in the capillary arterioles consists solely of scattered unstriped muscle fibres; the individual fibres are circularly disposed, but do not entirely surround the vessel. In small arteries the muscle cells are so far increased in amount that they form a continuous though thin layer. As the arteries increase in size additional layers of muscle cells are added, and the greater thickness of the arterial wall is mainly due to this increase of the muscular elements of the middle coat. In the larger vessels delicate laminæ of elastic tissue alternate with the layers of muscular fibres, and in the aorta and the carotid arteries, as well as in some of the branches of the latter, the elastic elements largely preponderate. In the first part of the aorta, in the pulmonary artery, and in the arteries of the retina, the muscular fibres are entirely replaced by elastic tissue.

The **external coat** (tunica externa) of an artery consists almost entirely of fibrillated connective tissue, with connective tissue corpuscles lying in corresponding spaces. In all but the smallest arteries numerous elastic fibres are also present. The elastic element is specially strong near the middle coat in small and medium sized vessels, and is sometimes described as the external elastic

membrane of Henle. In some arteries longitudinally arranged unstriped muscular fibres are also found in the external coat.

The **sheath of an artery** (vagina vasis).—In addition to the three coats above described, arteries are enclosed in a sheath of the surrounding connective tissue, and are more or less connected with it by fine strands of fibrillated connective tissue.

**Structure of Veins.**—The walls of veins are similar in structure to those of arteries; they are, however, thinner, so much so, that, although veins are cylindrical tubes when full of blood, they collapse when empty, and their lumina almost disappear. The structural details of the three coats vary somewhat in different veins; in most the inner coat is marked by folds which constitute valves. Like the arteries, the veins are enclosed in connective tissue sheaths.

The **inner coat** (tunica intima).—In the majority of the veins the inner coat includes an internal endothelial layer, a middle layer of sub-endothelial connective tissue, and an outer layer of elastic tissue. The inner coat of a vein is less brittle than the inner coat of an artery, and is more easily peeled off from the middle coat. The sub-endothelial tissue is a fine fibrillated connective tissue, less abundant than in the arteries, and indeed in many cases it is absent. The elastic layer consists of lamellæ of elastic fibres which are arranged longitudinally, and it rarely forms a fenestrated membrane.

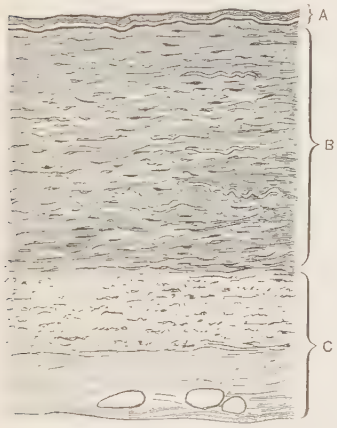

Fig. 612.—Transverse Section of the Wall of a Vein.

A, Tunica intima. B, Tunica media. C, Tunica externa.

One of the chief peculiarities of the inner coat is the presence of folds of its substance which constitute **valves**. The valves are of semilunar shape, and they are usually arranged in pairs. Their convex borders are continuous with the vessel wall, and their free borders are turned towards the heart; whilst, therefore, they do not interfere with the free flow of blood onwards, they prevent any backward flow towards the periphery, and they help to sustain the column of blood in all vessels in which there is an upward flow. Each valve consists of a fold of the inner or endothelial layer, strengthened by a little connective tissue. As a general rule, the wall of the vein is dilated above each valve into a shallow pouch or sinus; consequently, when the veins are distended they assume a nodulated appearance. The valves are more numerous in the deep than in the superficial veins, and in the veins of children than in the veins of adults.

The **middle coat** (tunica media) is much thinner than the corresponding coat of an artery, and it contains a smaller amount of muscular and a larger amount of ordinary connective tissue; indeed, so much does the latter preponderate that it separates the muscular fibres into a number of bands isolated from each other by strands of connective tissue, and the muscle fibres do not form a continuous layer. In some of the veins the more internal muscular fibres do not retain the transverse direction which is usually met with both in arteries and veins; on the contrary, they run longitudinally. This condition is met with in the branches of the mesenteric veins, in the femoral and iliac veins, and in the umbilical veins. The middle coat is absent in the thoracic part of the inferior vena cava; it is but slightly developed in many of the larger veins, whilst in the jugular veins its muscular tissue is very small in amount.

The **external coat** (tunica externa).—This coat consists of white fibrous and elastic tissue. In many of the larger veins a considerable amount of muscular tissue is also present; this is the case in the iliac and axillary veins, the abdominal part of the inferior vena cava, the azygos veins, and in the renal, spermatic, splenic, superior mesenteric, portal, and hepatic veins. The striped muscle fibres of the heart are prolonged into it at the terminations of the venæ cavæ. The external coat is frequently thicker than the middle coat, and the two are not easily separable from one another.

**Vascular and Nervous Supply of Arteries and Veins.**—Blood-vessels.—The

walls of the blood-vessels are supplied by numerous small arteries, called *vasa vasorum*, which are distributed to the outer and middle coats. They arise either from the vessels they supply or from adjacent arteries, and after a short course enter the walls of the vessels in which they end. The blood is returned by small venæ vasorum.

**Lymphatics.**—Although the cell spaces in the middle and inner coats may be regarded as the commencement of lymphatics, definite lymphatic vessels are limited to the outer coat.

**Nerves.**—Arteries and veins are well supplied with both medullated and non-medullated nerve-fibres. The fibres form dense plexuses on the outer surfaces of the vessels, from which filaments pass to the middle coat to be distributed almost entirely to its muscular fibres.

**Divisions of the Blood-Vascular System.**—Blood-vessels convey blood to or from the tissues of the body generally, or to and from the lungs. The former constitute the **systemic vessels** or **general system**; the latter form the **pulmonary system.** These two systems are connected together by the heart.

The venous trunks passing to the liver form a subsidiary part of the general systemic group of vessels, which is known as the **portal system.**

## THE HEART.

The **heart** (cor) is a hollow muscular organ, and is enclosed in a fibro-serous sac known as the pericardium. It receives blood from the veins, and propels it into and along the arteries. The cavity of the fully developed heart is completely separated into right and left halves by an obliquely placed longitudinal septum, and each half is divided into an upper receiving chamber, the **auricle**, and a lower ejecting chamber, the **ventricle.** The separation of the auricle from the ventricle, however, is not complete. Externally a comparatively shallow constriction, running transversely to the long axis of the organ, indicates the distinction between the auricles and ventricles; internally a wide aperture is left between the auricle and ventricle of each side. Each **auriculo-ventricular aperture** is provided with a valve which allows the free passage of blood from the auricle to the ventricle, but effectually prevents its return.

It has already been pointed out that the delicate walls of the blood capillaries allow of the free passage outwards of nutritive plasma from the blood. It passes into spaces, or intercellular channels, in which the tissue elements lie; thus the latter are directly bathed in blood plasma. The intercellular spaces form the commencement of the lymph-vascular system. They communicate together, and open into lymph-vessels which carry the used plasma back to the blood-vascular system, but in addition they also convey new nutritive material, the product of digestive processes, from the alimentary canal.

Lymph-vessels, in other words, convey material from the tissues. Blood-vessels convey material both to and from the tissues.

The removal of waste products from the blood is provided for by special organs, some of which are simply interposed in the course of the general circulation—*e.g.* the liver, the kidneys, and the skin. The lungs, however, where the impure or venous blood receives its main supply of oxygen and gives up most of its carbonic oxide, etc., do not lie in the course of the general or systemic circulation; from them a secondary or pulmonary circulation is established, by which venous blood is conveyed from the heart to the lungs by the pulmonary artery and its branches, and, after passing through the pulmonary capillaries, is returned again to the heart as pure arterial blood by the pulmonary veins.

The heart, anatomically a single organ, is correspondingly modified, and, as described above, it is divided by a septum into a right and a left part. The right side receives the blood from the systemic veins, and ejects it into the pulmonary artery; whilst the left side receives blood from the pulmonary veins, and ejects it into the main systemic artery—the aorta.

The **shape** of the heart is that of an irregular and somewhat flattened cone; and a base, an apex, two surfaces (inferior and antero-superior), and two borders (right and left) are distinguishable.

An oblique groove—the **auriculo-ventricular groove** (sulcus coronarius)—runs transversely to the long axis of the organ, and separates the upper auricular portion from the lower ventricular part. The separation of the auricular portion into right and left chambers is only marked externally at the base of the heart,

where an indistinct interauricular groove exists. The division of the lower part into right and left ventricles is more definitely marked on the surface by anterior and inferior interventricular sulci (sulci longitudinales).

The heart lies in the middle mediastinum. It is enclosed in the pericardium, and this latter accordingly intervenes between it and the neighbouring structures. It rests below on the diaphragm. Its long axis, from base to apex, runs obliquely from behind forwards, downwards, and to the left.

The *base* (basis cordis), formed entirely by the auricles, and almost entirely by the left auricle, is directed upwards, backwards, and to the right. It lies in front of the descending thoracic aorta, the œsophagus, and the lower right pulmonary vein, which separate it from the bodies of the sixth, seventh, and eighth dorsal vertebræ.

On the whole the base is somewhat flattened, and is irregularly quadrilateral

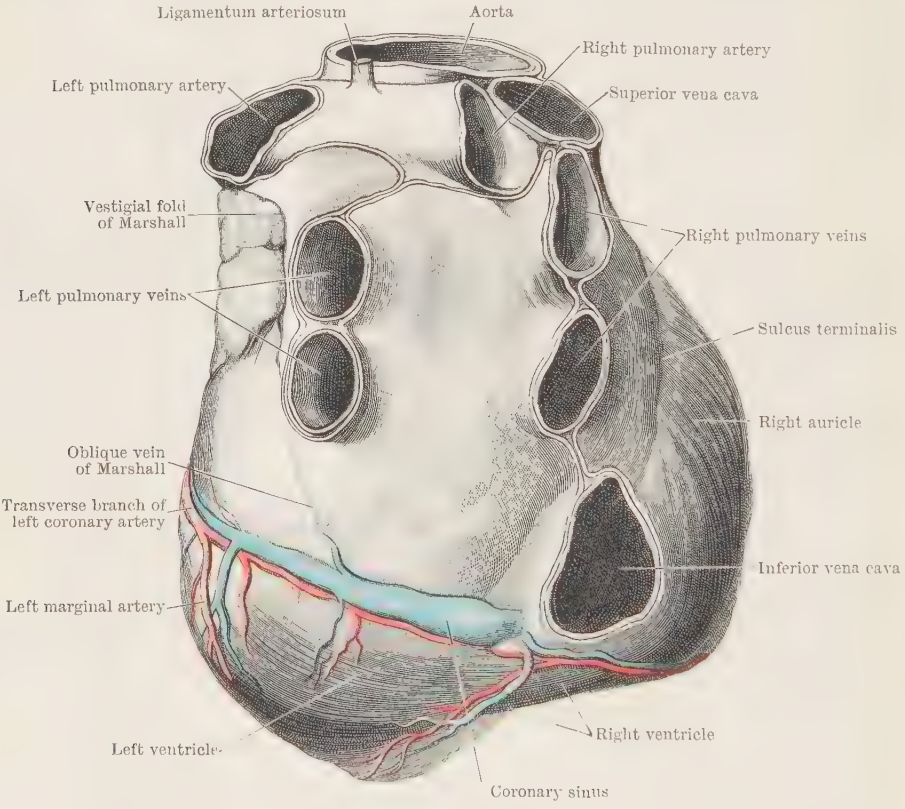

FIG. 613.—THE BASE AND INFERIOR SURFACE OF THE HEART, showing the openings of the great vessels and the line of reflection of the serous pericardium.

in form. It presents the orifices of the superior and inferior venæ cavæ and the four pulmonary veins. The opening of the superior vena cava is situated at the upper right angle, that of the inferior cava occupies the lower angle on the right side; between and a little to the left of these openings are the orifices of the two right pulmonary veins, and immediately to the right of the latter is the indistinct posterior interauricular sulcus, which descends to the left of the orifice of the inferior vena cava. The openings of the two left pulmonary veins are situated near the left border of the base; and the portion of the surface which lies between the right and left pulmonary veins forms the anterior boundary of the great oblique sinus of the pericardium.

The base is limited below by the lower part of the auriculo-ventricular groove, in which the coronary sinus lies; its upper border is in relation with the bifurcation of the pulmonary artery. A fold of pericardium, the vestigial fold of Marshall (ligamentum v. cavæ sinistræ) descends, near the left border of the base,

from the left branch of the pulmonary artery above to the left superior pulmonary vein below; and from the lower end of this fold, crossing obliquely below the left pulmonary vein to reach the coronary sinus, is the small oblique vein of Marshall (v. obliqua atrii sinistri [Marshalli]). Further, it is from the base that the visceral layer of the pericardium, which elsewhere completely invests the heart, is reflected, the lines of reflection corresponding with the orifices of the great vessels.[1]

The *apex* (apex cordis), bluntly rounded, is formed entirely by the left ventricle. It is directed downwards, forwards, and to the left, and is situated, under cover of the anterior border of the left lung and pleura, behind the fifth left intercostal space, three and a quarter inches from the anterior mesial line.

The *inferior surface* (facies diaphragmatica) is formed by the ventricular part

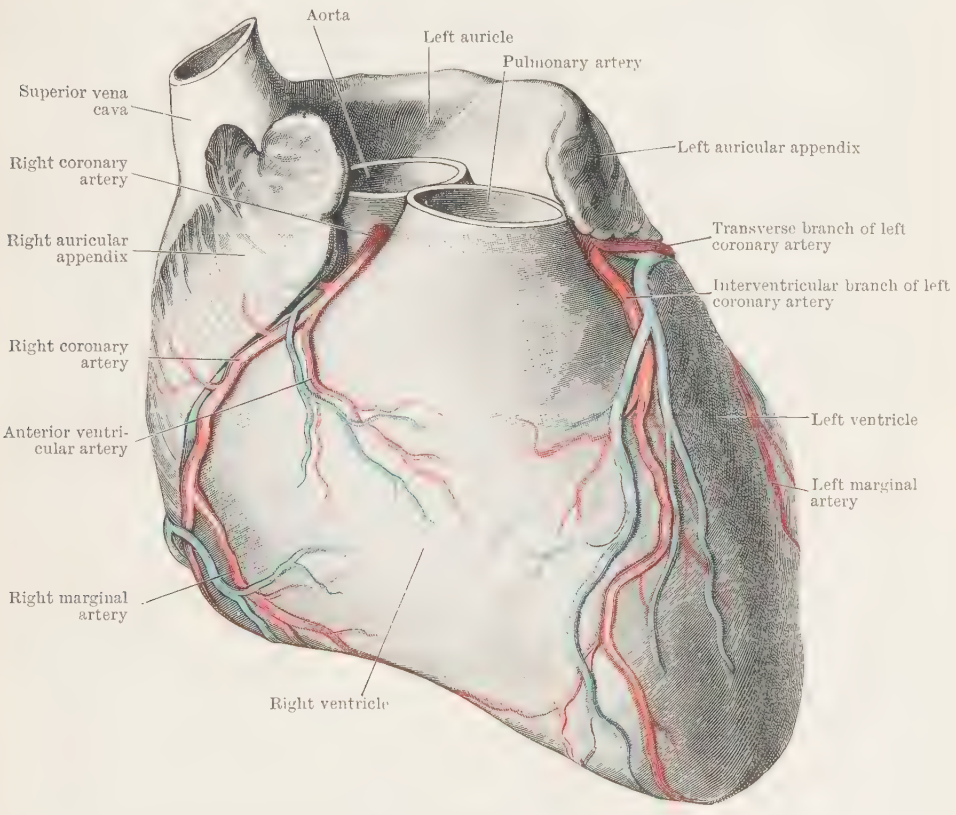

FIG. 614.—THE ANTERO-SUPERIOR SURFACE OF THE HEART.

of the heart. It rests upon the diaphragm, chiefly on the central tendon, but upon the left side, on a small portion of the muscular substance also, and it is divided into two areas—a smaller to the right side and a larger to the left side—by an oblique antero-posterior groove, the **inferior interventricular sulcus**. It is separated from the base by the posterior or inferior portion of the auriculo-ventricular sulcus.

The *antero-superior surface* (facies sterno-costalis) is directed upwards, forwards, and to the left. It lies behind the body of the sternum and the inner extremities of the cartilages of the third, fourth, fifth, and sixth ribs on the right side, and a greater extent of the corresponding cartilages on the left side. This surface is separated into upper and lower sections by the anterior portion of the auriculo-ventricular groove, which runs obliquely from above downwards, and from left to right, from the level of the third left to that of the sixth right costal cartilage. The upper section of the surface, which is concave, is formed

[1] In the fœtus and young child the auricular portion of the heart forms not only the base, but also the posterior part of the inferior or diaphragmatic surface.

by the auricles; it is separated from the sternum by the roots of the aorta and the pulmonary artery, and is continuous laterally with the auricular appendices which, projecting forwards, embrace the great vessels. The lower section of the antero-superior surface is convex; it is formed by the ventricular part of the heart, and is divided by an anterior interventricular sulcus into a smaller left and a larger right part. At the junction of the auricular and ventricular parts of this surface are the orifices of the pulmonary artery and the aorta, the former lying in front of the latter.

The *right margin* of the heart consists of an upper auricular part and a lower ventricular part. The former is almost vertical; it lies behind the cartilages of the third, fourth, fifth, and sixth ribs on the right side about half an inch from the margin of the sternum; it is in relation with the right pleura and lung, the phrenic nerve with its accompanying vessels intervening, and it is marked by a shallow groove—the sulcus terminalis—which passes from the front of the superior vena cava to the front of the inferior vena cava. The lower part of the right margin (margo acutus) is sharp, thin, and usually concave, corresponding with the curvature of the anterior part of the diaphragm; it is formed by the right ventricle, and it lies almost horizontally in the angle between the diaphragm and the anterior wall of the thorax, passing from the sixth right costal cartilage behind the lower part of the body of the sternum, or the ensiform cartilage, and behind the cartilages of the sixth and seventh ribs on the left side to the apex of the heart.

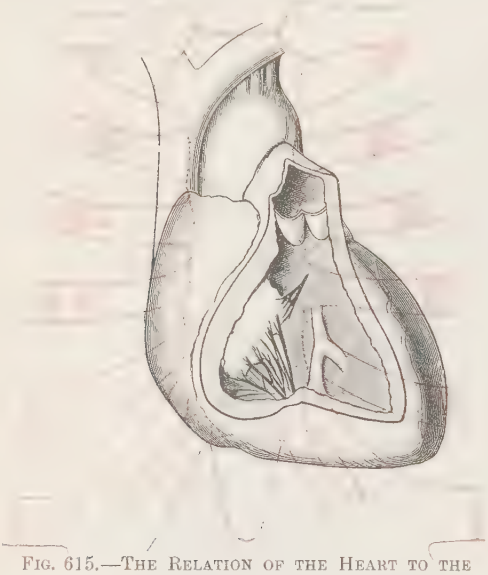

Fig. 615.—The Relation of the Heart to the Anterior Wall of the Thorax.

I, II, III, IV, V, VI, the upper six costal cartilages.

The *left margin* (margo obtusus) is formed mainly by the left ventricle, and only to a small extent by the left auricle. It is thick and rounded. It lies in relation with the left pleura and lung, the phrenic nerve and its accompanying vessels intervening, and it passes from just above the third left costal cartilage, about an inch from the sternum, to the apex of the heart, descending obliquely and with a convexity to the left.

## THE CHAMBERS OF THE HEART.

**Auricles** (auricula cordis).—The auricular or basal portion of the heart is cuboidal in form. Its long axis, which lies transversely, is curved, with the concavity of the curve forwards. It is divided into two chambers—the right and left auricles—by a septum which runs from the front backwards and to the right, so obliquely that the right auricle lies in front and to the right, and the left auricle behind and to the left.

Each auricle is also somewhat cuboidal in form, the long axes of both being vertical, and each chamber possesses a well-marked ear-shaped, forward prolongation, which projects from the anterior and upper angle, and is known as the **auricular appendix.**

The **right auricle** (atrium dextrum) receives, posteriorly, the superior vena cava above and the inferior vena cava below. Between these, and a little above its middle, it is crossed posteriorly by the lower right pulmonary vein. It is continuous below and in front with the right ventricle at the auriculo-ventricular aperture. Above and in front it is in relation with the ascending aorta, and from the junction of this aspect with the right lateral boundary the right auricular appendix

is prolonged forwards. On the right side it forms the upper portion of the right margin of the heart, and is in relation with the right phrenic nerve and its accompanying vessels, and with the right pleura and lung, the pericardium intervening. On the left the auricle is limited by the oblique septum which separates it from the left auricle. The **sulcus terminalis** is a shallow groove on the surface of the right auricle, which passes from the front of the superior vena cava to the front of the inferior vena cava, and indicates the junction of the primitive sinus venosus with the auricle proper.

The interior of the auricle is lined with a glistening membrane, the **endocardium**; its walls are smooth, except anteriorly and in the auricular appendix where muscular bundles, the **musculi pectinati**, form a series of small vertical

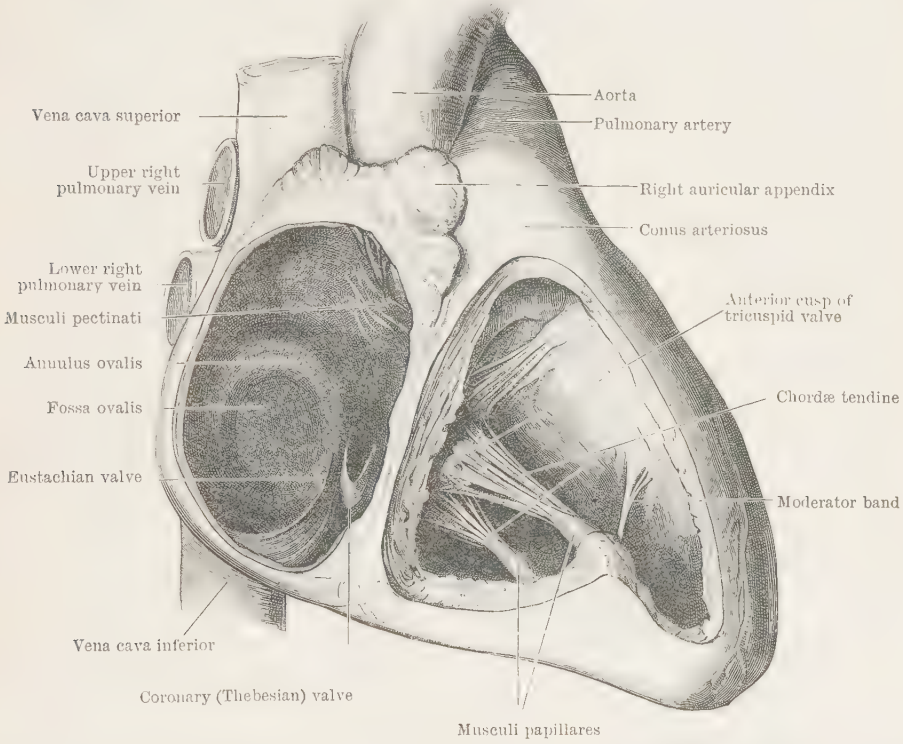

FIG. 616.—THE CAVITIES OF THE RIGHT AURICLE AND RIGHT VENTRICLE OF THE HEART.

columns. These terminate above in a crest, the **crista terminalis**, which corresponds in position with the sulcus terminalis externally.

At the upper and back part of the cavity is the opening of the superior vena cava, devoid of a valve. At the lower and back part is the orifice of the inferior vena cava, bounded in front by the rudimentary Eustachian valve; and immediately in front and to the left of the Eustachian valve, between it and the auriculo-ventricular orifice, is the opening of the coronary sinus, guarded by the Thebesian valve. The auriculo-ventricular aperture, guarded by a tricuspid valve, is known as the **tricuspid orifice**. It is situated in the inferior part of the anterior boundary, and admits three fingers. A number of small fossæ, **foramina Thebesii** (foramina venarum minimarum), are scattered over the walls, and into some of these the **venæ minimi cordis** open. In the septal wall is an oval depression, the **fossa ovalis**, bounded above and in front by a raised margin, the **annulus ovalis** (limbus fossæ ovalis), which is continuous inferiorly with the Eustachian valve; this fossa is the remains of an aperture, the **foramen ovale**, through which the two auricles communicated with each other before birth, and even in the adult a portion of the aperture persists at the upper part of the fossa in about one in five cases. Between the apertures of the superior and inferior venæ cavæ, and behind the upper part

of the fossa ovalis, a small eminence may be distinguished, which is called the **tubercle of Lower** (tuberculum intervenosum); in the fœtus it probably directs the blood from the superior vena cava to the tricuspid orifice.

The **Eustachian valve** (valvula venæ cavæ inferioris) is a thin and sometimes fenestrated fold of endocardium and sub-endocardial tissue, which extends from the anterior and lower margin of the orifice of the inferior vena cava to the anterior part of the annulus ovalis. Varying very much in size, it is usually of falciform shape, its apex being attached to the annulus and its base to the margin of the inferior caval orifice. It is an important structure in the fœtus, directing the blood from the inferior vena cava through the foramen ovale into the left auricle.

The **Thebesian valve** (valvula sinus coronarii) is usually a single fold of endocardium which is placed at the orifice of the coronary sinus; occasionally it consists of two cusps. It is almost invariably incompetent.

The **left auricle** (atrium sinistrum) is in relation behind with the descending thoracic aorta and the œsophagus. Below and in front it is continuous with the left ventricle. Its antero-superior surface is concave, and lies in close relation to the roots of the ascending aorta, the pulmonary artery, and the left coronary

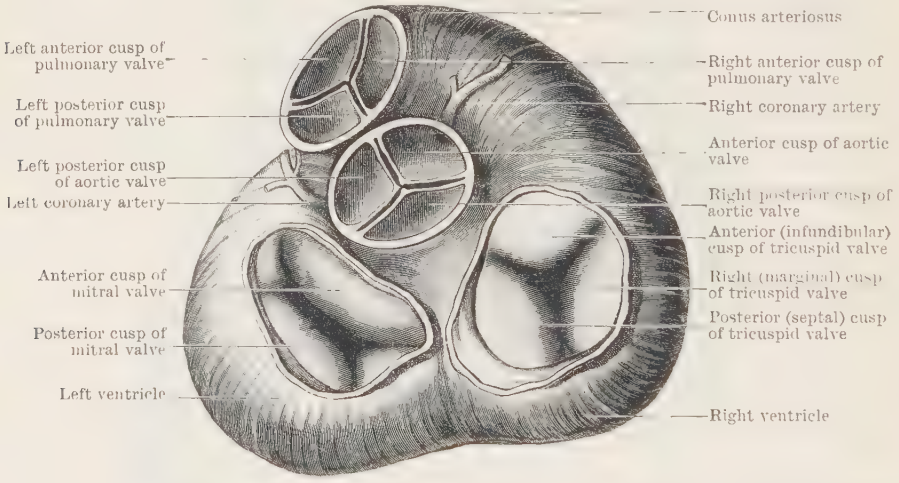

Fig. 617.—The Bases of the Ventricles of the Heart, showing the auriculo-ventricular, aortic, and pulmonary orifices and their valves.

artery. Its right side, formed by the interauricular septum, is directed forwards and to the right. Its left side forms a very small portion of the left margin of the heart, and from its junction with the antero-superior surface the long and narrow auricular appendix is prolonged forwards round the left side of the ascending portion of the aorta and the trunk of the pulmonary artery.

The four pulmonary veins enter the upper part of the posterior surface, two on each side.

The interior of the left auricle is lined with endocardium, and its walls are smooth, except in the auricular appendix where musculi pectinati are present, and on the septum, in a position corresponding with the upper part of the fossa ovalis on the right side, where there are several musculo-fibrous bundles radiating forwards and upwards. These septal bundles are separated at their bases by small semilunar depressions, in the largest of which remains of the foramen ovale may be found. Foramina Thebesii, and the apertures of venæ minimi cordis, are scattered irregularly over the inner aspect, whilst in the inferior part of the anterior boundary is the auriculo-ventricular aperture. The latter is oval in form; its long axis is placed obliquely from before backwards, and from left to right, and is capable of admitting two fingers. It is guarded by a valve formed of two large cusps, and is known as the **mitral orifice**.

**Ventricles.**—The ventricular portion of the heart is conical and somewhat

flattened. The base, directed upwards and backwards, is partly continuous with the auricular portion and partly free. It is perforated by four orifices, the two auriculo-ventricular, the aortic, and the pulmonary. The auriculo-ventricular orifices are placed one on each side below and behind; in front and between them is the aortic orifice, whilst the orifice of the pulmonary artery is still farther forward, and slightly to the left of the aortic.

In the triangle (trigona fibrosa) between the auriculo-ventricular and the aortic orifices is embedded the central fibro-cartilage, a mass of fibro-cartilaginous tissue which is the representative of the os cordis of the ox. It is continuous with the upper part of the interventricular septum, and with fibrous rings which surround the apertures at the bases of the ventricles.

The inferior surfaces and the antero-superior surfaces of the ventricles constitute respectively the greater portions of the corresponding surfaces of the heart; the former rest upon the diaphragm, whilst the latter are directed upwards and forwards towards the sternum and the costal cartilages of the left side. The apex of the left ventricle forms the **apex** of the heart.

The right margin, which is thin, forms the horizontal portion of the right margin of the heart; and the left margin, which is thick and rounded, forms almost the whole of the left margin of the heart.

The ventricular portion of the heart is divided into right and left chambers. The **interventricular septum** (septum ventriculorum) is placed obliquely, with one surface directed forwards and to the right, and the other backwards and to the left; it bulges into the right ventricle, and its lower margin lies to the right of the apex of the heart, which is, therefore, formed entirely by the left ventricle. The margins of the septum are indicated on the surfaces by anterior and inferior interventricular sulci.

The **right ventricle** (ventriculus dexter) is triangular in form. Its base is directed upwards and to the right, and in the greater part of its extent it is continuous with the right auricle, with which it communicates by the auriculo-ventricular orifice; but its left and anterior angle projects in front of the auricle, and gives origin to the pulmonary artery. Its inferior wall rests upon the diaphragm. The antero-superior wall lies behind the lower part of the left half of the sternum and the cartilages of the fourth, fifth, and sixth ribs of the left side. The left or septal wall, which is directed backwards and to the left, bulges into its interior, and on this account the transverse section of the cavity has a semilunar outline. The cavity itself is a bent tube consisting of an inferior portion or **body** into which the auriculo-ventricular orifice opens, and of an antero-superior part, the **infundibulum** or **conus arteriosus,** which terminates in the pulmonary artery. The angle between the two limbs is formed by a thick ledge of muscle.

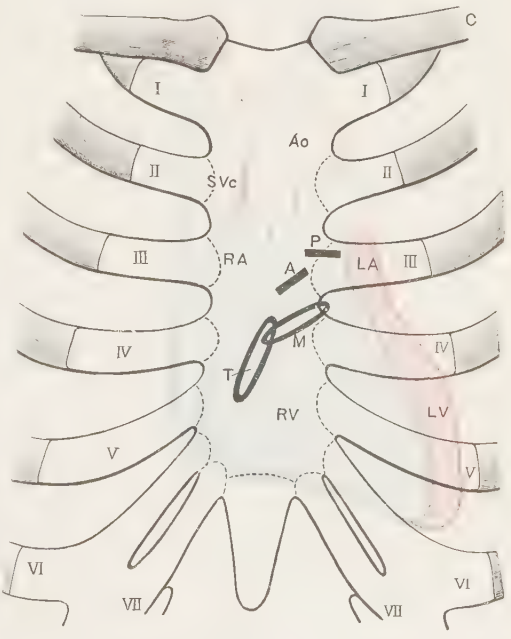

Fig. 618.—The Relations of the Heart and the Auriculo-Ventricular, Aortic, and Pulmonary Orifices to the Anterior Thoracic Wall.

I to VII, Costal cartilages.
A, Aortic orifice.
Ao, Aorta.
C, Clavicle.
LA, Left auricle.
LV, Left ventricle.
M, Mitral orifice.
P, Pulmonary orifice.
RA, Right auricle.
RV, Right ventricle.
SVc, Superior vena cava.
T, Tricuspid orifice.

The **right auriculo-ventricular orifice** is guarded by a **tricuspid valve** (valvula tricuspidalis). The three cusps of this valve are a right or marginal (cuspis medialis), a left or infundibular (cuspis anterior), which intervenes between the auriculo-ventricular orifice and the infundibulum, and a posterior or septal (cuspis

posterior). Each cusp consists of a fold of endocardium, strengthened by a little intermediate fibrous tissue, and the bases of the cusps are generally continuous with each other at the auriculo-ventricular orifice, where they are attached to a fibrous ring, but they may be separated by small intermediate cusps which fill the angles between the main segments. The apices of the cusps hang down into the ventricle. The margins, which are thinner than the central portions, are notched and irregular. The auricular surfaces are smooth. The ventricular surfaces are roughened, and, like the margins and apices, they give attachment to fine tendinous cords, the **chordæ tendineæ**, the opposite extremities of which are attached to muscular bundles, the **musculi papillares**, which project from the wall into the cavity of the ventricle.

The **pulmonary orifice**, which lies in front and to the left of the tricuspid orifice, is guarded by a **pulmonary valve** composed of three semilunar segments (valvulæ semilunares a. pulmonalis), two of which are placed anteriorly and one posteriorly. The convexity or outer border of each semilunar segment is attached to the wall of the pulmonary artery. The inner border is free, and it presents at its centre a small nodule, the **corpus Arantii** (nodulus valvulæ semilunaris), and on each side of this body a small, thin marginal segment of semilunar form, the **lunule** (lunula valvulæ semilunaris). Each segment of the valve is formed by a layer of endocardium on its ventricular surface, an endothelial layer of the inner coat of the artery on its arterial surface, and an intermediate stratum of fibrous tissue. Both the attached and the free margins of the cusps are strengthened by tendinous bands, and strands of condensed fibrous tissue radiate from the outer borders to the corpora Arantii, but they do not enter the lunulæ. When the valve closes the corpora Arantii are closely apposed, the lunulæ of the adjacent segments of the valve are pressed together, and they project vertically upwards into the interior of the artery.

The cavity of the right ventricle is lined by endocardium; the walls are smooth in the conus arteriosus, but are rendered rugose and sponge-like in the body by the inward projection of numerous muscular bundles, the **columnæ carneæ** (trabeculæ carneæ). These bundles are of three kinds; the simplest are merely columns raised in relief on the wall of the ventricle; those of the second class are rounded bundles, free in the middle, but attached at each end to the wall of the ventricle. One special bundle of this group, called the **moderator band**, is attached by one extremity to the septum, and by the other to the antero-superior wall, at the base of the anterior papillary muscle; it tends to prevent over-distension of the cavity. The third group of columnæ carneæ are the **musculi papillares**, conical bundles continuous at their bases with the muscular wall of the ventricle, and terminating at their apices in numerous chordæ tendineæ which are attached to the apices, the borders, and ventricular surfaces of the cusps of the tricuspid valve.

The musculi papillares of the right ventricle are—(1) a large anterior muscle, from which the chordæ pass to the infundibular and marginal segments of the valve; (2) a smaller and more irregular posterior muscle, sometimes represented by two or more segments, from which chordæ pass to the marginal and septal cusps; and (3) a group of muscular bundles, varying in size and number, which spring from the septum and are united by chordæ to the infundibular and septal cusps.

The walls of the right ventricle, the septal excepted, are much thinner than those of the left, but the columnæ carneæ of the first and second classes are coarser and less numerous in the right than in the left ventricle.

The **left ventricle** (ventriculus sinister) is a conical chamber, and its cavity is oval in transverse section. The base is directed upwards and backwards, and in the greater part of its extent it is continuous with the corresponding auricle with which it communicates through the mitral orifice, but in front and to the right of its communication with the auricle it is continued into the ascending aorta.

The **mitral orifice** is oval; its long axis runs obliquely from above and to the left downwards and to the right, and it is guarded by a valve consisting of two cusps, which is known as the **mitral valve** (valvula bicuspidalis). The two cusps of the valve are triangular and of unequal size. The smaller of the two, placed to the left and behind, is named the marginal, and the larger, placed to the

right and in front, between the mitral and aortic orifices, is known as the **aortic cusp**. The bases of the cusps are either continuous with each other at their attachments to the fibrous ring round the mitral orifice, or they are separated by small intermediate cusps of irregular form and size. The apices of the cusps hang down into the cavity of the ventricle. The auricular surfaces are smooth; the ventricular surfaces are roughened by the attachments of the chordæ tendineæ, which are also connected with the irregular and notched margins and with the apices. The structure is the same as that of the cusps of the tricuspid valve, but the ventricular surface of the anterior (or aortic) cusp is relatively smooth; therefore the blood flow into the aorta is facilitated.

The **aortic orifice** is circular; it lies immediately in front and to the right of the mitral orifice, from which it is separated by the anterior cusp of the mitral valve, and it is guarded by the **aortic valve**, formed of three semilunar segments (valvulæ semilunares aortæ), one of which is placed anteriorly and the other two posteriorly. The structure of these cusps and their attachments are similar to those of the cusps of the pulmonary valve.

The cavity of the left ventricle is separable, like that of the right, into two portions, the body and the aortic vestibule; the latter is a small section placed immediately below the aortic orifice, and its walls are non-contractile, consisting of fibrous and fibro-cartilaginous tissue. The cavity is lined by endocardium. The inferior wall and the apex are rendered sponge-like by numerous fine columnæ carneæ of the first and second classes, whilst the upper part of the antero-superior wall and the septum are relatively smooth.

There are two papillary muscles of much larger size than those met with in the right ventricle—an anterior and a posterior; each is connected by chordæ tendineæ with both cusps of the mitral valve.

The walls of the left ventricle, with the exception of the septum, are three times as thick as those of the right ventricle, and they are thickest in the region of the widest portion of the cavity, which is situated about a fourth of its length from the base. The muscular portion of the wall attains its minimum thickness at the apex, but the thinnest portion of the boundary is at the upper part of the septum, which consists entirely of fibrous tissue; here it is occasionally deficient, and an aperture is left through which the cavities of the two ventricles communicate.

The **interventricular septum** (septum ventriculorum) is a musculo-membranous partition. It is placed obliquely, one surface looking forwards and to the right, and bulging into the right ventricle, and the other backwards and to the left towards the left ventricle. Its antero-superior and inferior margins correspond respectively with the anterior and inferior portions of the interventricular sulcus, and it extends from the right of the apex to the interval between the pulmonary and aortic orifices. In the main part of its extent it is muscular (septum musculare ventriculorum), and this portion is developed from the wall of the ventricular part of the heart; but its upper and posterior portion, the **pars membranacea** (septum membranaceum ventriculorum), which is developed from the septum of the aortic bulb, is entirely fibrous, and constitutes the thinnest portion of the ventricular walls. The pars membranacea lies between the aortic vestibule on the left and the upper part of the right ventricle, as well as the lower and left part of the right auricle, on the right.

## Structure of the Heart.

The walls of the heart consist mainly of peculiar striped muscle, the **myocardium**, which is enclosed between the visceral layer of the pericardium, or **epicardium**, externally, and the **endocardium** internally. The muscular fibres differ from those of ordinary voluntary striped muscle in several ways: they are shorter, many of them being oblong cells with forked extremities which are closely cemented to similar processes of adjacent cells; they form a reticulum, and the nuclei lie in the centres of the cells. Moreover, in some of the lower mammals, in the young child up to the end of the first year, and occasionally in the human adult also, still more peculiar fibres, the **fibres of Purkinje**, are found immediately beneath the sub-endocardial tissue. These are large cells which unite with each other at their extremities; their central portions consist of granular protoplasm, in which sometimes one, but more frequently two nuclei are embedded, and the peripheral portion of each cell is transversely striated. These cells, in short, present in a permanent form a condition which is transitory in all other striped muscle cells.

The reticulating cardiac muscle cells are grouped in sheets and strands which have a more or less characteristic and definite arrangement in different parts of the heart; by careful dissection, and after special methods of preparation, it is possible to recognise many layers and bundles, some of which are, however, probably artificially produced.

In the **auricles** the muscular fasciculi fall naturally into two groups, those special to each auricle, and those common to both auricles; the former are situated deeply under cover of the latter.

The *deep special fibres* are—(*a*) Looped fibres which pass over the auricles from before backwards or from side to side; their extremities are attached to the fibrous rings which surround the auriculo-ventricular orifices. (*b*) Annular fibres which surround (1) the extremities of the large vessels which open into the auricle, (2) the auricular appendices, and (3) the fossa ovalis.

The *superficial fibres*, which are common to both auricles, for the most part run transversely across the auricles, but a few of them turn into the interauricular septum. They are most numerous on the anterior aspect.

In the **ventricles**, also, two main groups of fasciculi, a superficial and a deep, have been described, but it is in this region especially that there is doubt regarding the individuality of many of the muscular bundles which have been noted, for it appears probable that many of them are artificial products due to the method adopted by the dissector. There is no doubt that in the middle of the thickness of the ventricular walls the arrangement of the fibres is mainly circular, some surrounding one and some both ventricles. Near the surfaces the fasciculi assume an oblique direction, and it is not improbable that many of the bundles are arranged in figure of 8 loops, whose upper extremities are attached to the fibrous rings round the auriculo-ventricular orifices.

The *superficial fibres* of the ventricles are attached above to the fibrous rings at the base, and from this attachment they pass obliquely downwards to the apex, those on the anterior surface trending towards the left, and those on the inferior surface towards the right. On the inferior surface almost all the fasciculi appear to pass across the septum, but on the anterior surface the middle fasciculi dip into it, and only those near the base and apex cross from right to left. All the superficial fibres which reach the apex are coiled there into a whorl or vortex, through which they pass upwards into the substance of the left ventricle, those descending from the front and left side entering the base of the posterior papillary muscle, whilst those from the back and right side terminate in the anterior papillary muscle. The muscular fasciculi which enter the papillary muscles are continued, by means of the chordæ tendineæ, to the flaps of the mitral valve and so to the fibrous ring round the mitral orifice; obviously, therefore, many of the superficial fasciculi of the ventricles form simple oblique loops which commence externally at the fibrous rings round the right and left auriculo-ventricular orifices, and terminate internally by gaining attachment to the ring round the left of these orifices (mitral).

The *deep fasciculi* of the ventricles may be subdivided into two main groups—(1) Those common to both ventricles, and (2) those special to each ventricle.

The fasciculi common to both ventricles include—(*a*) Fibres which commence above from the posterior sections of the fibrous ring at the base of the right ventricle; either directly or by means of the chordæ tendineæ of the posterior papillary muscle they pass obliquely downwards to the septum, traverse it, and ascend to the front of the fibrous ring at the base of the left ventricle. (*b*) Fibres from the anterior portions of the fibrous ring at the base of the right ventricle, which pass obliquely downwards and assume a transverse course in the posterior wall of the left ventricle. (*c*) Annular fibres which encircle both ventricles.

The deep special fibres of the left ventricle are (*a*) V-shaped loops which commence at the fibrous ring at the base, and descend to the apex, where they turn upwards in the septum, and terminate by joining the central fibro-cartilage; (*b*) fibres which descend from the base, enter the lower and front part of the septum, and, passing through it, assume an annular course in the posterior wall.

The deep special fibres of the right ventricle are (*a*) looped fibres which pass downwards in the external wall from the fibrous rings to the apex, where they enter the septum and ascend to the central fibro-cartilage; (*b*) circular fibres round the pulmonary orifice; and (*c*) radiating fasciculi from the base of the anterior papillary muscle to the front part of the pulmonary orifice.

The **epicardium**, or visceral portion of the pericardium, consists of white connective and of elastic tissue, the latter forming a distinct reticulum in the deeper part. The surface which looks towards the pericardial cavity is covered with flat polygonal endothelial plates, which are partially separated here and there by stomata through which the pericardial cavity communicates with the lymphatics of the epicardium.

The **endocardium** lines the cardiac cavities and is continuous with the inner coats of the vessels which enter and leave the heart. It consists, like the epicardium, of white connective tissue and elastic fibres, but it is much thinner than the epicardium, and its elastic fibres are in some places blended into a fenestrated membrane. Its inner surface is covered with endothelial cells, and it rests externally upon the sub-endocardial tissue, in which there are blood-vessels and nerves; the endocardium itself is entirely devoid of vessels.

**Size of the Heart.**—The heart is about five inches (125 mm.) long, three and a half inches (87 mm.) broad; its greatest depth from its antero-superior to its inferior surface is two and a half inches (62 mm.), and it is roughly estimated as being about the same size as the closed fist. The size, however, is variable, the volume increasing at first rapidly, and then gradually, with increasing age, from 22 cc. at birth to 155 cc. at the fifteenth year, and to 250 cc. by the twentieth year. From this period to the fiftieth year, when the maximum volume (280 cc.) is attained, the in-

crease is much more gradual, and after fifty a slight decrease sets in. The volume is the same in both sexes up to the period of puberty, but thereafter it preponderates in the male.

**Weight.**—The average weight of the heart in the male adult is 11 ounces (310 grms.), and in the female adult 9 ounces (255 grms.); but the weight varies greatly, always, however, in definite relation to the weight of the body, the relative proportions changing at different periods of life. Thus at birth the heart weighs 13½ drachms (24 grms.), and its relation to the body weight is as 1 to 130, whilst in the adult the relative proportion is as 1 to 205. The heart is said to increase rapidly in weight up to the seventh year, then more slowly up to the age of puberty, when a second acceleration sets in; but after the attainment of adult life the increase, which continues till the seventieth year, is very gradual.

The above changes affect the whole heart, but the several parts also vary in their relation to each other at different periods of life. During fœtal life the right auricle is heavier than the left; in the first month after birth the two become equal, and at the second year the right again begins to preponderate, and it is heavier than the left during the remainder of life. In the latter part of fœtal life the two ventricles are equal; after birth the left grows more rapidly than the right, until, at the end of the second year, a position of stability is gained, when the right is to the left as 1 to 2, and this proportion is maintained until death.

**Capacity.**—During life the capacity of the ventricles is probably the same, and each is capable of containing about four ounces of blood, whilst the auricles are a little less capacious. After death the cavity of the right ventricle appears larger than that of the left.

**Vascular Supply of the Heart.**—The walls of the heart are supplied by the **coronary arteries** (p. 800), the branches of which pass through the interstitial tissue to all parts of the muscular substance and to the sub-endocardial and sub-epicardial tissues; the endocardium and the valves are devoid of vessels. The capillaries, which are numerous, form a close-meshed network around the muscular fibres. Sometimes the valves contain a few muscular fibres, and in these cases they also receive some minute vessels. The majority of the veins of the heart end in the coronary sinus, which opens into the lower part of the right auricle; some few very small veins, however, open directly into the right auricle, and others are said to end in the left auricle, and in the cavities of the ventricles.

**Lymphatics of the Heart.**—Lymphatic vessels are freely distributed throughout the whole substance of the heart, but they are most numerous in the sub-endocardial and the sub-pericardial tissues, and the vessels which lie in the latter situation communicate through stomata with the pericardial cavity. The smaller lymphatic vessels accompany the blood-vessels; ultimately they converge to two main trunks—an anterior and an inferior—which lie respectively, at their commencements, in the anterior and the inferior auriculo-ventricular sulci. Each is formed by one or more tributaries which collect lymph from the ventricles and auricles. The inferior trunk accompanies the right and the anterior trunk the left coronary artery. At the upper part of the heart the trunks pass backwards, at the sides of the pulmonary artery, pierce the pericardium, and they terminate in the glands which lie round the bifurcation of the trachea.

**Nerves of the Heart.**—The heart receives its nerves from the superficial and deep cardiac plexuses which lie beneath the arch of the aorta, and through them it is connected with the vagus, the spinal accessory (through the vagus), and the sympathetic nerves. After leaving the plexuses many of the nerve-fibres enter the walls of the auricles, and anastomose together in the sub-epicardial tissue, forming a plexus in which many ganglion cells are embedded, especially near the terminations of the inferior vena cava and the pulmonary veins. From the sub-epicardial auricular plexus, nerve filaments, on which nerve ganglion cells have been found, pass into the substance of the auricular walls.

Other fibres from the cardiac plexuses accompany the coronary arteries to the ventricles, and upon these also ganglion cells are found in the region immediately below the auriculo-ventricular sulcus.

The nerve-fibres which issue from the ganglionated plexuses of the heart are non-medullated. They form fine plexuses round the muscle fibres, and they terminate either in fine fibrils on the surfaces of the muscle fibres, or in nodulated ends which lie in contact with the muscle cells.

## THE PERICARDIUM.

The **pericardium** is a fibro-serous sac which surrounds the heart. It lies in the middle mediastinum, and is attached below to the diaphragm, and above and behind to the roots of the great vessels. Anteriorly and posteriorly it is in relation with adjacent structures; laterally it is in close apposition with the pleural sacs.

The **fibrous pericardium** is a strong fibrous sac of conical form; its base is attached to the central tendon and to a part of the muscular substance of the diaphragm, and it is pierced by the inferior vena cava. At its apex and posteriorly it is gradually lost upon the great vessels which enter and emerge from the heart, giving sheaths to the aorta, the two branches of the pulmonary artery, the superior vena cava, the four pulmonary veins, and the ligamentum arteriosum. Its anterior surface forms the posterior boundary of the anterior mediastinum, and it gives attachment, above and below, to the superior and inferior sterno-pericardial

ligaments. In the greater part of its extent it is separated from the anterior wall of the thorax by the anterior margins of the lungs and pleural sacs, but it is in direct relation with the left half of the lower portion of the body of the sternum and, in many cases, with the inner ends of the cartilages of the fourth, fifth, and sixth ribs of the left side. Its posterior surface forms the anterior boundary of the posterior mediastinum; it is in relation with the œsophagus and the descending aorta, both of which it separates from the back of the left auricle. Each lateral aspect is in close contact with the mediastinal portion of the parietal pleura, the phrenic nerve and its accompanying vessels intervening. The inner surface of the fibrous sac is lined by the serous pericardium, which is closely attached to it.

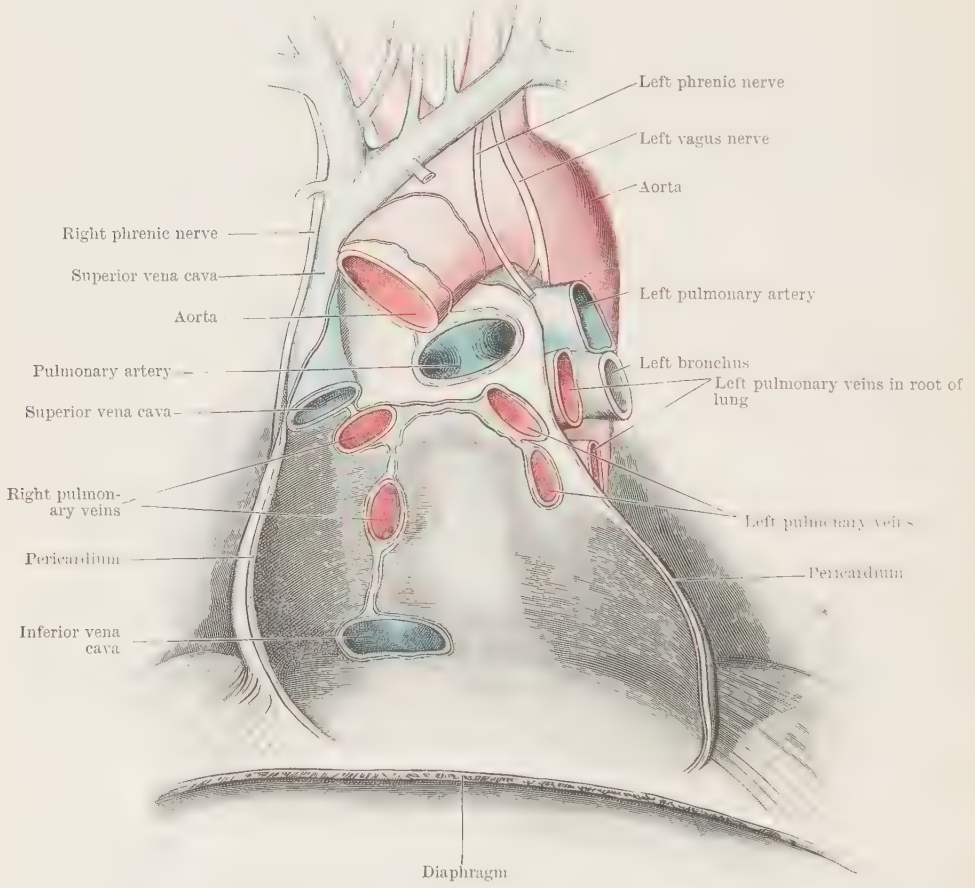

FIG. 619.—POSTERIOR WALL OF THE PERICARDIUM AFTER REMOVAL OF THE HEART, showing the relation of the serous pericardium to the great vessels. From a formalin preparation made by Professor Birmingham.

The **serous pericardium** is a closed sac containing a little fluid (liquor pericardii). It is surrounded by the fibrous pericardium and invaginated by the heart. It is, therefore, separable into two portions—the parietal, which lines the inner surface of the fibrous sac, and the visceral, which ensheaths, or partially ensheaths, the heart and the great vessels; but the two portions are, of course, continuous with each other where the serous layer is reflected on to the great vessels as they pierce the fibrous layer. The majority of the great vessels receive only partial coverings from the visceral layer: thus the superior vena cava is covered in front and laterally; the pulmonary veins in front, above, and below; and the inferior vena cava, for a very short distance, in front and laterally. The aorta and the pulmonary artery are enclosed together in a complete sheath of the visceral layer; and when the pericardial sac is opened from the front it is possible to pass the fingers behind them and in front of the auricles, from the right to the left side, through a passage called the **great transverse sinus** of the pericardium. The

spaces or pouches which intervene between the vessels which receive partial coverings from the serous pericardium are also called sinuses; and the largest of them, which is bounded below and on the right by the inferior vena cava, and above and on the left by the left inferior pulmonary vein, is known as the **great oblique sinus**. It passes upwards and to the right behind the left auricle, and lies in front of the œsophagus and the descending thoracic aorta.

A small fold of the serous pericardium, the **vestigial fold** of Marshall (ligamentum v. cavæ sinistræ), passes from the left pulmonary artery to the left superior pulmonary vein behind the left extremity of the transverse sinus. It merits special attention because it encloses the remains of the left superior vena cava, which atrophies at an early period of fœtal life.

**Structure.**—The fibrous pericardium consists of ordinary connective tissue fibres felted together into a dense, unyielding membrane. The serous pericardium is covered on its inner aspect by a layer of flat endothelial cells which rest upon a basis of mixed white and elastic fibres in which run numerous blood-vessels, lymphatics, and nerves.

# THE ARTERIES.

## THE PULMONARY ARTERY.

The **pulmonary artery** (a. pulmonalis) springs from the anterior and left angle of the base of the right ventricle, at the termination of the infundibulum. It is slightly larger at its commencement than the aorta, and is dilated immediately above the valves into three pouches, the sinuses of Valsalva. It runs upwards and backwards towards the concavity of the aortic arch, curving from the front round the left side of the ascending aorta to reach a plane posterior to the latter; and it terminates, by dividing into right and left branches, opposite the sixth dorsal vertebræ. Its length is a little more than two inches.

**Relations.**—The pulmonary artery is enclosed within the fibrous pericardium, and enveloped along with the ascending aorta in a common sheath of the visceral layer of the serous pericardium. It lies behind the inner extremity of the second left intercostal space, from which it is separated by the anterior margins of the left lung and pleural sac.

Its posterior relations are the root of the aorta, the anterior wall of the left auricle, and the first part of the left coronary artery. To the right it is in relation with the right coronary artery and the right auricular appendix, and to the left with the left coronary artery and the left auricular appendix. Immediately above its bifurcation, between it and the aortic arch, is the superficial cardiac plexus.

The **right branch of the pulmonary artery** is longer and larger than the left. It passes to the hilum of the right lung, forming one of the constituents of its root, and, entering the lung, descends with the main bronchus to the lower extremity of the organ.

**Relations.**—Before it enters the lung the right pulmonary artery passes behind the ascending aorta, the superior vena cava, and the upper right pulmonary vein. At first it lies below the arch of the aorta and the right bronchus, in front of the œsophagus, and above the left auricle and the lower right pulmonary vein; then it crosses in front of the right bronchus immediately below the eparterial branch, and reaches the hilum of the lung. After entering the lung the artery descends, behind and to the outer side of the main bronchus and between its ventral and dorsal branches.

**Branches.**—Before entering the hilum it gives off a large branch to the upper lobe which accompanies the eparterial bronchus, and in the substance of the lung it gives off numerous branches which correspond with and accompany the dorsal, ventral, and accessory branches of the right bronchus.

The **left branch of the pulmonary artery**, shorter, smaller, and somewhat higher in position than the right, passes outwards and backwards from the bifurcation of the pulmonary stem, and runs in the root of the left lung to the hilum; it then descends in company with the main bronchus to the lower end of the lung.

**Relations.**—Before it enters the lung it is crossed in front by the upper left pulmonary vein; *behind* it, is the left bronchus and the descending aorta; *above*, the aortic arch, to which it is connected by the ligamentum arteriosum, and the left recurrent

laryngeal nerve; *below*, it is in relation with the lower left pulmonary vein. After entering the lung it descends, like the right pulmonary artery, behind and on the outer side of the stem bronchus, and between its ventral and dorsal branches.

**Branches.**—Just before passing through the hilum it gives off a branch to the upper lobe, and in the substance of the lung its branches correspond with the ventral, dorsal, and accessory branches of the bronchial tube.

# THE SYSTEMIC ARTERIES.

## THE AORTA.

The **aorta** is the main trunk of the arterial system. It commences at the base of the left ventricle and ascends, with an inclination to the right, to the level of the second right costal cartilage; then curving backwards and to the left, it reaches the left side of the lower border of the fourth dorsal vertebra, and finally descends through the thorax into the abdomen, where it terminates, on the left of the mesial plane, at the level of the fourth lumbar vertebra, by bifurcating into the two common iliac arteries. The portion of the aorta which is situated in the thorax is, for convenience, termed the thoracic aorta, and the rest of the vessel is known as the abdominal aorta.

## THE THORACIC AORTA.

The thoracic aorta is subdivided into the ascending portion, the arch, and the descending portion.

The **ascending aorta** (aorta ascendens) lies in the middle mediastinum. It springs from the base of the left ventricle, behind the left margin of the sternum, opposite the lower border of the third left costal cartilage and the body of the sixth dorsal vertebra. From its origin it passes upwards, forwards, and to the right, and it terminates in the arch of the aorta, behind the right margin of the sternum, at the level of the second costal cartilage. Its *length* is from 2 to $2\frac{1}{4}$ inches (50 to 57 mm.), and its breadth is $1\frac{1}{8}$ inches (28 mm.) In the adult it is a little narrower at its commencement than the pulmonary artery is, but in old age it enlarges and exceeds the latter vessel in size. The diameter, however, is not uniform throughout the whole length of the ascending aorta; four distinct dilatations are present. Three of these, small and pouch-like, are known as the sinuses of Valsalva (sinus aortæ). They are situated at the origin of the aorta, immediately above the semilunar cusps of the valve which guards the aperture of communication with the left ventricle; one is anterior in position, and two are situated posteriorly. The fourth dilatation is formed by a diffuse bulging of the right wall, and is known as the *great sinus* of the aorta.

**Relations.**—The ascending aorta is completely enclosed within the fibrous pericardium which blends above with the sheath of the vessel. It is enveloped, together with the stem of the pulmonary artery, in a tubular prolongation of the serous pericardium, and at its origin has the pulmonary artery in front, the anterior wall of the left auricle behind, and the right auricular appendix on its right side. In the upper part of its course the ascending aorta is overlapped by the anterior margins of the right lung and right pleural sac, whilst behind it are the right auricle, the right branch of the pulmonary artery, the right bronchus, and the left margin of the superior vena cava. The superior vena cava lies on the right side, and partly behind the upper part of the ascending aorta, whilst the pulmonary artery is at first in front of it and then, at a higher level, on its left side.

**Branches.**—Two branches arise from the ascending aorta, viz. the right and the left coronary arteries. The former springs from the anterior, and the latter from the left posterior sinus of Valsalva (p. 800).

The **arch of the aorta** (arcus aortæ) lies in the superior mediastinum behind the lower part of the manubrium sterni, and connects the ascending with the descending aorta. It commences behind the right margin of the sternum, on a level with the second costal cartilage, and extends to the lower border of the fourth dorsal vertebra. As its name implies, it forms an arch; in this there are two curvatures, one with the convexity upwards, and the other with the convexity forwards and to the left. From its origin it runs for a short distance upwards, backwards, and to the left, in front of the trachea; then it passes backwards, round the left side of the trachea to the left side of the body of the fourth dorsal vertebra, and finally turns downwards to become continuous with the descending aorta.

At its commencement it has the same diameter as the ascending aorta, $1\frac{1}{8}$ inches (28 mm.), but after giving off three large branches, the diameter is reduced to a little less than one inch (23 mm.)

**Relations.**—It is overlapped in front and on the left side by the right and left lungs and pleural sacs, but much more by the latter than the former, and in the interval between and behind the pleural sacs it is covered by the remains of the thymus gland. As it turns backwards it is crossed vertically on the left side by four nerves in the following order from before backwards:—the left phrenic, the inferior cervical cardiac branch of the left vagus, the superior cardiac branch of the left sympathetic, and the trunk of the left vagus, and the left superior intercostal vein passes obliquely upwards and to the right between the vagus and phrenic nerves.

*Behind* and *to the right side* of the arch are the trachea, deep cardiac plexus, the left recurrent laryngeal nerve, the left border of the œsophagus, and the thoracic duct. *Above* are its three large branches—the innominate, the left common carotid, and the left subclavian arteries—and crossing in front of the roots of these is the left innominate vein. *Below* is the bifurcation of the pulmonary artery and the root of the left lung; the ligamentum arteriosum, which is also below, attaches it to the commencement of the left pulmonary artery, whilst to the right of the ligament is the superficial cardiac plexus, and to its left is the left recurrent laryngeal nerve.

**Branches.**—The three great vessels which supply the head and neck, part of the thoracic wall, and the upper extremities—viz. the innominate, the left common carotid, and the left subclavian arteries—arise from the aortic arch.

The **descending aorta** (aorta descendens).—The thoracic portion of the descending aorta lies in the posterior mediastinum; it extends from the termination of the arch, at the lower border of the left side of the fourth dorsal vertebra, to the aortic opening in the diaphragm, where, opposite the twelfth dorsal vertebra, it becomes continuous with the abdominal portion. Its length is from seven to eight inches (17·5 to 20 cm.), and its diameter diminishes from 23 mm. at its commencement to 21 mm. at its termination.

**Relations.**—Immediately *behind* it is the vertebral column and the anterior common ligament. It rests also on the vena azygos minor superior and the vena azygos minor inferior, whilst from its posterior aspect the aortic intercostal branches are given off.

*In front* it is in relation, from above downwards, with the root of the left lung, the pericardium which separates it from the back of the left auricle, the œsophagus with the œsophageal plexus of nerves, and the crura of the diaphragm which separate it from the Spigelian lobe of the liver. On the *left side* are the left lung and pleura. On the *right side* the thoracic duct and the vena azygos major form immediate relations along its whole length. The œsophagus also lies to the right of the upper part of the descending aorta, whilst the right lung and pleura are in close relation below.

**Branches.**—Nine pairs of aortic intercostal arteries, two left bronchial arteries, four or five œsophageal, some small pericardial, and a few posterior mediastinal branches, usually arise from the descending aorta.

## THE ABDOMINAL AORTA.

The abdominal portion of the descending aorta lies in the epigastric and umbilical regions of the abdomen. It extends from the middle of the lower border of the last dorsal vertebra to the left side of the body of the fourth lumbar vertebra, where it bifurcates into the right and left common iliac arteries. The point of division is a little below and to the left of the umbilicus, opposite a line drawn transversely across the abdomen on a level with the highest points of the iliac crests.

At its commencement it is 21 mm. in diameter, but after the origin of two large branches, the cœliac axis and the superior mesenteric arteries, it diminishes considerably, and then retains a fairly uniform diameter to its termination.

**Relations.**—*Behind*, it is in contact with the upper four lumbar vertebræ and

intervening intervertebral discs, the anterior common ligament, and the left lumbar veins; the lumbar and the middle sacral arteries spring from this aspect of the vessel. In *front*, and in close relation with it, there are from above downwards the following structures: the cœliac axis and solar plexus, the pancreas and splenic vein, the superior mesenteric artery, the left renal vein, the third part of the duodenum, the root of the mesentery, the aortic plexus, the inferior mesenteric artery, the peritoneum and coils of small intestine. More superficially the stomach, the transverse colon, and the great and small omenta, are in front. On the *right side*, in the upper part of its extent, are the thoracic duct and

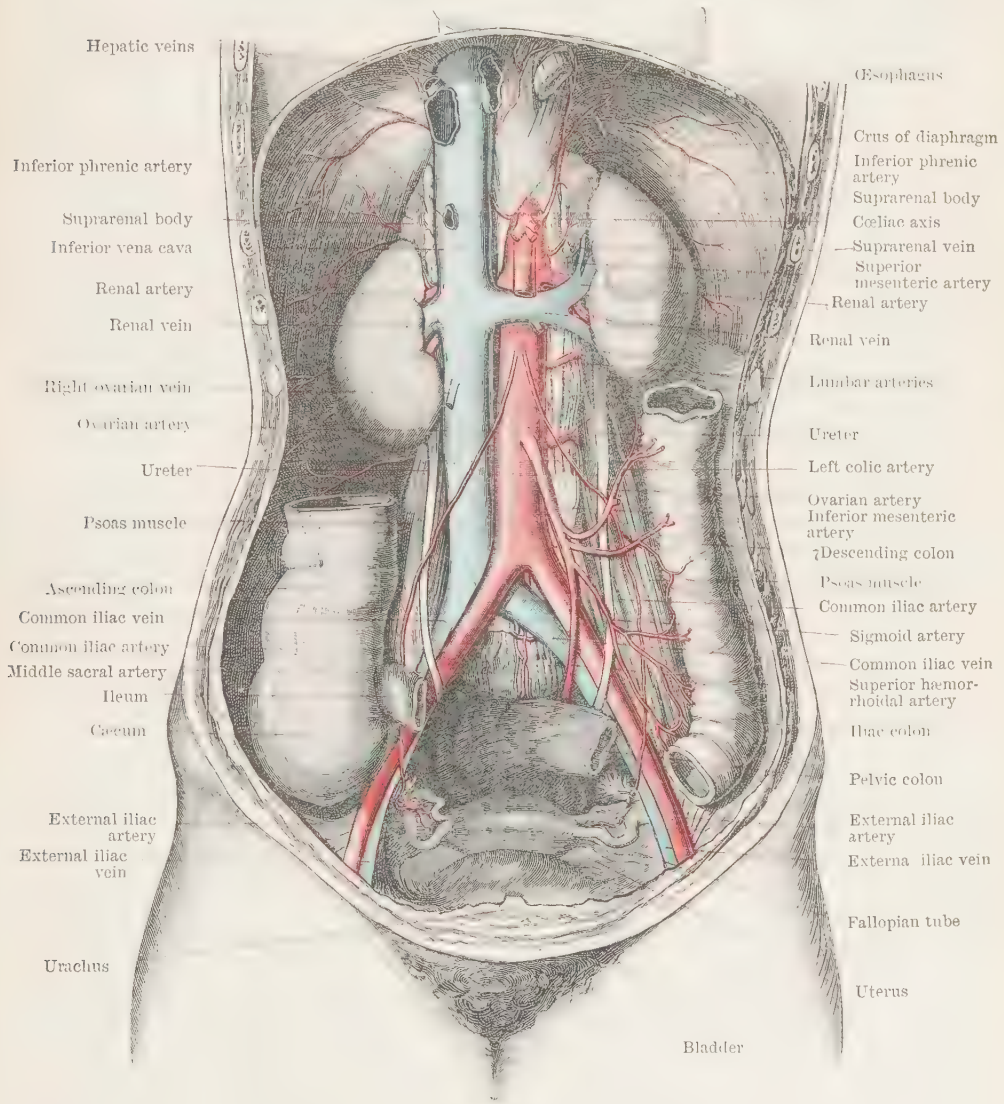

Fig. 621.—The Abdominal Aorta and its Branches.

receptaculum chyli, the vena azygos major, and the right crus of the diaphragm, the latter separating it from the right semilunar ganglion and from the upper part of the inferior vena cava. In its lower part it is in direct relation with the inferior vena cava. On the *left side*, the left crus of the diaphragm with the left semilunar ganglion, and the fourth part of the duodenum, are in close relation with its upper part, whilst in the lower portion of its extent the peritoneum and some coils of the small intestine are in contact with it.

**Branches.**—The branches form two groups, visceral and parietal, and each group consists of paired and unpaired vessels, as follows:—

| Visceral. | | Parietal. | |
|---|---|---|---|
| **Unpaired.** | **Paired.** | **Unpaired.** | **Paired.** |
| Cœliac axis<br>Superior mesenteric<br>Inferior mesenteric | Suprarenal<br>Renal<br>Spermatic or ovarian | Middle sacral | Inferior phrenic<br>Lumbar (four pairs)<br>Common iliac |

## BRANCHES OF THE ASCENDING AORTA.

### Coronary Arteries.

The coronary arteries are two in number, a right and a left; they are distributed almost entirely to the heart, but give also some small branches to the roots of the great vessels, and to the pericardium (Figs. 613, 614, and 617).

The **right coronary artery** (a. coronaria dextra) springs from the anterior sinus of Valsalva. It runs forwards, between the root of the pulmonary artery and the right auricular appendix, to the auriculo-ventricular sulcus, in which it passes to the right, and then, turning round the margin of the heart, is continued to the left as far as the posterior end of the inferior interventricular sulcus, where it ends by dividing into two terminal branches. It is accompanied by branches from the cardiac plexus, and is in relation with the right coronary vein.

**Branches.**—Of the two terminal branches, one, the **transverse** (ramus circumflexus), is of small size; it is simply the continuation of the main trunk which runs farther to the left to anastomose with the transverse branch of the left coronary artery. The other, the **interventricular** (ramus descendens), is much larger than the transverse branch. It runs forwards in the inferior interventricular sulcus, supplies both ventricles, and anastomoses, at the apex of the heart, with the interventricular branch of the left coronary artery.

In addition to the terminal branches small **aortic** and **pulmonary twigs** are distributed to the roots of the aorta and pulmonary artery respectively. A **right auricular branch** passes upwards on the anterior surface of the right auricle, between it and the ascending aorta; one or more preventricular branches, of small size, descend on the anterior surface of the right ventricle; a branch of larger size, the **marginal artery**, descends along the right margin and gives branches to both surfaces of the right ventricle.

The **left coronary artery** (a. coronaria sinistra) arises from the left posterior sinus of Valsalva. In its course and distribution it resembles in many respects the right coronary artery, the chief difference being that it divides much sooner into its two terminal branches; the trunk of the artery is therefore correspondingly short. From its origin it runs forwards between the root of the pulmonary artery and the left auricular appendix, and, reaching the auriculo-ventricular sulcus at the upper end of the anterior interventricular groove, divides immediately into transverse and interventricular terminal branches.

**Branches.**—The **transverse terminal branch** (ramus circumflexus) runs to the left margin of the heart, and there turns to the inferior surface where it comes into relation with the coronary sinus; it ends by anastomosing with the transverse branch of the right coronary artery. It supplies the left auricle, the left margin of the heart, and the posterior part of the lower surface of the left ventricle. The **interventricular terminal branch** (ramus descendens anterior) passes down the anterior interventricular sulcus to the apex of the heart, where it anastomoses with the interventricular branch from the right coronary; it supplies both ventricles, and is accompanied by cardiac nerves and by the great cardiac vein.

A **left auricular branch**, or branches of small size, pass to the wall of the left auricle, and small **aortic** and **pulmonary branches** are also given to the roots of the aorta and pulmonary artery.

## BRANCHES OF THE ARCH OF THE AORTA.

The branches which arise from the arch of the aorta supply the head and neck, the upper extremities, and part of the body wall.

They are three in number, viz. the **innominate**, the **left common carotid**, and

the **left subclavian arteries**. The innominate is a short trunk from the termination of which the right common carotid and the right subclavian arteries spring (Figs. 620 and 624); thus there is at first a difference between the stem vessels of opposite sides, but beyond this the subsequent course and the ultimate distribution of these vessels closely correspond.

## THE INNOMINATE ARTERY.

The **innominate artery** (a. anonyma, Fig. 620) arises behind the middle of the lower part of the manubrium sterni, from the convexity of the arch of the aorta near its right or anterior extremity, and terminates opposite the right sterno-clavicular articulation, where it divides into the right subclavian and right common carotid arteries.

**Course.**—The trunk, which measures from one and a half to two inches (37 to 50 mm.) in length, runs upwards, backwards, and outwards in the superior mediastinum.

**Relations.**—*Posterior.*—It is in contact behind, with the trachea below and with the right pleural sac above.

*Anterior.*—The left innominate vein crosses in front of the lower part of the artery, and above this the sterno-thyroid muscle separates it from the sterno-hyoid and the right sterno-clavicular joint. The remains of the thymus gland, which separate it from the manubrium sterni, are also in front.

*Lateral.*—The right innominate vein and the upper part of the superior vena cava are on the right side of the artery. On its left side is the origin of the left common carotid artery, whilst at a higher level the trachea is in contact with it.

**Branches.**—As a rule the innominate artery does not give off any branches except its two terminals, but occasionally it furnishes an additional branch, the thyroidea ima

The **thyroidea ima** is an inconstant and slender vessel. When present it sometimes arises from the arch of the aorta, but it usually springs from the lower part of the innominate. It passes upwards in front of the trachea, through the anterior part of the superior mediastinum and the lower part of the neck, and gives off branches to the lateral lobes and isthmus of the thyroid body and to the trachea.

## THE ARTERIES OF THE HEAD AND NECK.

The vessels distributed to the head and neck are chiefly derived from the carotid trunks; there are, however, in addition, other vessels which arise from the main arterial stems of the upper extremities, and it will be advantageous to describe the most important of these, viz. the vertebral arteries, with the carotid system. The smaller additional branches will be considered along with the remaining branches of the subclavian arteries.

The **carotid system of arteries** consists on each side of a **common carotid trunk,** which divides into **internal** and **external carotid arteries,** from which numerous branches are given off.

The internal carotid arteries are distributed almost entirely to the contents of the cranial cavity internal to the dura mater, and to the structures in the cavity of the orbit. The external carotid arteries, on the other hand, supply structures of the head and neck more externally situated.

It is to be observed, however, that the vascular supply of the brain is not wholly derived from the internal carotid vessels, but that the vertebral arteries also contribute largely to it.

## THE COMMON CAROTID ARTERIES.

The right and the left common carotid arteries are of unequal length. The right common carotid commences at the bifurcation of the innominate artery, behind the right sterno-clavicular articulation; the left arises in the superior mediastinum from the arch of the aorta, but each terminates at the level of the upper border of the thyroid cartilage; the left artery has thus a short intra-

thoracic course, and so far its relations call for separate consideration; whilst in the rest of its course it passes, like the right common carotid, upwards in the neck and has almost similar relations.

**Thoracic Portion of the Left Common Carotid.**—The thoracic or mediastinal portion of the left common carotid artery (a. carotis communis sinistra) extends from the upper aspect of the aortic arch, a little behind and to the left of the origin of the innominate artery, to the left sterno-clavicular articulation, where the cervical portion commences. It is about one or one and a half inches in length (25 to 37 mm.), and it runs upwards and slightly outwards through the upper part of the superior mediastinum, lying farther back than the innominate artery.

**Relations.**—*Posterior.*—The vessel is in contact behind and from below upwards with the trachea, the left recurrent laryngeal nerve, the œsophagus, and the thoracic duct.

*Anterior.*—The left innominate vein runs obliquely across the front of the artery, upon which cardiac branches from the left vagus and sympathetic descend vertically. These structures, together with the remains of the thymus gland and the anterior margins of the left lung and pleura, separate the artery from the manubrium sterni, and from the origins of the sterno-hyoid and sterno-thyroid muscles.

*Lateral.*—The innominate artery below and the trachea above are on the right side. The left pleura, and, on a posterior plane, the left phrenic and vagus nerves and the left subclavian artery are on its left side.

**Cervical Portion of the Left Common Carotid Artery.**—The cervical part of the left common carotid artery is about three and a half inches long; it extends from the left sterno-clavicular articulation to the level of the upper border of the thyroid cartilage and the lower border of the third cervical vertebra, where it ends by dividing into the external and internal carotid arteries.

**Course.**—It runs upwards, outwards, and backwards, through the muscular and the lower part of the carotid divisions of the anterior triangle of the neck. In the lower part of its extent it is separated from its fellow of the opposite side by the trachea and the œsophagus, and in the upper part by the relatively wide pharynx.

**Relations.**—It is enclosed, together with the internal jugular vein and the vagus nerve, in a sheath of deep cervical fascia—the **carotid sheath**.

*Posterior.*—The longus colli and scalenus anticus below, and the rectus capitis anticus major above, are separated from the posterior surface of the artery and sheath by the prevertebral fascia and the sympathetic cord. The inferior thyroid artery crosses close behind the vessel about the level of the first ring of the trachea; lower down the vertebral artery and the thoracic duct are posterior to it, and the vagus nerve lies behind and to its outer side.

*Anterior.*—The descendens cervicis nerve descends superficial to the artery, usually outside the sheath, but sometimes enclosed in it. Opposite the sixth cervical vertebra the omo-hyoid muscle and the sterno-mastoid branch of the superior thyroid artery cross the carotid artery, which is overlapped, above the omo-hyoid muscle, by the anterior border of the sterno-mastoid, and it is frequently crossed, in this part of its extent, by the superior thyroid vein. Below the omo-hyoid the artery is covered by the sterno-thyroid, the sterno-hyoid, and the sterno-mastoid muscles, and it may be overlapped by the lateral lobe of the thyroid body; it is also crossed beneath the muscles by the middle thyroid vein, whilst occasionally a communication between the common facial and anterior jugular veins descends in front of the artery along the anterior border of the sterno-mastoid. Just above the sternum the anterior jugular vein is in front of the artery, but separated from it by the sterno-hyoid and sterno-thyroid muscles.

*Lateral.*—The trachea and œsophagus, with the recurrent laryngeal nerve in the angle between them, are internal to the lower part of the artery; the pharynx and larynx are internal to its upper part. The carotid gland lies immediately to the inner side of the termination of the artery.

The internal jugular vein occupies the outer part of the carotid sheath, and lies not only to the outer side of the artery, but also overlaps it in front, especially in the lower part of its extent.

**Branches.**—As a rule no branches are given off from either of the common carotid arteries except the terminal branches and some minute twigs from each to the corresponding carotid sheath and carotid body.

The **right common carotid artery**, as already stated, differs as regards origin from the left common carotid. In length and general position it corresponds with the cervical portion of the left common carotid, and its relations also are very similar. Such differences as exist may be briefly summarised as follows:—The internal jugular vein on both sides lies external to the artery; on the left side it runs well in front of the carotid artery in the lower part of the neck, whilst on the right side the vein is separated from the outer surface of the artery at its lower end by a well-marked interval in which the vagus nerve appears. The thoracic duct does not come into relation with the right common carotid, and there is also a

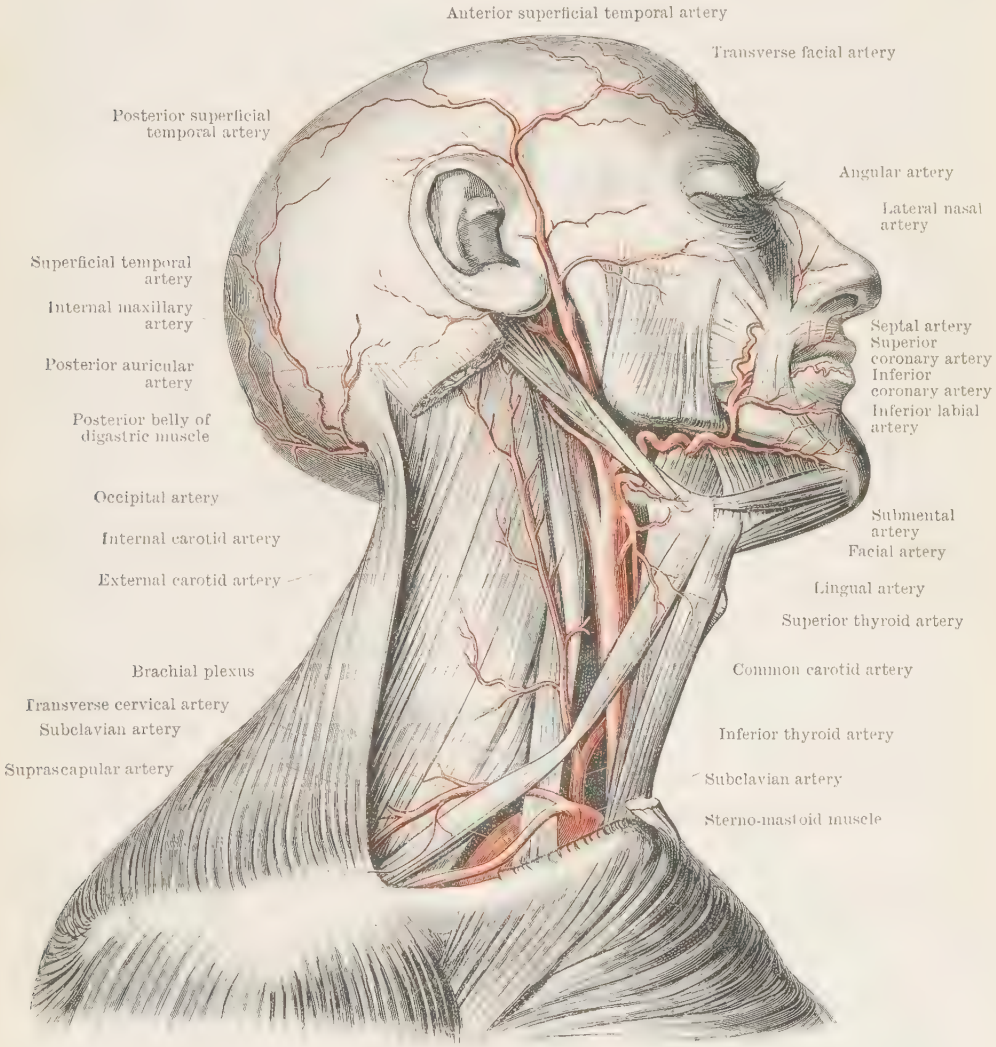

FIG. 622.—THE CAROTID AND SUBCLAVIAN ARTERIES AND THEIR BRANCHES.

difference in the relations of the recurrent laryngeal nerves to the arteries on the two sides. On the left side the nerve crosses behind the mediastinal part of the left artery, and lies internal to its cervical part, whilst the corresponding nerve on the right side passes behind the lower part of the carotid artery in the neck to reach its inner side, and the œsophagus has a less intimate relation with the right than with the left common carotid artery.

## THE EXTERNAL CAROTID ARTERY.

The external carotid artery (a. carotis externa, Fig. 623) is the smaller of the two terminal branches of the common carotid; its length is about two and a half inches

(62 mm.) It extends from the upper border of the thyroid cartilage to the back of the neck of the mandible, where it terminates by dividing into the superficial temporal and the internal maxillary arteries.

**Course.**—It commences in the carotid triangle, passes upwards internal to the posterior belly of the digastric and the stylo-hyoid muscles to enter the posterior part of the submaxillary triangle, where it disappears behind the lower part of the parotid gland, and it terminates under cover, or in the substance, of the upper part of the gland.

At its commencement it lies somewhat in front of and to the inner side of the internal carotid artery, but, inclining slightly backwards as it ascends, it becomes superficial to the latter vessel, and its course is indicated by a line drawn from the lobule of the ear to the posterior extremity of the great cornu of the hyoid bone.

**Relations.**—*Posterior.*—In the lower part of its extent it is in close relation with the internal carotid, and in the upper part of its course with the cartilaginous portion of the external auditory meatus.

*Lateral.*—At its commencement the fibres of the inferior constrictor muscle are in contact with its inner side, but at a higher level the structures which intervene between it and the internal carotid—viz. the stylo-pharyngeus muscle, the tip of the styloid process, the stylo-glossus muscle, the glosso-pharyngeal nerve, and the pharyngeal branch of the vagus—separate it from the wall of the pharynx; whilst internal both to it and to the internal carotid artery are the external and internal laryngeal branches of the superior laryngeal nerve.

*Superficial.*—In the carotid triangle the lingual, ranine, common facial, and superior thyroid veins are superficial to it, and the hypoglossal nerve crosses the artery immediately below the origin of its occipital branch. On the boundary line between the carotid and the submaxillary triangles the posterior belly of the digastric and the stylo-hyoid muscles cover the artery, and from the tip of the mastoid process downwards it is overlapped by the anterior border of the sterno-mastoid muscle. Above the posterior belly of the digastric the parotid gland is superficial to the artery, while still more superficially are the superficial fascia and the skin. In the substance of the parotid gland the temporo-maxillary vein descends on the outer side of the artery, and the facial nerve crosses on the outer side of the vein at a right angle to it.

**Branches.**—Eight branches arise from the external carotid artery; of these three—the superior thyroid, the lingual, and the facial—spring from its anterior aspect in the carotid triangle; two arise from its posterior aspect, viz. the occipital and the posterior auricular, the former commencing below the posterior belly of the digastric and the latter above it; one from its inner side, viz. the ascending pharyngeal, which rises in the carotid triangle; and two from its termination, viz. the superficial temporal and the internal maxillary.

### Branches of the External Carotid Artery.

(1) **Superior Thyroid Artery** (a. thyroidea superior, Figs. 622 and 624).—This vessel springs from the front of the lower part of the external carotid artery, just below the tip of the great cornu of the hyoid bone, and terminates at the upper extremity of the lateral lobe of the thyroid body by dividing into its terminal branches.

**Course.**—From its commencement in the carotid triangle the artery runs at first forwards and a little upwards; it then turns downwards to its termination.

**Relations.**—*Internally* it is in relation with the inferior constrictor muscle and the external laryngeal branch of the superior laryngeal nerve.

*Superficially* it is covered at its origin by the anterior border of the sterno-mastoid; afterwards, for a short distance, by fascia, platysma, and skin, and in the lower part of its extent by the omo-hyoid, the sterno-hyoid, and the sterno-thyroid muscles, and it is overlapped by an accompanying vein.

**Branches.**—(1) *In the carotid triangle* (*a*) an **infra-hyoid branch** (ramus hyoideus) runs along the lower border of the great cornu of the hyoid bone, under cover of the thyro-hyoid muscle, to anastomose with its fellow of the opposite side and with the supra-hyoid branch of the lingual artery. It supplies the thyro-hyoid muscle and membrane.

(*b*) A **laryngeal branch** (a. laryngea superior) runs forwards beneath the thyro-hyoid muscle. It pierces the thyro-hyoid membrane in company with the internal laryngeal nerve, supplies the muscles, ligaments, and mucous membrane of the larynx, and

anastomoses with its fellow of the opposite side, with branches of the crico-thyroid artery, and with the terminal branches of the inferior thyroid artery.

(*c*) The **sterno-mastoid branch** (ramus sterno-cleidomastoideus) passes downwards and backwards along the upper border of the anterior belly of the omo-hyoid muscle, and across the common carotid artery to the under surface of the sterno-mastoid muscle. It anastomoses, in the sterno-mastoid, with branches of the occipital and suprascapular arteries.

(2) *In the muscular triangle* (*d*) a **crico-thyroid branch** (ramus crico-thyroideus) runs forwards, either over or under the sterno-thyroid, and crosses the crico-thyroid muscle to anastomose in front of the crico-thyroid membrane with its fellow of the opposite side, and, by branches which perforate the crico-thyroid membrane, with laryngeal branches of the superior and inferior thyroid arteries. It supplies the adjacent muscles and membrane.

(*e*) The **terminal branches** are **anterior** and **posterior** respectively.

The **anterior terminal branch** (ramus anterior), often much larger than the crico-thyroid artery, descends along the anterior border of the lateral lobe of the thyroid body, and, extending on to the upper border of the thyroid isthmus, anastomoses with its fellow of the opposite side. The **posterior branch** (ramus posterior) descends along the posterior border of the lateral lobe, and both terminal branches supply the thyroid body (rami glandulares). They anastomose with each other and with branches from the inferior thyroid artery.

(2) **Lingual Artery.**—The lingual artery (a. lingualis, Figs. 622 and 624) springs from the front of the external carotid, opposite the tip of the great cornu of the hyoid bone, and terminates, as the ranine artery, beneath the tip of the tongue, where it anastomoses with its fellow of the opposite side.

**Course.**—From its commencement, and whilst in the carotid triangle, the first part of the artery forms a loop with the convexity upwards. A second part passes forwards, internal to the hyo-glossus muscle, immediately above the great cornu of the hyoid bone, to the anterior border of the muscle, where it gives off a sublingual branch. A third part passes obliquely forwards and upwards under cover of the anterior border of the hyo-glossus, and a fourth part runs directly forwards on the under surface of the tongue to the tip. The third and fourth parts are frequently described together as the **ranine artery** (a. profunda linguæ).

**Relations.**—The first part of the lingual artery is crossed superficially by the hypoglossal nerve, but besides this it is only covered by skin, fascia, and the platysma; it rests internally against the middle constrictor of the pharynx. In the rest of its course the artery is for the most part more deeply placed. The second part, remaining in contact internally with the middle constrictor, passes internal to the hyo-glossus muscle, by which it is separated from the hypoglossal nerve, the ranine vein, and the lower part of the submaxillary gland. The third part ascends almost vertically, parallel with and under the anterior fibres of the hyo-glossus, which is here covered by the mylo-hyoid, and between it and the genio-hyo-glossus. The fourth part runs forwards between the inferior lingualis and the genio-hyo-glossus muscles, and is only covered on its lower surface by the mucous membrane of the tongue. Thus the lingual artery at its termination, near the frænum linguæ, is again comparatively superficial.

**Branches.**—(*a*) The **supra-hyoid** (ramus hyoideus), a small branch which arises in the carotid triangle and runs along the upper border of the great cornu of the hyoid bone. It anastomoses with its fellow of the opposite side and with the infra-hyoid branch of the superior thyroid artery.

(*b*) The **dorsalis linguæ** (ramus dorsalis linguæ) is a branch of moderate size which arises from the second part of the artery. It ascends external to the genio-hyo-glossus to the dorsum of the tongue, where it branches and anastomoses with its fellow of the opposite side round the foramen cæcum. It supplies the posterior part of the tongue as far back as the epiglottis, and sends branches backwards to the tonsil which anastomose with the tonsillar branches of the ascending palatine branch of the facial and with the ascending pharyngeal artery.

(*c*) A **sublingual branch** (a. sublingualis) arises at the lower part of the anterior border of the hyo-glossus muscle and runs forwards and upwards, between the mylo-hyoid and the genio-hyo-glossus, to the sublingual gland, which it supplies; it also supplies the mylo-hyoid, the genio-hyo-glossus, and the genio-hyoid muscles, and it anastomoses with its fellow of the opposite side, with the continuation of the lingual by a branch which it sends along the frænum linguæ, and through the mylo-hyoid muscle with the submental branch of the facial.

(3) **Facial Artery.**—The facial or external maxillary artery (a. maxillaris externa, Fig. 622) springs from the front of the external carotid immediately above the lingual, and terminates at the side of the nose, where it divides into lateral nasal and angular branches.

**Course.**—It commences in the carotid triangle and passes upwards internal to the posterior belly of the digastric and the stylo-hyoid muscles. It turns over the upper border of the digastric, and runs forwards and downwards in a groove in the submaxillary gland to the anterior border of the lower margin of the ramus of the mandible, then it turns round the lower border of the body of the mandible, and is continued upwards and inwards, in the face, to its termination.

**Relations.**—In the carotid triangle the artery is comparatively superficial, except just at its origin, which is beneath the anterior fibres of the sterno-mastoid muscle. Its deep surface rests on the middle and superior constrictor muscles which separate it from the lower part of the tonsil. As it passes into the submaxillary triangle it is crossed by the stylo-hyoid muscle and by the posterior belly of the digastric. In the submaxillary triangle it is embedded in a groove in the posterior part of the submaxillary gland, and it is separated by the gland from the more superficially situated facial vein. In the upper part of the submaxillary region the artery is just under cover of the ramus of the lower jaw.

Turning round the lower border of the body of the jaw, which it grooves slightly, the artery becomes more superficial than in any other part of its course, being covered only by platysma, fascia, and skin. At this point the facial vein is close behind the artery, and lies on the surface of the masseter. On the face the artery lies between the platysma, the risorius, the zygomaticus major, and the levator labii superioris, which, with skin and fascia, are superficial to it, and the buccinator and levator anguli oris, which are deeper. The termination of the artery is in the substance of the levator labii superioris et alæ nasi.

The facial vein, though still posterior to the artery in the face, runs a somewhat straighter course, and is situated at some little distance from it.

**Branches.**—Four named branches are given off in the neck, and seven in the face.

*In the Neck.*—(*a*) The **ascending palatine** (a. palatina ascendens, Fig. 624) is a small artery which arises from the facial as it enters the submaxillary triangle. It ascends internal to the internal pterygoid and upon the superior constrictor, and, passing between the stylo-glossus and the stylo-pharyngeus muscles, reaches the apex of the petrous portion of the temporal bone, where it turns downwards accompanying the levator palati muscle, pierces the pharyngeal aponeurosis, and enters the soft palate.

It supplies the lateral wall of the upper part of the pharynx, the soft palate, the tonsils, and the Eustachian tube, and it anastomoses with the tonsillar branch of the facial, the dorsalis linguæ, the posterior palatine branch of the internal maxillary, and with the ascending pharyngeal artery which sometimes replaces it.

(*b*) The **tonsillar** (ramus tonsillaris), a small artery which arises close to the ascending palatine. It passes upwards between the internal pterygoid and the stylo-glossus, pierces the superior constrictor, and terminates in the tonsil. It supplies the middle and superior constrictor muscles, and it anastomoses with the dorsalis linguæ, with the ascending palatine branch, and with the ascending pharyngeal artery.

(*c*) The **submaxillary** or **glandular branch** is frequently represented by two or three small twigs (rami glandulares) which pass directly from the facial trunk into the substance of the submaxillary gland.

(*d*) The **submental branch** (a. submentalis) arises from the facial just as the latter vessel turns round the inferior border of the body of the jaw. It is the largest branch given off in the neck, and it runs forwards, on the outer surface of the mylo-hyoid muscle, and internal to the upper part of the submaxillary gland, to the symphysis menti, where it turns upwards round the margin of the jaw, and terminates by anastomosing with branches of the mental and inferior labial arteries. In the neck the submental artery supplies the mylo-hyoid muscle, and the submaxillary and sublingual glands, the latter by a branch which perforates the mylo-hyoid muscle. It anastomoses with the mylo-hyoid branch of the inferior dental and with the sublingual artery. In the face it supplies the structures of the lower lip, and anastomoses with the mental branch of the inferior dental, and with the inferior labial and inferior coronary branches of the facial artery.

*In the Face.*—(*e*) The **inferior labial branch** (a. labialis inferior) arises from the front of the facial artery immediately above the lower border of the mandible. It runs forwards beneath the depressor muscles of the angle of the mouth and the

lower lip, supplying the skin, muscles, and mucous membrane, and anastomoses with the mental branch of the inferior dental, with the inferior coronary, with the submental, and with its fellow of the opposite side.

(*f*) The **inferior coronary** springs from the front of the facial artery, either together with or directly above the inferior labial branch. It runs forwards beneath the depressor anguli oris, and between the fibres of the orbicularis oris and the mucous membrane of the lip. It supplies the adjacent parts, and anastomoses with its fellow of the opposite side, and with the mental, inferior labial, and submental arteries.

(*g*) The **superior coronary** (a. labialis superior) springs from the front of the facial beneath the zygomaticus major, and runs forwards and inwards between the orbicularis oris and the mucous membrane of the upper lip to the middle line. It supplies the skin, muscles, and mucous membrane of the upper lip, and by a *septal branch* the lower and front part of the septum of the nose. It anastomoses with its fellow of the opposite side, with the lateral nasal, and, on the septum nasi, with the naso-palatine branch of the spheno-palatine artery.

(*h*) The **masseteric branch**, sometimes represented by several twigs, arises from the posterior aspect of the facial trunk a short distance above the lower margin of the jaw. It passes upwards and backwards across the masseter, and anastomoses with the transverse facial artery.

(*i*) The **buccal** is an inconstant branch which, when present, arises from the back of the facial artery above the masseteric branch, and runs upwards and backwards, across the buccinator muscle, to anastomose with the buccal branch of the internal maxillary artery.

(*k*) The **lateral nasal**, one of the terminal branches of the facial artery, is usually small. It ramifies on the ala of the nose, supplying the skin, muscles, and lower lateral cartilages, and anastomosing with the angular branch, with the nasal branch of the ophthalmic, and with branches of the spheno-palatine artery.

(*l*) The **angular** (a. angularis), the other terminal branch of the facial, continues the direction of the main trunk along the side of the nose to the inner angle of the orbit. It supplies the skin and muscles of the side of the nose, and anastomoses with the lateral nasal, and with the nasal and palpebral branches of the ophthalmic artery.

(4) **Occipital Artery** (a. occipitalis, Figs. 622, 623, and 650).—This vessel arises from the back of the external carotid artery, below the posterior belly of the digastric muscle, and terminates near the inner end of the superior curved line of the occipital bone by dividing into internal and external terminal branches.

**Course.**—It commences in the carotid triangle and runs upwards and backwards, parallel with and under cover of the posterior belly of the digastric, to the interval between the transverse process of the atlas and the base of the skull, where it turns backwards in a groove on the under surface of the mastoid portion of the temporal bone; as it leaves the groove it alters its direction and runs upwards and inwards on the superior oblique muscle to the junction of the inner and middle thirds of the superior curved line of the occipital bone, where it enters the superficial fascia of the scalp.

**Relations.**—In the first or ascending part of its course the occipital artery crosses successively the internal carotid artery, the hypoglossal nerve, the vagus nerve, the internal jugular vein, and the spinal accessory nerve; it is covered by the lower fibres of the posterior belly of the digastric and the anterior part of the sterno-mastoid muscle, and, close to its origin, it is crossed by the hypoglossal nerve. In the second, or more horizontal part of its course, it is still under cover of the sterno-mastoid and digastric, and lies internally against the rectus capitis lateralis, which separates it from the vertebral artery. In the third part of its course it rests upon the superior oblique and complexus, and is under cover of the sterno-mastoid, the splenius capitis, and the trachelo-mastoid muscles. At its termination it is crossed by the great occipital nerve; it passes either through the trapezius or between the trapezius and the sterno-mastoid, and pierces the deep fascia of the neck before it enters the superficial fascia of the scalp.

**Branches.**—(*a*) **Muscular branches** (rami musculares) go to the surrounding muscles. The **sterno-mastoid branch** (a. sternocleido-mastoidea) is the most important of this group; it springs from the commencement of the occipital, is looped downwards across the hypoglossal nerve, and is continued downwards and backwards, below and in front of the spinal accessory nerve, into the sterno-mastoid muscle where it anastomoses with the sterno-mastoid branch of the superior thyroid artery.

(*b*) The **meningeal** are irregular branches (rami meningei) given off from the occipital

behind the mastoid process. They enter the posterior fossa of the skull through the anterior condyloid foramen, or through the foramen lacerum posterius; they supply the upper part of the internal jugular vein, the lateral sinus, and the dura mater in the posterior fossa of the skull, and they anastomose with the middle meningeal and with meningeal branches of the ascending pharyngeal artery.

(*c*) The **mastoid**, a small and irregular branch (ramus mastoideus) given off from the occipital behind the mastoid process. It enters the posterior fossa of the skull through the mastoid foramen, supplies the dura mater, and anastomoses with branches of the middle meningeal artery.

(*d*) The **princeps cervicis** (ramus descendens) is a large branch given off from the occipital upon the surface of the superior oblique. It passes inwards to the outer border of the complexus, where it divides into superficial and deep branches. The superficial branch runs over the complexus, between it and the trapezius, and anastomoses with the superficial cervical artery. The deep branch runs between the complexus and the underlying semispinalis colli, and anastomoses with branches of the vertebral and profunda cervicis arteries.

(*e*) The **auricular** (ramus auricularis) is an inconstant branch which, as a rule, is only given off from the occipital when the posterior auricular artery is absent. It ramifies over the mastoid process, and supplies the inner surface of the pinna.

(*f*) The **terminal branches** (rami occipitales) are internal and external. They ramify in the superficial fascia of the posterior part of the scalp, anastomosing with the posterior auricular and superficial temporal arteries. They are both accompanied by branches of the great occipital nerve, and the internal branch gives off a parietal twig, which passes into the skull through the parietal foramen to supply the walls of the superior longitudinal sinus, and to anastomose with the middle meningeal artery.

(5) **Posterior Auricular Artery** (a. auricularis posterior, Figs. 622, 623).—The posterior auricular artery springs from the back of the external carotid, immediately above the posterior belly of the digastric muscle, and terminates between the mastoid process and the back of the pinna by dividing into mastoid and auricular branches.

**Course and Relations.**—Commencing in the posterior part of the submaxillary triangle, it runs upwards and backwards, under cover of the posterior part of the parotid gland, to the interval between the mastoid process and the external auditory meatus. It is accompanied in the terminal part of its course by the posterior auricular branch of the facial nerve.

**Branches.**—(*a*) **Muscular branches** are given to the sterno-mastoid, the digastric, and the styloid group of muscles.

(*b*) **Parotid branches** pass to the lower and posterior part of the parotid gland.

(*c*) A **stylo-mastoid branch** (a. stylomastoidea) is given off at the lower border of the external auditory meatus. It runs upwards by the side of the facial nerve, enters the stylo-mastoid foramen, and ascends, in the aqueduct of Fallopius, to the upper part of the inner wall of the tympanum where it terminates by anastomosing with the petrosal branch of the middle meningeal artery. It supplies branches to the external auditory meatus, the mastoid cells, the vestibule, and semicircular canals, the stapedius muscle, and the tympanic cavity (a. tympanica posterior). One of the latter branches, anastomosing with the tympanic branch of the internal maxillary, forms, in young subjects, a vascular circle round the membrana tympani; other branches anastomose with tympanic branches from the internal carotid and the ascending pharyngeal arteries, and with the auditory branch of the basilar.

(*d*) The **auricular**, or anterior terminal branch (ramus auricularis), ascends beneath the retrahens aurem muscle. It gives branches to the scalp in the posterior part of the temporal region, which anastomose with the superficial temporal and occipital arteries, and to the pinna. The latter branches supply both surfaces of the pinna, piercing or turning round the margins of the cartilage to gain the outer surface, and they anastomose with the auricular branches of the superficial temporal artery.

(*e*) The **mastoid**, or posterior terminal branch (ramus occipitalis), runs upwards and backwards along the insertion of the sterno-mastoid muscle. It supplies the sterno-mastoid, the occipito-frontalis, and the skin, and it anastomoses with the occipital artery.

(6) **Ascending Pharyngeal Artery** (a. pharyngea ascendens, Fig. 624).—This

arises from the inner surface of the lower part of the external carotid, and terminates in the wall of the pharynx and in the soft palate.

**Course.**—Commencing in the carotid triangle, usually as the first or second branch of the external carotid, it ascends on the wall of the pharynx to the apex of the petrous portion of the temporal bone.

**Relations.**—Internally it is in relation with the constrictor muscles of the pharynx. Behind it are the transverse processes of the cervical vertebræ, the sympathetic cord, and the rectus capitis anticus major. Externally it is in relation with the internal carotid artery, and it is crossed by the stylo-pharyngeus muscle, the glosso-pharyngeal nerve, and the pharyngeal branch of the vagus.

**Branches.**—The branches of this artery are very irregular and inconstant, but the following have received names :— .

(*a*) **Pharyngeal Branches** (rami pharyngei).—Small twigs which ramify on the walls of the pharynx and supply the middle and superior constrictor muscles, the tonsil, and the lower part of the Eustachian tube. They anastomose with branches of the superior thyroid, lingual, and facial arteries.

(*b*) **Prevertebral.**—Small branches distributed to the prevertebral muscles and fascia, the deep cervical glands, and the large nerve trunks. They anastomose with the ascending cervical and vertebral arteries.

(*c*) **Meningeal** (a. meningea posterior), one or more small branches which enter the cranium by the anterior condyloid, the posterior lacerate, or the middle lacerate foramen, and supply the dura mater. They anastomose with branches of the middle meningeal and vertebral arteries.

(*d*) **Tympanic** (a. tympanica inferior), a small artery which accompanies the tympanic branch of the glosso-pharyngeal nerve to the tympanic cavity, where it anastomoses with the other tympanic arteries.

(*e*) **Palatine.**—A very variable artery which sometimes replaces the ascending palatine branch of the facial artery. When present it springs from the upper part of the ascending pharyngeal artery, pierces the pharyngeal aponeurosis above the upper border of the superior constrictor muscle, and descends into the soft palate with the levator palati muscle. It supplies the mucous membrane of the supero-lateral part of the pharyngeal wall and the tissues of the soft palate, and it anastomoses with the palatine branches of the internal maxillary, the facial, and the lingual arteries

(7) **Superficial Temporal Artery** (a. temporalis superficialis, Fig. 622).—This artery, one of the terminal branches of the external carotid, commences in the upper part of the parotid gland, behind the neck of the mandible, and terminates in the scalp, from one to two inches (25 to 50 mm.) above the zygoma, by dividing into an anterior and a posterior terminal branch.

**Course.**—The artery ascends over the posterior root of the zygoma, and passes into the superficial fascia of the temporal region. It is accompanied by the auriculo-temporal nerve and by the superficial temporal vein which usually lies posterior to it. As it crosses the zygoma it lies immediately beneath the skin, and it may be easily compressed against the subjacent bone.

**Branches.**—(*a*) **Parotid,** small branches (rami parotidei) to the upper part of the parotid gland ·

(*b*) **Articular,** to the temporo-mandibular articulation.

(*c*) **Auricular.**—Small branches (rami auriculares anteriores) to the outer surface of the pinna and to the external auditory meatus. They anastomose on the surface of the pinna with branches of the posterior auricular artery, and in the external meatus with branches of the internal maxillary artery.

(*d*) **Transverse Facial** (a. transversa faciei).—A branch of moderate size which rises in the substance of the parotid gland. It emerges from the upper part of the anterior border of the gland, runs forwards across the masseter, below the zygoma and above Stenson's duct, accompanied by the infra-orbital branches of the facial nerve which may lie either above or below it. It is distributed to the parotid gland, the masseter, Stenson's duct, and the skin, and it terminates in branches which anastomose with the infra-orbital and buccal branches of the internal maxillary artery, and with the buccal and masseteric branches of the facial artery.

(*e*) **Middle Temporal** (a. temporalis media).—A branch which usually springs from the superficial temporal in the parotid gland. It crosses the zygoma, pierces the temporal

fascia and the temporal muscle, and terminates in the temporal fossa by anastomosing with the deep temporal branches of the internal maxillary artery.

(*f*) **Orbital** (a. zygomatico-orbitalis).—This branch may spring directly from the superficial temporal, but it is frequently a branch of the middle temporal. It runs forwards above the zygoma between the two layers of the temporal fascia. It supplies branches to the orbicularis palebrarum, and anastomoses, through the malar bone and round the outer margin of the orbit, with the lachrymal and palpebral branches of the ophthalmic artery.

(*g*) The **anterior terminal branch** (ramus frontalis) runs forwards and upwards, in a tortuous course, through the superficial fascia of the scalp towards the frontal eminence, lying at first upon the temporal fascia, and then upon the epicranial aponeurosis. It supplies the frontalis and the orbicularis palpebrarum, and anastomoses with the lachrymal

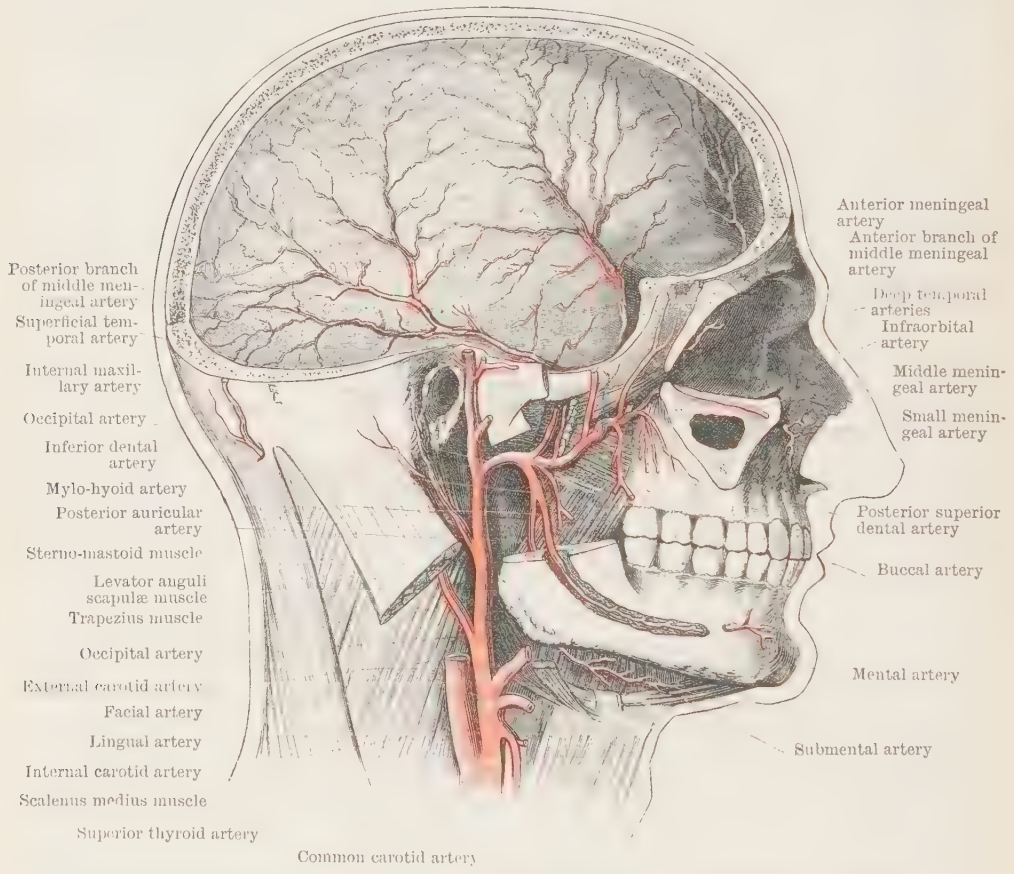

FIG. 623.—THE EXTERNAL CAROTID, INTERNAL MAXILLARY, AND MENINGEAL ARTERIES.

and supraorbital branches of the ophthalmic artery, with the posterior terminal branch of the superficial temporal, and with its fellow of the opposite side.

(*h*) The **posterior terminal branch** (ramus parietalis), less tortuous than the anterior, runs upwards and backwards in the superficial fascia of the scalp. It anastomoses, anteriorly, with the anterior terminal branch, posteriorly with the posterior auricular and occipital arteries, and, across the middle line, with its fellow of the opposite side. It supplies the skin and fascia, and the attrahens and attollens aurem muscles.

(8) **Internal Maxillary Artery** (a. maxillaris interna).—The internal maxillary artery commences in the parotid gland behind the neck of the lower jaw, and terminates in the spheno-maxillary fossa.

**Course and Relations.**—Although the internal maxillary artery is only a short trunk it has many important relations, in the consideration of which it is convenient to arbitrarily divide the vessel into three parts. The **first part** extends from the back of the neck of the mandible forwards into the zygomatic fossa as

far as the lower border of the external pterygoid muscle. It lies between the spheno-mandibular ligament and the neck of the jaw, along with the auriculo-temporal nerve and the internal maxillary vein. The **second part** is in the zygomatic fossa, and ascends upwards and forwards. It may lie superficial to, or under cover of, the lower head of the external pterygoid muscle. In the former case it is situated between the temporal and external pterygoid muscles, and in the latter between the external pterygoid muscle and the branches of the third division of the fifth nerve. The **third part** passes between the upper and the lower heads of the external pterygoid, through the pterygo-maxillary fissure and into the spheno-maxillary fossa.

**Branches.**—*From the first part.*—(*a*) **Deep auricular** (a. auricularis profunda), a small branch which rises in the parotid gland and passes upwards to enter the external auditory meatus. It supplies the temporo-mandibular joint, the parotid gland, and the external meatus, and anastomoses with branches of the superficial temporal and posterior auricular arteries.

(*b*) The **tympanic** (a. tympanica anterior), a variable and small branch which commences in the parotid gland. It runs upwards and backwards, traverses the Glasserian fissure, and enters the tympanum through its outer wall. In the tympanic cavity it anastomoses with tympanic branches from the internal carotid and the ascending pharyngeal arteries, and with the stylo-mastoid branch of the posterior auricular, forming with the latter, in young subjects, a circular anastomosis round the tympanic membrane.

(*c*) **Middle Meningeal** (a. meningea media).—The largest branch of the internal maxillary. It ascends between the external pterygoid muscle and the spheno-mandibular ligament, and passes between the two roots of the auriculo-temporal nerve and through the foramen spinosum, to enter the middle fossa of the cranial cavity. Before it enters the skull it lies behind the third division of the fifth nerve, and is accompanied by two venæ comites which also pass through the foramen spinosum. In the middle cranial fossa it passes forward, and upwards for a short distance, in a groove on the great wing of the sphenoid, between the dura mater and the bone, and divides into anterior and posterior terminal branches.

**Branches.**—(i.) **Petrosal** (ramus petrosus superficialis).—A small branch which arises from the middle meningeal soon after it enters the cranium. It passes through the hiatus Fallopii and anastomoses with the stylo-mastoid branch of the posterior auricular artery; it also sends some small branches into the tympanic cavity

(ii.) **Gasserian.**—Minute branches which supply the Gasserian ganglion and the roots of the fifth cranial nerve.

(iii.) **Tympanic** (a. tympanica superior).—A small twig which reaches the tympanic cavity through the canal for the tensor tympani muscle, or through the petro-squamous suture.

(iv.) **Orbital.**—An anastomosing branch which occasionally arises from the anterior terminal branch. It passes through the foramen lacerum anterius into the orbit, and anastomoses with the lachrymal artery.

(v.) **Anterior terminal**, the larger of the two terminal branches, passes upwards along the great wing of the sphenoid to the antero-inferior angle of the parietal bone, where it is sometimes enclosed in a distinct bony canal; it is continued upwards a short distance behind the anterior border of the parietal bone almost to the vertex of the skull, sending branches forwards into the anterior, and backwards towards the posterior cranial fossa.

(vi.) The **posterior terminal branch** passes backwards from the great wing of the sphenoid to the squamous part of the temporal bone, beyond which it ascends to the middle of the inner surface of the parietal bone. It sends branches upwards to the vertex, and backwards towards the posterior cranial fossa.

By means of its various branches the middle meningeal artery anastomoses with its fellow of the opposite side, with meningeal branches from the occipital, ascending pharyngeal, ophthalmic, and lachrymal arteries; also with the stylo-mastoid branch of the posterior auricular, the small meningeal artery, with the deep temporal arteries through the substance of the temporal bone, and with its fellow of the opposite side.

(*d*) A **small meningeal branch** (ramus meningeus accessorius) may arise either directly from the first part of the internal maxillary or from its middle meningeal branch. It passes upwards, on the inner side of the external pterygoid muscle, enters the middle fossa of the skull through the foramen ovale, supplies the Gasserian ganglion and the dura mater, and terminates by anastomosing with branches of the middle meningeal and internal carotid arteries.

(*e*) The **inferior dental** (a. alveolaris inferior) is a branch of moderate size which passes downwards between the spheno-mandibular ligament and the mandible to the mandibular foramen. It is accompanied by the inferior dental nerve which lies in front.

After entering the foramen it descends in the mandibular canal, and terminates at the mental foramen by dividing into mental and incisive branches.

**Branches.**—Before it enters the mandibular foramen it gives off two branches.

(i.) The **lingual,** a small twig to the buccal mucous membrane which accompanies the lingual nerve. (ii.) The **mylo-hyoid** (ramus mylohoideus), a small branch which is given off immediately above the mandibular foramen. It pierces the spheno-mandibular ligament, and descends in the mylo-hyoid groove, in company with the mylo-hyoid nerve, to the floor of the mouth, where it anastomoses, on the superficial surface of the mylo-hyoid muscle, with the submental branch of the facial artery.

In the mandibular canal the following branches are given off:—

(i.) **Molar branches** to the molar teeth. (ii.) **Bicuspid branches** to the bicuspid teeth. (iii.) The **incisive terminal branch**, which supplies the incisor teeth and anastomoses with its fellow of the opposite side. (iv.) The **mental terminal branch** (a. mentalis), which passes through the mental foramen, emerges beneath the depressor labii inferioris, and anastomoses with its fellow of the opposite side, with the inferior coronary, the inferior labial, and with the submental arteries.

*From the second part.*—(*a*) The **masseteric** (a. masseterica), a small branch which passes directly outwards, through the sigmoid notch, to the deep surface of the masseter muscle. It anastomoses in the substance of the muscle with branches of the transverse facial and with the masseteric branches of the facial artery.

(*b*) **Deep Temporal.**—Two in number, anterior (a. temporalis profunda anterior) and posterior (a. temporalis profunda posterior). They ascend between the temporal muscle and the squamous portion of the temporal bone, supplying the muscle and anastomosing with the temporal and lachrymal arteries, and, through the substance of the temporal bone, with the middle meningeal artery.

(*c*) Small **pterygoid branches** (rami pterygoidei) supply the internal and external pterygoid muscles.

(*d*) The **buccal** (a. buccinatoria), a long, slender branch which passes obliquely forwards and downwards with the long buccal nerve. It supplies the buccinator muscle, the skin and mucous membrane of the cheek, and anastomoses with the buccal branch of the facial artery.

*From the third part.*—(*a*) A **posterior superior dental branch** (a. alveolaris superior posterior) descends in the zygomatic fossa, on the posterior surface of the superior maxilla, and ends in branches which supply the molar and bicuspid teeth and the mucous membrane of the antrum, they also give twigs to the gums and to the buccinator muscle.

(*b*) An **infra-orbital branch** (a. infra-orbitalis) commences in the spheno-maxillary fossa. It enters the orbit through the spheno-maxillary fissure, and runs forwards in the infra-orbital groove and canal to the infra-orbital foramen, through which it passes to emerge on the face beneath the levator labii superioris. Whilst in the infra-orbital groove it gives branches to the inferior rectus, the inferior oblique and the lachrymal gland. In the infra-orbital canal it gives small twigs to the incisor and canine teeth (aa. alveolares superiores anteriores) and to the antrum. In the face it sends branches upwards to the lower eyelid, to the lachrymal sac, and to the nasal process of the superior maxilla, which anastomose with branches of the ophthalmic and facial arteries; other branches run downwards to the upper lip, where they anastomose with the superior coronary artery; lastly, some branches run outwards into the cheek to unite with the transverse facial and the buccal arteries.

(*c*) The **posterior** or **descending palatine** (a. palatina descendens) runs downwards through the spheno-maxillary fossa, passes through the posterior palatine canal, and reaches the mucous membrane of the roof of the mouth, where it runs forwards, internal to the alveolar process, to terminate in a small branch which ascends through the anterior palatine fossa and Stensen's canal and anastomoses with the spheno-palatine branch of the internal maxillary artery. As it descends it gives off several small twigs which pass through the accessory palatine canals to supply the soft palate, and to anastomose with the ascending palatine and tonsillar branches of the facial and with the ascending pharyngeal artery. In its course forwards in the roof of the mouth it supplies the gums and the mucous membrane of the hard palate, and also the palate and superior maxillary bones.

(*d*) The **Vidian** (a. canalis pterygoidei) is a long, slender branch which runs backwards through the Vidian canal with the Vidian nerve. It supplies branches to the upper part of the pharynx, to the levator and tensor palati muscles, and to the Eustachian tube. One of the latter branches passes along the wall of the Eustachian tube to the tympanic cavity, where it anastomoses with the other tympanic arteries.

(*e*) The **pterygo-palatine** is a small artery which runs backwards, with the pharyngeal branch of Meckel's ganglion, to the roof of the pharynx. It supplies the upper and back

part of the roof of the nose, the roof of the pharynx, the sphenoidal sinus, and the lower part of the Eustachian tube, and anastomoses with the Vidian branch of the internal carotid.

(*f*) The **spheno-palatine branch** (a. spheno-palatina) springs from the termination of the internal maxillary artery. It passes inwards through the spheno-palatine foramen into the nasal cavity, where it divides into many branches. One of these, the internal nasal or **naso-palatine**, which is sometimes looked upon as the continuation of the artery, crosses the back part of the roof of the nose, and descends in a groove on the vomer to the incisive foramen, where it anastomoses with the termination of the posterior palatine artery and with the septal branch of the superior coronary. The outer or external nasal branches of the spheno-palatine artery supply the greater part of the outer wall of the nasal fossa and the cavity of the antrum, anastomosing with branches of the infraorbital, ethmoidal, and lateral nasal arteries. Branches are also distributed to the ethmoidal cells, to the sphenoidal sinus, and to the upper part of the pharynx.

## THE INTERNAL CAROTID ARTERY.

The **internal carotid artery** (a. carotis interna, Figs. 622, 624, and 627) commences at the termination of the common carotid, opposite the upper border of the

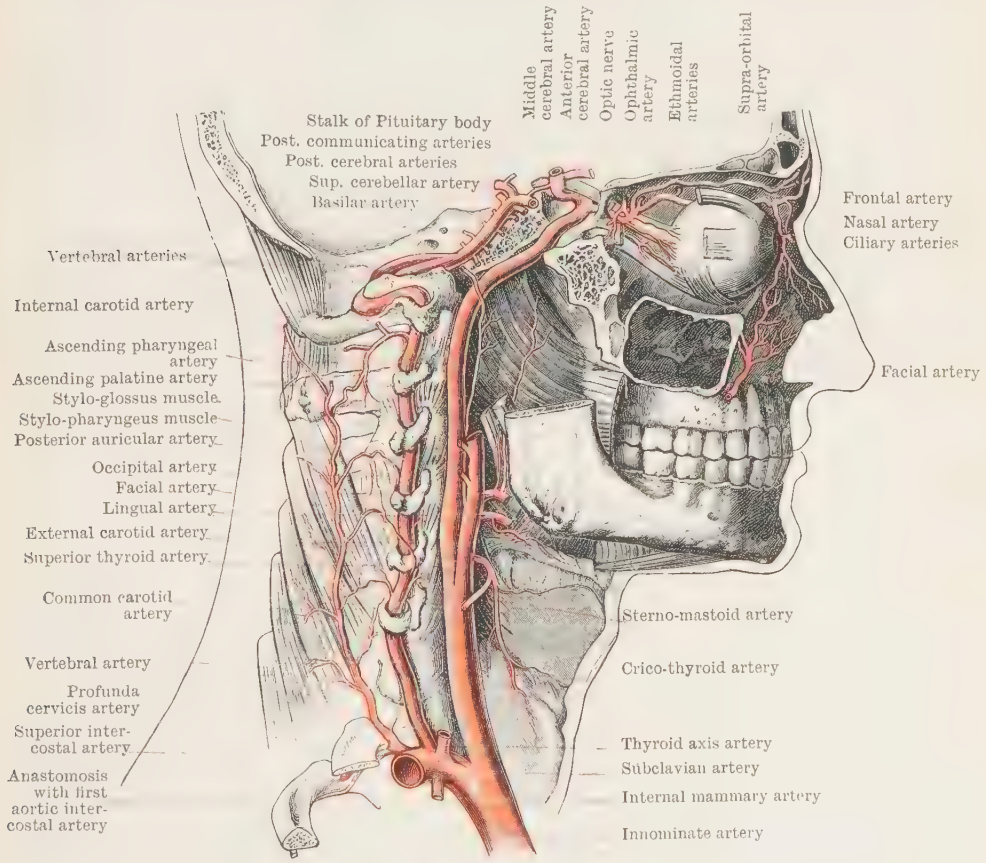

FIG. 624.—THE CAROTID, SUBCLAVIAN, AND VERTEBRAL ARTERIES AND THEIR MAIN BRANCHES.

thyroid cartilage, and terminates in the middle fossa of the skull, close to the commencement of the fissure of Sylvius, where it divides into the middle and anterior cerebral arteries.

**Course.**—It passes through the carotid and submaxillary triangles, traverses the carotid canal of the temporal bone, crosses the upper part of the foramen lacerum medium, and runs in the outer wall of the cavernous sinus in the middle fossa of the skull.

At its origin it lies behind and to the outer side of the external carotid, but as

it ascends internal to the posterior belly of the digastric and the stylo-hyoid it gets to the inner side of that vessel. After entering the submaxillary triangle it ascends, in relation with the posterior surface of the parotid gland, to the carotid canal in the temporal bone, through which it passes to the apex of the petrous portion of the temporal bone, where it turns upwards, through the upper part of the foramen lacerum medium, into the middle cranial fossa. It then runs forwards in the outer wall of the cavernous sinus to the lower root of the small wing of the sphenoid, there it turns upwards and then backwards and outwards to its termination.

**Relations.**—The relations of the various parts of the artery require separate consideration.

*In the Neck.—Posterior.*—The rectus capitis anticus major, the prevertebral fascia, and the sympathetic cord, separate it from the transverse processes of the cervical vertebræ, and somewhat to its outer side are the internal jugular vein and the vagus nerve. The spinal accessory and the glosso-pharyngeal nerves are also behind and to the outer side of the artery for a short distance in the upper part of the neck, and they intervene between it and the internal jugular vein. *Internal* or deep to the internal carotid is the external carotid artery for a short distance below, and afterwards the wall of the pharynx, the ascending pharyngeal artery, the pharyngeal plexus of veins, and the external and internal laryngeal nerves. Just before it enters the temporal bone the levator palati muscle is to its inner side. *External* or superficial to it are the sterno-mastoid, skin, and fascia, and it is crossed beneath the sterno-mastoid from below upwards by the hypoglossal nerve, the occipital artery, and the posterior auricular artery. It is also crossed more superficially by the digastric and stylo-hyoid muscles, and in the upper part of its extent it is covered by the posterior part of the parotid gland. Passing obliquely across its anterior and outer surface, and separating it from the external carotid artery, are the following structures, viz.: the stylo-pharyngeus, the tip of the styloid process or the stylo-glossus muscle, and the stylo-hyoid ligament, the glosso-pharyngeal nerve, the pharyngeal branch of the vagus, and some sympathetic twigs.

*In the Carotid Canal.*—The artery, as it passes upwards and inwards, is in front of and below the cochlea and the tympanum; behind and internal to the canals for the Eustachian tube and the tensor tympani; and below the Gasserian ganglion. The thin lamina of bone which separates it from the tympanum is frequently perforated, and that between it and the Gasserian ganglion is not infrequently absent. In its course through the canal it is accompanied by small veins and nerves. The veins are tributaries from the tympanum, which communicate above with the cavernous sinus and below with the internal jugular vein. The nerves are the upward continuations of the sympathetic cord; they form two plexuses—one on the outer side of the artery, the carotid plexus, and one on the inner side, the cavernous plexus.

As it enters the cavity of the cranium the internal carotid artery pierces the external layer of the dura mater and passes between the lingula and the sixth cranial nerve externally, and the posterior petrosal process of the body of the sphenoid internally.

*In the Cranial Cavity.*—The artery runs forwards in the outer wall of the cavernous sinus in relation with the third, fourth, the ophthalmic division of the fifth, and the sixth cranial nerves externally, and with the endothelial wall of the sinus internally. When it reaches the lower root of the small wing of the sphenoid it turns upwards to the inner side of the anterior clinoid process, pierces the inner layer of the dura mater, and comes into close relation with the under surface of the optic nerve immediately behind the optic foramen. It then turns abruptly backwards beneath the optic nerve, and on the inner side of the anterior clinoid process which it frequently grooves; inclining outwards, it runs between the second and third nerves, and beneath the anterior perforated space, to the inner end of the stem of the Sylvian fissure, where it turns upwards, at some distance from the outer side of the optic chiasma, and, after piercing the arachnoid, divides into its two terminal branches, the anterior and middle cerebral arteries.

### Branches of the Internal Carotid Artery.

Branches are given off from the internal carotid in the temporal bone and in the cranium, but, as a rule, no branches are given off in the neck.

*In the Temporal Bone.*—(1) A **tympanic branch** (ramus carotico-tympanicus), very small, perforates the posterior wall of the carotid canal, and anastomoses in the tympanum with the stylo-mastoid artery and with the tympanic branches of the internal maxillary and ascending pharyngeal arteries.

(2) The **Vidian** is a small and inconstant branch which accompanies the great deep petrosal nerve in the Vidian canal; it anastomoses with the Vidian branch of the internal maxillary artery.

*In the Cranium.*—(1) **Cavernous**, small branches to the walls of the cavernous sinus and to the third, fourth, fifth, and sixth nerves.

(2) **Gasserian**, minute twigs which supply the Gasserian ganglion.

(3) **Pituitary branches** pass to the pituitary body.

(4) **Meningeal branches** ramify in the dura mater of the middle cranial fossa, anastomosing with the branches of the middle and small meningeal arteries.

(5) **Ophthalmic Artery** (a. ophthalmica, Fig. 624).—This artery springs from the front and inner side of the internal carotid as it turns upwards on the inner side of the anterior clinoid process. It passes forwards and outwards, beneath the optic nerve and through the optic foramen into the orbital cavity. In the orbit it runs forwards for a short distance on the outer side of the optic nerve, and it is in relation externally with the lenticular ganglion and the external rectus muscle; turning upwards and inwards, it crosses between the optic nerve and

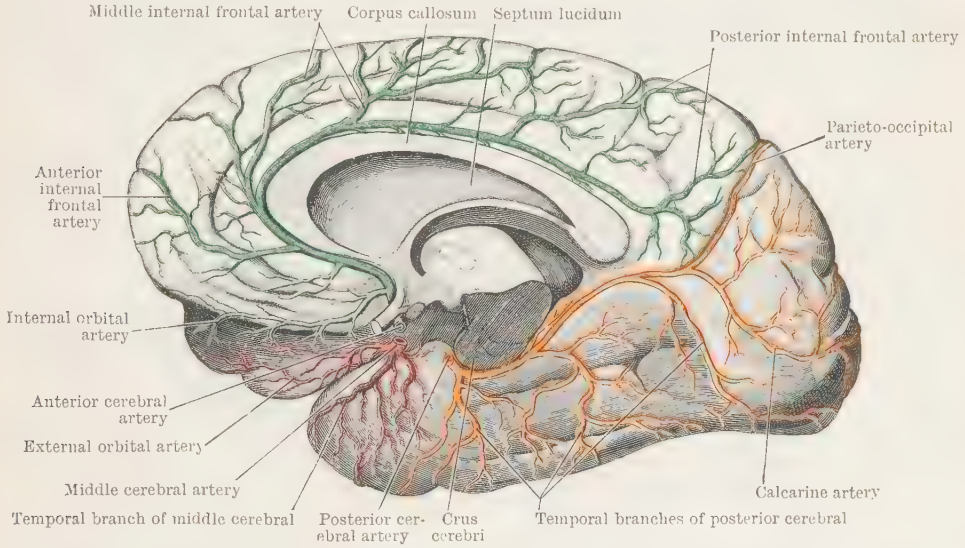

FIG. 625.—DISTRIBUTION OF THE CEREBRAL ARTERIES ON THE MESIAL, TENTORIAL, AND INFERIOR SURFACES OF THE CEREBRAL HEMISPHERES.

The anterior cerebral artery is coloured green, the middle cerebral artery red, and the posterior cerebral artery orange.

the superior rectus to the inner wall of the orbit, where it turns forwards to terminate at the inner and front part of the orbital cavity by dividing into frontal and nasal branches. It is accompanied at first by the nasal nerve, and in the terminal part of its course by the infra-trochlear nerve.

**Branches.**—The branches of the ophthalmic artery are numerous. (*a*) The **posterior ciliary**, usually six to eight in number, run forwards at the sides of the optic nerve; they soon divide into numerous branches which pierce the back part of the sclerotic coat; the majority terminate in the choroid coat of the eye as the *short ciliary arteries* (aa. ciliares posteriores breves), but two of larger size, the *long ciliary arteries* (aa. ciliares posteriores longæ), run forwards, one on each side, almost in the horizontal plane of the eyeball, between the sclerotic and the choroid coats, to the base of the iris, where they divide. The resulting branches anastomose together and form a circle at the outer periphery of the iris, from which secondary branches run inwards and anastomose together in a second circle near the inner margin of the iris.

(*b*) The **central artery of the retina** (a. centralis retinæ) arises near to, or in common with, the preceding vessels. It pierces the inner and under side of the optic nerve, about half an inch (12 mm.) behind the sclera, and runs in its centre to the retina, where it breaks up into terminal branches.

(*c*) **Recurrent** (a. meningea anterior).—A small branch which passes backwards through the sphenoidal fissure into the middle fossa of the cranium, where it anastomoses with the middle and small meningeal arteries, and with the meningeal branches of the internal carotid and lachrymal arteries.

(*d*) The **lachrymal artery** (a. lacrimalis) arises from the ophthalmic on the outer side of the optic nerve. It runs forwards along the upper border of the external rectus to the upper and outer angle of the orbit, and in its course gives off branches to the lachrymal gland, muscular branches to the external and superior recti, palpebral branches to the upper eyelid and the upper and outer part of the forehead, temporal and malar branches, which accompany the temporal and malar branches of the temporo-malar nerve, to the face and the temporal fossa respectively; *anterior ciliary branches* (aa. ciliares anteriores), which perforate the sclera behind the corneo-scleral junction and anastomose with the posterior ciliary arteries; and a recurrent meningeal branch, which passes backwards through the outer part of the sphenoidal fissure to anastomose in the middle fossa of the skull with the middle meningeal artery.

(*e*) **Muscular.**—These branches are usually arranged in two sets, outer and inner. The former supply the upper and outer, and the latter the lower and inner orbital muscles. They anastomose with muscular branches from the lachrymal and the supra-orbital vessels, and they give off *anterior ciliary branches.*

(*f*) The **supra-orbital branch** (a. supra-orbitalis) is given off as the ophthalmic artery crosses above the optic nerve. It passes round the inner borders of the superior rectus and levator palpebræ muscles, and runs forwards between the latter and the periosteum to the supra-orbital notch, accompanying the frontal and supra-orbital nerves. Passing through the notch it reaches the scalp, and, perforating the frontalis muscle, anastomoses with the superficial, temporal, and frontal arteries.

(*g*) **Ethmoidal branches,** anterior (a. ethmoidalis anterior) and posterior (a. ethmoidalis posterior), arise from the ophthalmic as it runs forwards along the inner boundary of the orbital

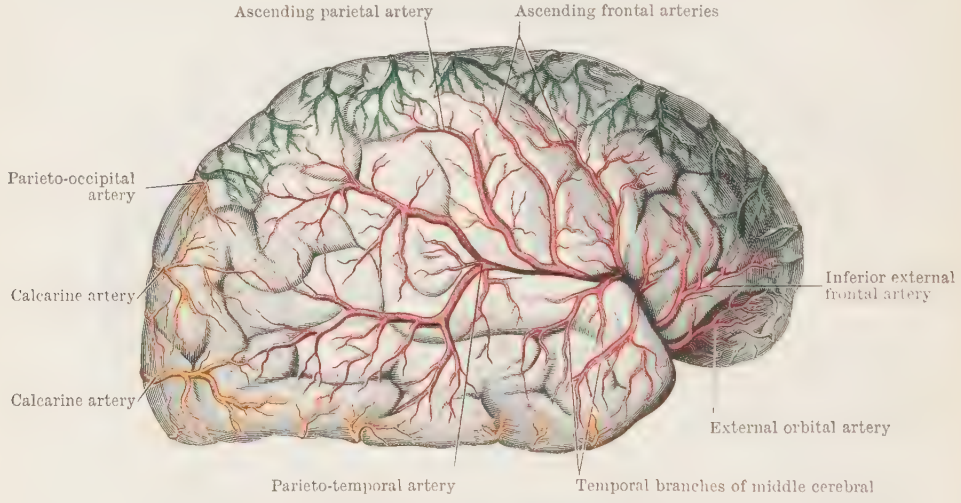

FIG. 626.—DISTRIBUTION OF CEREBRAL ARTERIES ON THE OUTER SURFACE OF THE CEREBRUM.
Anterior cerebral artery is coloured green, the middle cerebral red, and the posterior cerebral orange.

cavity. They pass inwards between the superior oblique and the internal rectus. The posterior, which is much the smaller of the two, traverses the posterior ethmoidal canal, and supplies the posterior ethmoidal cells and the posterior and upper part of the outer wall of the nasal cavity. The anterior ethmoidal artery passes through the anterior ethmoidal canal with the nasal nerve, enters the anterior fossa of the skull, and crosses the cribriform plate of the ethmoid to the nasal notch, through which it reaches the nasal cavity, where it descends with the nasal nerve in a groove on the back of the nasal bone, and finally passes between the upper lateral cartilage and the lower border of the nasal bone to the tip of the nose. It supplies branches to the membranes of the brain in the anterior cranial fossa as well as to the anterior ethmoidal cells, the frontal sinus, the anterior and upper part of the nasal mucous membrane, and the skin on the dorsum of the nose.

(*h*) **Palpebral branches** (aa. palpebrales), upper and lower, are given off near the termination of the ophthalmic. They are distributed to the upper and lower eyelids, and they anastomose with the lachrymal, supra-orbital, and infra-orbital arteries.

(*i*) The **nasal terminal branch** (a. dorsalis nasi) passes out of the orbit above the internal tarsal ligament. It pierces the palpebral fascia, and terminates on the side of the nose by anastomosing with the angular branch of the facial artery.

(*k*) The **frontal terminal branch** (a. frontalis) pierces the palpebral fascia at the upper and inner part of the orbit, and ascends, with the supra-trochlear nerve, in the superficial fascia of the anterior and mesial part of the scalp, anastomosing with its fellow of the opposite side and with the supra-orbital artery.

(6) The **posterior communicating artery** (a. communicans posterior) rises from the internal carotid near its termination. It runs backwards below the optic tract and in

front of the crus cerebri, and passing above the third nerve, joins the posterior cerebral artery forming part of the circle of Willis. It gives branches to the optic tract, the crus cerebri, the interpeduncular region, and the uncinate convolution of the brain. The posterior communicating artery varies much in size; it may be small on one or both sides, sometimes it is very large on one side; occasionally it replaces the posterior cerebral artery, and it sometimes arises from the middle cerebral artery.

(7) The **anterior choroidal** (a. choroidea) is a small branch, which also rises near the termination of the internal carotid; it passes backwards and outwards, between the crus cerebri and the uncinate convolution, to the lower and front part of the choroidal fissure which it enters, and it terminates in the choroidal plexus in the descending cornu of the lateral ventricle. It supplies the optic tract, the crus cerebri, the uncinate convolution, and the posterior part of the internal capsule.

(8) **Anterior Cerebral Artery** (a. cerebri anterior). This is the smaller of the two terminal branches of the internal carotid. It passes forwards and inwards, above the optic chiasma and immediately in front of the lamina cinerea, to the commencement of the great longitudinal fissure, where it turns round the genu of the corpus callosum, and runs backwards to the parietal lobe of the brain. At the commencement of the great longitudinal fissure it is closely connected with its fellow of the opposite side by a wide but short **anterior communicating artery** (a. communicans anterior), and in the remainder of its course it is closely accompanied by its fellow artery of the opposite side.

**Branches.**—Branches of all the cerebral arteries are distributed both to the basal ganglionic masses of the brain and to the cerebral cortex; they therefore form two distinct groups—(*a*) **central or ganglionic**; (*b*) **cortical.**

The branches of the anterior cerebral include:

(*a*) *Central or ganglionic branches.*—The **antero-mesial arteries**, a small group of vessels, constitute the central branches of the anterior cerebral artery; they pass upwards into the base of the brain in front of the optic chiasma, and supply the rostrum of the corpus callosum, the lamina cinerea, and the septum lucidum.

(*b*) *Cortical branches.*—(*b*$^1$) **Internal orbital**, one or more small branches which supply the internal orbital convolution, the gyrus rectus, and the olfactory lobe.

(*b*$^2$) **Anterior internal frontal**, one or more branches which are distributed to the anterior and lower part of the marginal convolution, and to the anterior portions of the superior and middle frontal convolutions.

(*b*$^3$) A **middle internal frontal** is distributed to the posterior part of the marginal convolution, and to the upper portions of the superior and ascending frontal and ascending parietal convolutions.

(*b*$^4$) The **posterior internal frontal** runs backwards to the quadrate lobule. It supplies the corpus callosum, the quadrate lobe, and the upper part of the superior parietal lobule.

(9) **Middle Cerebral Artery** (a. cerebri media).—The middle cerebral is the larger of the two terminal branches, and the more direct continuation of the internal carotid artery. It passes outwards in the fissure of Sylvius to the outer surface of the island of Reil, which it crosses; and divides, in the posterior limiting sulcus of Reil, into parieto-temporal and temporal terminal branches.

**Branches.**—(*a*) *Central or ganglionic.*—Numerous and very variable in size. These branches are given off at the base of the brain, in the region of the anterior perforated space. Two sets, known as the internal and the external striate arteries, are distinguishable.

(*a*$^1$) The **internal striate arteries** pass upwards through the two inner segments of the lenticular nucleus (globus pallidus) and the internal capsule to terminate in the caudate nucleus. They supply the anterior portions of the lenticular and caudate nuclei and of the internal capsule.

(*a*$^2$) The **external striate arteries** pass upwards through the outer segment (putamen) of the lenticular nucleus, or between it and the external capsule, and they form two sets: an anterior, the lenticulo-striate, and a posterior, the lenticulo-optic; both sets traverse the lenticular nucleus and the internal capsule, but the *lenticulo-striate arteries* terminate in the caudate nucleus, and the *lenticulo-optic* in the optic thalamus. One of the lenticulo-striate arteries, which passes in the first instance round the outer side of the lenticular nucleus, and afterwards through its substance, is larger than its companions; it frequently ruptures, and is known as the artery of cerebral hæmorrhage.

($b$) *Cortical branches* are given off as the middle cerebral artery passes over the surface of the island of Reil at the bottom of the Sylvian fissure, as follows:—

($b^1$) The **inferior external orbital** runs forwards and outwards, and is distributed to the outer part of the orbital surface of the frontal lobe and to the inferior frontal convolution.

($b^2$) The **ascending frontal branch** turns round the upper margin of the Sylvian fissure, and is distributed to the ascending frontal convolution and to the posterior part of the middle frontal convolution.

($b^3$) The **ascending parietal branch** emerges from the Sylvian fissure and passes upwards along the posterior border of the ascending parietal convolution, supplying that convolution and the superior parietal lobule.

($b^4$) The **temporal branch** passes out of the Sylvian fissure, and turns downwards to supply the superior and middle temporal convolutions.

($b^5$) The **parieto-temporal branch** continues backwards, in the direction of the main stem, and emerges from the posterior end of the Sylvian fissure; it supplies the inferior parietal lobule, the external occipital convolutions, and the posterior part of the temporo-sphenoidal lobe.

### Vertebral Artery.

The **vertebral artery** (a. vertebralis, Figs. 624 and 627) is the first branch given off from the subclavian trunk; it arises from the upper and back part of the parent stem, opposite the interval between the anterior scalene and the longus colli muscles, and terminates at the lower border of the pons Varolii by uniting with its fellow of the opposite side to form the basilar artery.

**Course and Relations.**—The vertebral artery is divisible into four parts.

The **first part** runs upwards and backwards, between the scalenus anticus and the outer border of the longus colli, to the foramen in the transverse process of the sixth cervical vertebra. It is surrounded by a plexus of sympathetic nerve fibres, covered anteriorly by the vertebral and internal jugular veins, and crossed in front by the inferior thyroid artery. On the left side the terminal part of the thoracic duct also passes in front of it. The **second part** runs upwards through the foramina in the transverse processes of the upper six cervical vertebræ. As far as the second cervical vertebra its course is almost vertical; as it passes through the transverse process of the axis, however, it is directed obliquely upwards and outwards to the atlas. It is surrounded by a plexus of sympathetic nerve fibres, and also by a plexus of veins. The artery lies in front of the trunks of the cervical nerves, and internal to the intertransverse muscles. The **third part** emerges from the foramen in the transverse process of the atlas, between the anterior primary division of the sub-occipital nerve internally and the rectus capitis lateralis externally, and runs almost horizontally backwards and inwards round the outer side and back of the superior articular process of the atlas. In this course it enters the sub-occipital triangle, where it lies in the groove on the upper surface of the posterior arch of the atlas (sulcus arteriæ vertebralis). It is separated from the bone by the sub-occipital nerve, and is overlapped superficially by the adjacent borders of the superior and inferior oblique muscles. Finally, this part of the artery passes beneath the oblique ligament of the atlas and enters the spinal canal.

The **fourth part** pierces the spinal dura mater and runs upwards into the cranial cavity. It passes between the roots of the hypoglossal nerve above and the first dentation of the ligamentum denticulatum below, pierces the arachnoid, and, gradually inclining inwards in front of the medulla, reaches the lower border of the pons Varolii, where it unites with its fellow of the opposite side to form the basilar artery.

**Branches.**—*From the first part.*—As a rule there are only a few small muscular twigs from this portion of the artery.

*From the second part.*—(1) **Muscular branches** which vary in number and size. They supply the deep muscles of the neck, and anastomose with the profunda cervicis, the ascending cervical, and the occipital arteries.

(2) **Spinal branches** (rami spinales) pass from the inner side of the second part of the vertebral artery through the intervertebral foramina into the spinal canal, where they give off twigs which pass along the roots of the spinal nerves to reinforce the anterior and

posterior spinal arteries; they supply the bodies of the vertebrae and the intervertebral discs, and they anastomose with corresponding arteries above and below.

*From the third part.*—(1) **Muscular branches** to the sub-occipital muscles.

(2) **Anastomotic branches** which unite with the princeps cervicis branch of the occipital and with the profunda cervicis artery.

*From the fourth part.*—(1) **Meningeal** (rami meningei).—One or two small branches given off before the vertebral artery pierces the dura mater. They ascend into the posterior fossa of the skull, where they anastomose with meningeal branches of the occipital and ascending pharyngeal arteries, and occasionally with branches of the middle meningeal artery.

(2) **Posterior Spinal** (a. spinalis posterior).—The posterior spinal branch springs from

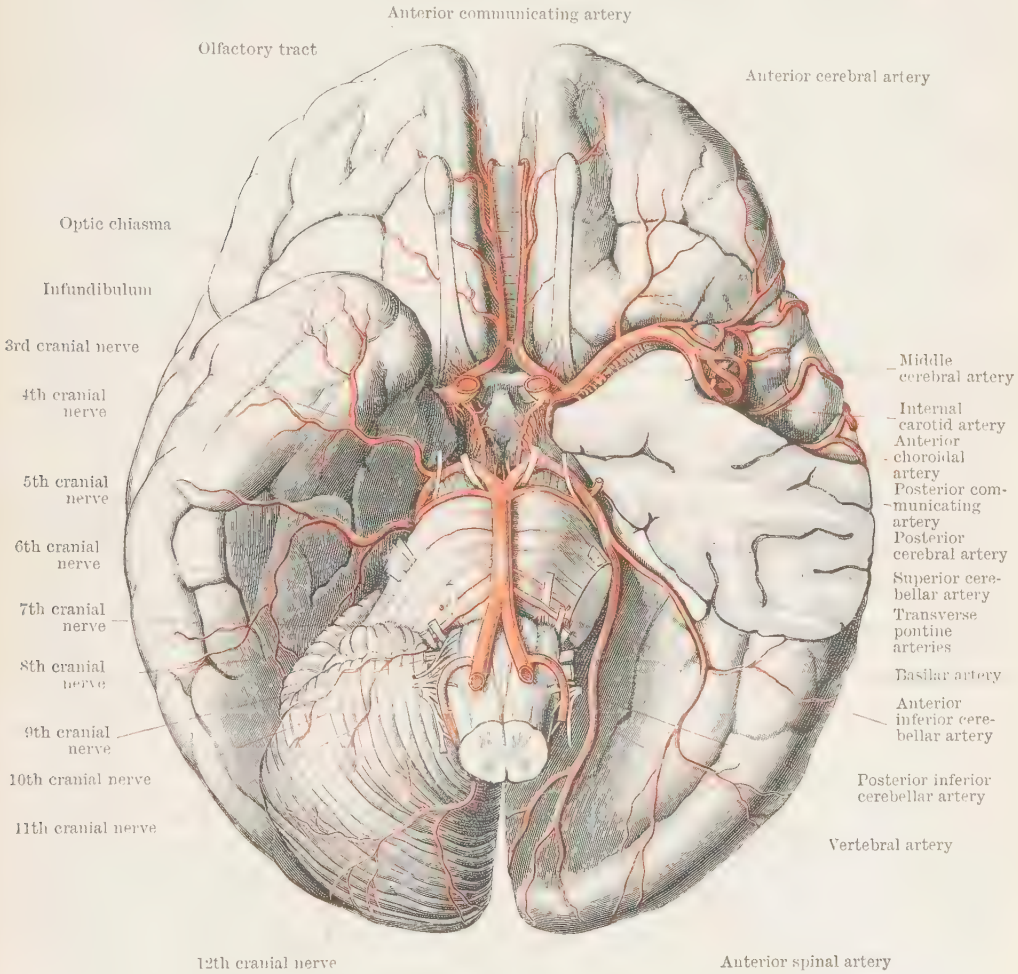

FIG. 627.—THE ARTERIES OF THE BASE OF THE BRAIN. THE CIRCLE OF WILLIS.

the vertebral directly after it has pierced the dura mater. It runs downwards upon the side of the medulla and the spinal cord in front of the posterior nerve roots. It is a slender artery, which is continued to the lower part of the cord by means of reinforcements from the spinal branches of the vertebral and intercostal arteries. It gives off branches to the pia mater, which form more or less regular anastomoses on the inner sides of the posterior nerve roots, and it terminates below by joining the anterior spinal artery.

(3) The **anterior spinal branch** (a. spinalis anterior) arises near the termination of the vertebral. It runs obliquely downwards and inwards, in front of the medulla, and unites with its fellow of the opposite side to form a single anterior spinal artery, which descends in front of the anterior fissure of the spinal cord, and is continued as a fine vessel along the filum terminale. The anterior spinal artery is reinforced as it descends by anastomos-

ing twigs from the spinal branches of the vertebral, intercostal, and lumbar arteries. It gives off branches which pierce the pia mater and supply the cord, and it unites below with the posterior spinal arteries.

(4) The **posterior inferior cerebellar** (a. cerebelli inferior posterior) is the largest branch of the vertebral artery. It arises a short distance below the pons and passes obliquely backwards round the medulla, at first between the roots of the hypoglossal nerve, and then between the roots of the spinal accessory and vagus nerves, into the vallecula of the cerebellum, where it divides into external and internal terminal branches.

The trunk of the artery gives branches to the medulla and to the choroid plexus of the fourth ventricle. The internal terminal, or vermiform branch, runs backwards between the inferior vermiform process and the lateral lobe of the cerebellum; it supplies principally the former structure, and anastomoses with its fellow of the opposite side. The external or hemispheric branch passes outwards on the lower surface of the hemisphere and anastomoses with the superior cerebellar artery.

**Basilar Artery** (a. basilaris).—This artery is formed by the junction of the two vertebral arteries; it commences at the lower border and terminates at the upper border of the pons Varolii, bifurcating at its termination into the two posterior cerebral arteries.

**Course and Relations.**—It runs upwards in a shallow groove on the front of the pons Varolii, behind the sphenoidal section of the basi-cranial axis and between the sixth nerves.

**Branches.**—(1) The **transverse**, a series of small arteries which pass round the sides of the pons, supplying it (rami ad pontem), the middle peduncles of the cerebellum, and the roots of the fifth cranial nerve.

(2) The **auditory** (a. auditiva interna), a pair of long but slender branches which accompany the eighth cranial nerve. Each enters the corresponding internal auditory meatus with the seventh and eighth nerves, and, passing through the lamina cribrosa, is distributed to the internal ear.

(3) The **anterior inferior cerebellar** (a. cerebelli inferior anterior), two branches which arise, one on each side, from the middle of the basilar artery. They pass backwards on the anterior parts of the lower surfaces of the lateral lobes of the cerebellum, and anastomose with the posterior inferior cerebellar branches of the vertebral arteries.

(4) The **superior cerebellar** (aa. cerebelli superiores) branches, two in number, arise near the termination of the basilar. Each passes outwards at the upper border of the pons, directly below the third nerve of the same side, and turning round the outer side of the crus cerebri below the fourth nerve, reaches the upper surface of the cerebellum, where it divides into an internal and an external branch. The internal branch supplies the upper surface of the vermiform process and the valve of Vieussens. The external branch is distributed over the upper surface of the lateral hemisphere, anastomosing at its margin with the inferior cerebellar arteries.

(5) **Posterior Cerebral Arteries** (aa. cerebri posteriores, Figs. 625 and 627).—These are the two terminal branches of the basilar. They run backwards and upwards, between the crura cerebri and the uncinate convolutions and parallel to the superior cerebellar arteries, from which they are separated by the third and fourth cranial nerves. Each posterior cerebral artery is connected with the internal carotid by the posterior communicating artery; it gives branches to the tentorial surface of the cerebrum, and is continued backwards, beneath the splenium of the corpus callosum, to the calcarine fissure, where it divides into calcarine and parieto-occipital branches, which pass to the outer surface of the occipital lobe and supply the inner and tentorial surfaces of the occipital lobe and the posterior part of its outer surface.

**Branches.**—(A) *Central or ganglionic.*—This group includes ($a^1$) A **postero-mesial** set of small vessels which pass on the inner side of the crus cerebri to the posterior perforated space. They supply the crus, the posterior part of the optic thalamus, the corpora albicantia, and the walls of the third ventricle.

($a^2$) A **postero-lateral** set of small vessels which pass round the outer side of the crus cerebri. They supply the corpora quadrigemina, the brachia, the pineal body, the crus, the posterior part of the optic thalamus, and the corpora geniculata.

($a^3$) A **posterior choroidal** set of small branches which pass through the upper part of

the choroidal fissure, and, after entering the posterior part of the velum interpositum, end in the choroid plexus in the body of the lateral ventricle and the upper part of its descending cornu.

(B) *Cortical.*—($b^1$) The **anterior temporal**, frequently a single branch of variable size, is not uncommonly replaced by several small branches. It supplies the anterior parts of the uncinate and the occipito-temporal convolutions.

($b^2$) The **posterior temporal** is a larger branch than the anterior. It supplies the posterior part of the uncinate gyrus, the greater part of the occipito-temporal convolution, and the lingual lobule.

($b^3$) The **calcarine branch** is the continuation of the posterior cerebral artery along the calcarine fissure. It supplies the cuneate lobe, the lingual lobule, and the posterior part of the outer surface of the occipital lobe.

($b^4$) The **parieto-occipital branch**, smaller than the calcarine, passes along the corresponding fissure to the cuneus and precuneus.

**Circle of Willis** (Fig. 627).—The cerebral arteries of opposite sides are intimately connected together at the base of the brain by anastomosing channels. Thus the two anterior cerebral arteries are connected with one another by the anterior communicating artery, whilst the two posterior cerebrals are in continuity through the basilar artery from which they rise. There is also a free anastomosis on each side between the carotid system of cerebral arteries and the vertebral system by means of the posterior communicating arteries, which connect the internal carotid trunks and posterior cerebral arteries.

The vessels referred to form the so-called **circle of Willis** (circulus arteriosus [Willisi]). This is situated at the base of the brain, in the region of the inter-peduncular space, and encloses the following structures: the posterior perforated space, the corpora albicantia, the tuber cinereum, the infundibulum, and the optic commissure. The "circle" is irregularly polygonal in outline, and is formed posteriorly by the termination of the basilar and by the two posterior cerebral arteries, postero-laterally by the posterior communicating arteries and the internal carotids, antero-laterally by the anterior cerebral arteries, and in front by the anterior communicating artery.

It is stated that this free anastomosis equalises the flow of blood to the various parts of the cerebrum, and provides for the continuation of a regular blood-supply if one or more of the main trunks of the basal vessels should be obstructed.

## ARTERIES OF THE UPPER EXTREMITY.

The main arterial stem of each upper extremity passes through the root of the neck, traverses the axillary space, and is continued through the upper arm to the forearm. In the latter it only runs a short distance, terminating just below the bend of the elbow by bifurcating into the radial and ulnar arteries which descend through the forearm to the hand. That portion of the common trunk which lies in the root of the neck is known as the **subclavian artery**, the part in the axillary space is termed the **axillary artery**, whilst the remaining part is called the **brachial artery**.

### THE SUBCLAVIAN ARTERIES.

On the right side the subclavian artery (a. subclavia, Figs. 620 and 622) commences at the termination of the innominate artery behind the sterno-clavicular articulation, whilst that on the left side arises from the arch of the aorta behind the lower part of the manubrium sterni.

The right artery is about three inches long (75 mm.), and it lies in the root of the neck. The left artery is about four inches (100 mm.) long, and is situated not only in the root of the neck, but also in the superior mediastinal part of the thorax. In the root of the neck each artery arches outwards across the apex of the lung and behind the anterior scalene muscle, and is divided into three parts, which lie respectively to the inner side, behind, and to the outer side of the muscle. The extent to which the arch rises above the level of the clavicle varies considerably, and not uncommonly it reaches the level of the lower part of the thyroid body.

The first parts of the subclavian arteries differ materially from each other both in extent and relations. The relations of the second and third parts are similar on both sides.

The **first part of the left subclavian artery** springs from the arch of the aorta to the left of and behind the commencement of the left common carotid and on the left side of the trachea. It ascends, almost vertically, in the superior mediastinum to the root of the neck, where it arches upwards and outwards to the inner border of the scalenus anticus.

**Relations.**—*Posterior.*—In the superior mediastinum, from below upwards, it is in relation *behind* and on its inner side with the left margin of the œsophagus, the thoracic duct, and the left longus colli muscle, whilst the outer part of its posterior surface is covered by pleura.

*Anterior.*—In front and to the right of the artery are the vagus, the left superior cardiac branch of the sympathetic, the left inferior cardiac branch of the vagus, the left phrenic nerve, and the left common carotid artery. It is also crossed obliquely by the left innominate vein above and by the left vagus nerve below, and it is overlapped on the left side by the left lung and pleura.

*Lateral.*—Internally it is in relation, from below upwards, with the trachea, the left recurrent laryngeal nerve, the œsophagus, and the thoracic duct.

Externally it is closely invested by the left pleura, and it ascends in a groove on the inner aspect of the left lung.

As it turns outwards at the root of the neck it lies behind the terminations of the internal jugular, vertebral, and subclavian veins, the phrenic nerve, the sterno-thyroid and sterno-hyoid muscles, the anterior jugular vein, and more superficially the sterno-mastoid muscle, and the deep cervical fascia; the thoracic duct arches obliquely over it, and it lies in front of the apex of the pleural sac.

The **first part of the right subclavian artery** (Fig. 620) extends from the back of the right sterno-clavicular articulation to the inner border of the scalenus anticus. It is thus limited to the root of the neck.

**Relations.**—*Posterior.*—Behind this part of the artery, and intervening between it and the upper two dorsal vertebræ, are the recurrent laryngeal nerve, the posterior part of the annulus Vieusseni, and the apex of the right pleural sac. *Anterior.*—In front it is in relation with the right vagus, the cardiac branches of the vagus and the sympathetic, the anterior portion of the annulus Vieusseni, the internal jugular and vertebral veins, and more superficially the sterno-hyoid and sterno-thyroid muscles, the anterior jugular vein, the sternal end of the clavicle, the sterno-clavicular ligaments, and the sterno-mastoid muscle. The recurrent laryngeal nerve passes *below* it and intervenes between it and the apex of the pleural sac.

The **second part of the subclavian artery**, on *each side*, extends from the inner to the outer border of the scalenus anticus, behind which it lies.

**Relations.**—*Behind* and *below* it is in relation with the pleural sac. In *front* it is covered by the anterior scalene and the sterno-mastoid muscles. The anterior scalene separates it from the subclavian vein, which also lies at a slightly lower level, from the transverse cervical and suprascapular arteries, from the anterior jugular vein, and, on the right side, from the phrenic nerve.

The **third part of the subclavian artery** is the most superficial portion. It extends from the outer border of the anterior scalene to the outer border of the first rib, lying partly in the clavicular portion of the posterior triangle and partly behind the clavicle and the subclavius muscle.

**Relations.**—It rests upon the upper surface of the first rib. Immediately *behind* it is the lowest trunk of the brachial plexus, which separates it from the middle scalene. In *front* of it and at a slightly lower level lies the subclavian vein. The external jugular vein crosses the inner part of this portion of the artery in its course to the subclavian vein, and just before its termination receives the transverse cervical and suprascapular veins; these vessels also pass superficial to the artery, which is thus covered by venous trunks; it is also crossed vertically, behind the veins, by the nerve to the subclavius muscle. The outer section of this part of the artery lies behind the clavicle and the subclavius muscle, and it is crossed from within outwards by the suprascapular artery,

which is separated from it by the layer of deep cervical fascia which binds the posterior belly of the omo-hyoid to the posterior border of the subclavian groove. More superficially the third part of the artery is covered by the superficial layer of the deep fascia, the descending clavicular branches of the cervical nerves, the platysma, and the skin.

### Branches of the Subclavian Artery.

(1) The **vertebral artery** is distributed almost entirely to the head and neck, and its chief function is to supply the posterior part of the brain. Its description has therefore been given with that of the other cerebral arteries (see p. 818).

(2) **Thyroid Axis** (truncus thyreo-cervicalis, Figs. 620 and 622).—This branch arises close to the inner border of the scalenus anticus, and directly above the origin of the internal mammary artery, from the upper and front part of the subclavian artery. After a short upward course of about two lines (4 mm.), it ends under cover of the internal jugular vein by dividing into three branches—viz. the inferior thyroid, the transverse cervical, and the suprascapular.

(A) The **inferior thyroid artery** (a. thyreoidea inferior, Fig. 620) ascends along the anterior border of the scalenus anticus, and turns inwards opposite the cricoid cartilage to the middle of the posterior border of the lateral lobe of the thyroid body; it then curves inwards and downwards, and descends to the lower end of the lobe, where it divides into ascending and inferior terminal branches.

**Relations.**—*Behind* it is the vertebral artery externally and the longus colli muscle internally; the recurrent laryngeal nerve passes either in front of or behind the vessel, opposite the lower border of the thyroid body. It is covered *in front* by the carotid sheath, which contains the common carotid artery, the internal jugular vein, and the vagus nerve; the middle cervical ganglion of the sympathetic lies in front of the artery as it bends inwards, and on the left side the thoracic duct also passes in front of it.

**Branches.**—It gives off the following branches:—

(*a*) **Muscular.**—Numerous small branches pass to the scalenus anticus, the longus colli, the infra-hyoid muscles, and the inferior constrictor of the pharynx.

(*b*) The **ascending cervical branch** (a. cervicalis ascendens) usually springs from the inferior thyroid near its origin, though not uncommonly it rises separately from the thyroid axis. It ascends parallel with and internal to the phrenic nerve, in the angle between the rectus capitis anticus major and the scalenus anticus, to both of which it gives branches. It also gives off spinal branches which pass through the intervertebral foramina to the spinal canal, and it anastomoses with branches of the vertebral, occipital, ascending pharyngeal, and deep cervical arteries.

(*c*) **Œsophageal** (rami œsophagei) are small branches given to the walls of the œsophagus, which anastomose with the œsophageal branches of the thoracic aorta.

(*d*) **Tracheal branches** (rami tracheales) are distributed to the trachea; they anastomose with branches of the superior thyroid and with the bronchial arteries.

(*e*) An **inferior laryngeal branch** (a. laryngea inferior) accompanies the recurrent laryngeal nerve to the lower part of the larynx. It enters the larynx, beneath the lower border of the inferior constrictor, gives branches to its muscles and mucous membrane, and anastomoses with the laryngeal branch of the superior thyroid.

(*f*) The **ascending terminal branch** supplies the posterior and lower part of the thyroid body, and anastomoses with branches of the superior thyroid artery.

(*g*) The **inferior terminal branch** is distributed to the lower and inner part of the thyroid body. It anastomoses with its fellow of the opposite side and with branches of the superior thyroid artery.

(B) The **transverse cervical artery** (a. transversa colli, Figs. 620 and 622) runs upwards, outwards, and backwards from the thyroid axis across the posterior triangle of the neck to the anterior border of the trapezius, where it divides into superficial cervical (ramus ascendens) and posterior scapular (ramus descendens) branches. It is very variable in size, and not infrequently the posterior scapular arises separately from the third part of the subclavian.

Immediately after its origin, under cover of the internal jugular vein, it crosses the scalenus anticus, lying superficial to the phrenic nerve and under cover of the sterno-mastoid muscle; on the left side it is also crossed superficially by the terminal part of the thoracic duct. Passing from beneath the sterno-mastoid, it enters the

lower part of the posterior triangle of the neck, where it lies upon the trunks of the brachial plexus, and, as it runs upwards and backwards to its termination, it passes beneath the posterior belly of the omo-hyoid.

**Branches.**—(*a*) Small **muscular branches** to the surrounding muscles.

(*b*) The **superficial cervical artery** (a. cervicalis superficialis), usually a slender branch, passes beneath the trapezius; it runs upwards over the levator anguli scapulæ

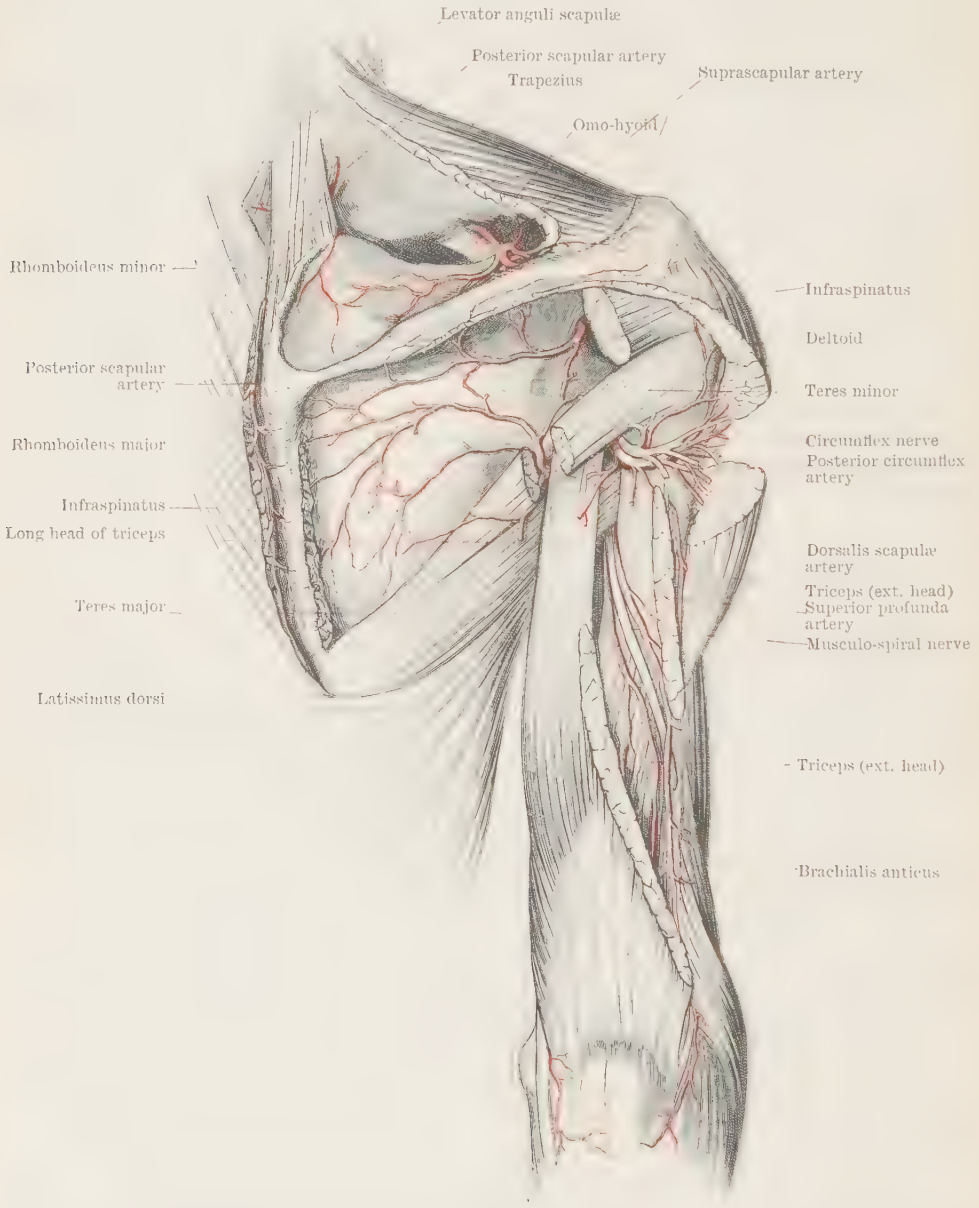

FIG. 628.—DISSECTION OF THE BACK OF THE SHOULDER AND UPPER ARM, showing the anastomosing vessels on the dorsum of the scapula, and the posterior circumflex and superior profunda arteries.

and upon the splenius, and anastomoses with the arteria princeps cervicis, a branch of the occipital artery, and it sends branches downwards which accompany the spinal accessory nerve and anastomose with the posterior scapular and suprascapular arteries.

(*c*) The **posterior scapular artery** descends in front of the levator anguli scapulæ and the rhomboid muscles, close to the posterior border of the scapula. It runs parallel with, and a short distance away from, the nerve to the rhomboid muscles, and it sends branches into the supraspinous, the infraspinous, and the subscapular fossæ, which

anastomose with branches of the suprascapular and subscapular arteries. It also sends branches backwards through and between the rhomboid muscles, which anastomose with the superficial cervical artery and with the dorsal branches of the intercostal arteries.

(C) The **suprascapular artery** (a. transversa scapulæ) springs from the thyroid axis, and terminates in the infraspinous fossa of the scapula. As a rule it is smaller than the transverse cervical artery.

Commencing behind the internal jugular vein, it crosses the scalenus anticus and phrenic nerve, and is covered in front by the sterno-mastoid and the anterior jugular vein; on the left side it lies behind the termination of the thoracic duct also. Continuing outwards and backwards behind the clavicle, and crossing superficially to the third part of the subclavian artery and the cords of the brachial plexus, it reaches the suprascapular notch and passes over the suprascapular ligament. From this point it descends with the suprascapular nerve through the supraspinous fossa and beneath the supraspinatus muscle, and passing through the great scapular notch in front of the spino-glenoid ligament, enters the infraspinous fossa, where it anastomoses with the dorsal branch of the subscapular and with branches of the posterior scapular arteries.

**Branches.**—(*a*) **Muscular**, to the sterno-mastoid, the subclavius, and the muscles on the dorsum of the scapula.

(*b*) The **medullary**, a small branch to the clavicle.

(*c*) The **suprasternal**, to the sternal end of the clavicle and the sterno-clavicular joint.

(*d*) **Acromial branches**, which ramify over the acromion process, anastomosing with the acromial branches of the acromio-thoracic and the posterior circumflex arteries.

(*e*) **Articular**, to the acromio-clavicular and shoulder-joints.

(*f*) The **subscapular**, which is given off as the artery, passes over the suprascapular ligament. It passes down into the subscapular fossa, gives branches to the subscapularis, and anastomoses with the branches of the subscapular and posterior scapular arteries.

(*g*) **Supraspinous**, which ramify in the supraspinous fossa, supplying the muscle, and anastomosing with the posterior scapular.

(*h*) **Terminal branches** ramify in the infraspinous fossa, and anastomose with the dorsalis scapulæ and with branches of the posterior scapular artery.

(3) **Internal Mammary Artery** (a. mammaria interna. Fig. 620).—This arises from the lower and front part of the subclavian at the inner border of the scalenus anticus and immediately below the origin of the thyroid axis. It terminates behind the inner extremity of the sixth intercostal space by dividing into the musculo-phrenic and the superior epigastric arteries.

The artery passes at first downwards, forwards, and inwards, lying upon the pleura, and behind the subclavian vein, the sternal end of the clavicle, and the cartilage of the first rib: it is crossed obliquely from without inwards by the phrenic nerve, which usually passes in front of it. From the cartilage of the first rib it descends vertically, about half-an-inch from the border of the sternum, and lies in the upper part of its course in front of the pleura, and in the lower part in front of the triangularis sterni. It is covered anteriorly by the cartilages of the upper six ribs, the intervening intercostal muscles, and the terminal portions of the intercostal nerves, and it is accompanied by two venæ comites, which unite together above and on its inner side to form a single trunk which terminates in the innominate vein.

**Branches.**—(*a*) The **comes nervi phrenici** (a. pericardiaco-phrenica), or superior phrenic artery, is a long slender branch which is given off from the upper part of the internal mammary. It accompanies the phrenic nerve through the superior and middle mediastinal spaces to the diaphragm, where it anastomoses with the inferior phrenic and musculo-phrenic arteries. In its course downwards the artery gives off numerous small branches to the pleura and pericardium, which anastomose with offsets of the mediastinal and pericardial branches of the aorta and internal mammary arteries, and also with the bronchial arteries, forming the wide-meshed subpleural plexus of Turner.

(*b*) **Mediastinal branches** (aa. mediastinales anteriores), small and numerous, pass to the areolar tissue of the anterior mediastinal space and supply the remains of the thymus gland and the sternum.

(*c*) **Pericardial.**—These are several small branches which ramify on the anterior aspect of the pericardium.

(*d*) The **anterior intercostal** (rami intercostales) are two in number in each of the upper six intercostal spaces. They pass outwards for a short distance either between the pleura or the triangularis sterni and the internal intercostal muscles; they then pierce the internal intercostal muscles, and ramify between them and the external intercostal muscles, anastomosing with the aortic and superior intercostal arteries and their collateral branches.

(*e*) The **anterior perforating branches** (rami perforantes), one in each of the upper six intercostal spaces, are small vessels which pass forwards with the intercostal nerves, piercing the internal intercostal muscle, the anterior intercostal membrane, and the pectoralis major, to terminate in the skin and subcutaneous tissue. They supply twigs to the sternum, and those in the third and fourth spaces, usually the largest of the series, give off branches to the mammary gland.

(*f*) The **musculo-phrenic** (a. musculo-phrenica), or external terminal branch of the internal mammary artery, runs downwards and outwards from the sixth intercostal space to the tenth costal cartilage. In the upper part of its course it lies upon the thoracic surface of the diaphragm, but it pierces the muscle about the level of the eighth costal cartilage, and terminates on its abdominal surface. Its branches are :—

(i.) **Muscular**, which supply the diaphragm and anastomose with the superior and inferior phrenic arteries.

(ii.) **Anterior intercostal branches**, two in each of the seventh, eighth, and ninth intercostal spaces; they are distributed in the same manner as the corresponding branches of the internal mammary artery, and terminate by anastomosing with the aortic intercostals and their collateral branches.

(*g*) The **superior epigastric** (a. epigastrica superior), or internal terminal branch of the internal mammary artery, descends into the anterior wall of the abdomen. It leaves the thorax, between the sternal and costal origins of the diaphragm, and enters the sheath of the rectus, lying first behind, and then in the substance of the rectus muscle. It terminates by anastomosing with branches of the deep epigastric artery. Its branches are :—

(i.) **Muscular**, to the rectus, to the flat muscles of the abdominal wall, and to the diaphragm.

(ii.) **Anterior Cutaneous.**—These branches pierce the rectus and the anterior portion of its sheath. They accompany the anterior terminal branches of the lower intercostal nerves, and terminate in the subcutaneous tissues and skin of the middle portion of the anterior abdominal wall.

(iii.) **Ensiform**, a small branch which crosses the front of the ensiform process to anastomose with its fellow of the opposite side. It supplies the adjacent muscles and skin.

(iv.) **Hepatic branches** of small size pass backwards in the falciform ligament to the liver, where they anastomose with branches of the hepatic artery.

(4) **Superior Intercostal Artery** (truncus costo-cervicalis. Fig. 624).—The superior intercostal artery springs from the back of the second part of the subclavian artery on the right side and from the first part on the left side. It runs upwards and backwards from its origin, over the apex of the pleural sac, to the neck of the first rib in front of which it descends, between the first thoracic ganglion of the sympathetic cord and the first dorsal nerve, to the first intercostal space, where it divides into two branches which are distributed to the upper two intercostal spaces.

**Branches.**—(*a*) The **profunda cervicis** (a. cervicalis profunda).—This branch sometimes arises from the subclavian artery directly; but more commonly it springs from the superior intercostal at the upper border of the neck of the first rib. It runs backwards, like the dorsal branch of an intercostal artery, passes between the first dorsal and last cervical nerves, and between the transverse process of the last cervical vertebra and the neck of the first rib to the back of the neck, where it ascends between the complexus and the semispinalis colli muscle to terminate by anastomosing with the deep branch of the princeps cervicis artery. It also anastomoses with branches of the ascending cervical and vertebral arteries, supplies the adjacent muscles, and sends a spinal branch, through the intervertebral foramen between the last cervical and the first dorsal vertebræ, into the spinal canal, where it anastomoses with the spinal branches of the vertebral and intercostal arteries.

(*b*) **Terminal.**—The two terminal branches run outwards—one in the first and one in the second intercostal space. Each runs near the upper border of its space, passing at first between the pleura and the posterior intercostal membrane, and then between the

internal and external intercostal muscles. The branches terminate by anastomosing with anterior intercostal branches of the internal mammary artery. Each gives off muscular branches to the intercostal muscles—a nutrient branch to the rib below which it lies, and a collateral branch which runs along the lower border of the space and terminates by anastomosing with an anterior intercostal branch of the internal mammary artery.

## THE AXILLARY ARTERY.

The **axillary artery** (a. axillaris) lies in the axillary space. It is the direct continuation of the subclavian artery, and it becomes the brachial artery.

The axillary artery commences at the outer border of the first rib, at the apex of the axillary space. It descends, with an outward inclination, along the external

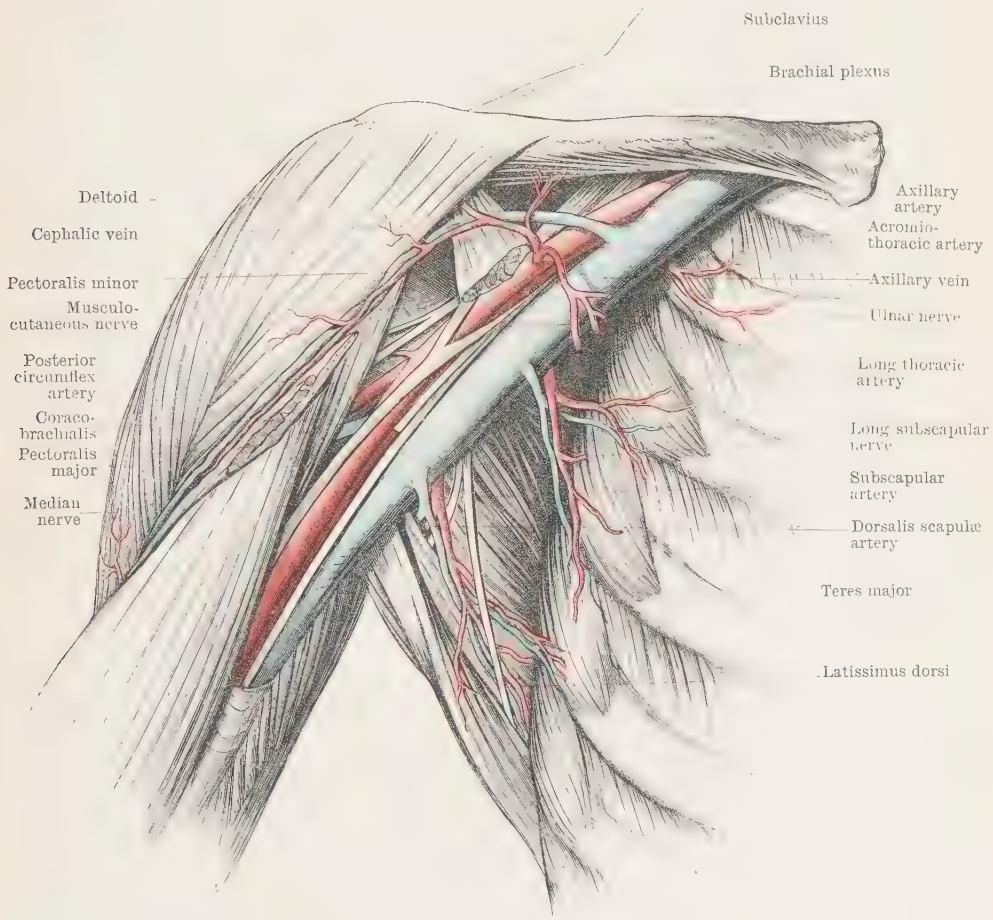

Fig. 629.—The Axillary Artery and its Branches and Relations.

wall of the space, *i.e.* to the inner side of the shoulder-joint and the humerus, to the lower border of the teres major, where it becomes the brachial artery. A line drawn from the middle of the clavicle to the inner border of the prominence of the coraco-brachialis and biceps muscles, when the arm is abducted until it is at right angles with the side, indicates the position and direction of the artery.

The position and direction, however, and to a certain extent the relations also of the axillary artery, are modified by changes in the position of the upper extremity. With the arm hanging by the side the axillary artery describes a curve with the concavity directed downwards and inwards, and the vein is to its inner side. When the arm is at right angles with the side, the axillary artery is almost straight, it lies closer to the outer wall of the axilla, and the vein overlaps it in front and on the inner side. When the arm is raised above the level of the

shoulder the axillary artery is curved over the head of the humerus, and the vein lies still more in front of it.

For descriptive purposes the artery is divided into three parts: the first part lies above, the second behind, and the third part below the pectoralis minor muscle.

Though we have followed the usual custom in describing three parts of the axillary artery,—a division which is perhaps of practical interest in so far as it emphasises the fact that the axillary artery is surgically accessible above the pectoralis minor,—it is to be noted that the upper border of the pectoralis minor is usually exactly opposite the outer border of the first rib, at the point where the axillary artery begins. In the strict sense, therefore, no part of the artery is above the pectoralis minor.

**Relations of the first part.**—*Posterior.*—The first part of the artery is enclosed, together with the vein and the cords of the brachial plexus, in a prolongation of the cervical fascia known as the axillary sheath, behind which is the upper serration of the serratus magnus muscle, the contents of the first intercostal space, the inner cord of the brachial plexus, the internal anterior thoracic and the posterior thoracic nerves, the latter descending vertically between the artery and the serratus magnus. *Anterior.*—It is covered in front by the costo-coracoid membrane, the upper part of which splits to enclose the subclavius muscle. The membrane intervenes between the artery and the cephalic vein, the branches of the external anterior thoracic nerve, the branches of the acromio-thoracic artery with their accompanying veins, and the clavicular part of the pectoralis major muscle, superficial to which are the deep fascia, the platysma, the descending clavicular branches of the cervical plexus, and the superficial fascia and the skin. Behind the costo-coracoid membrane the artery is crossed by a loop of communication between the external and internal anterior thoracic nerves. *Lateral.*—Above and to the outer side are the outer and posterior cords of the brachial plexus and the external anterior thoracic nerve. Below and to the inner side is the axillary vein, the internal anterior thoracic nerve intervening.

**Relations of the second part.**—*Posterior.*—Behind this portion of the artery is the posterior cord of the brachial plexus and a layer of fascia which separates it from the subscapularis muscle. *Anterior.*—In front is the pectoralis minor, and more superficially the pectoralis major, the fasciæ and skin. *Lateral.*—To the outer side lies the outer cord of the brachial plexus. On the inner side the inner cord of the plexus lies in close relation to the artery, and intervenes between it and the axillary vein.

**Relations of the third part.**—*Posterior.*—The third part of the artery rests posteriorly upon the lower border of the subscapularis, the latissimus dorsi, and the teres major. It is separated from the fibres of the subscapularis by the circumflex and musculo-spiral nerves, and from the latissimus dorsi and teres major by the musculo-spiral nerve alone. *Anterior.*—It is crossed in front by the inner head of the median nerve. In its upper half it lies under cover of the lower part of the pectoralis major, the fascia and skin, whilst its lower part, which is superficial, is covered by skin and fascia only. *Lateral.*—To the outer side lie the median and musculo-cutaneous nerves and the coraco-brachialis muscle. To the inner side is the axillary vein. The two vessels are, however, separated by two of the chief branches of the inner cord of the brachial plexus. In the angle between the vein and the artery, and somewhat in front of the latter, lies the internal cutaneous nerve; in the angle behind is the ulnar nerve. The lesser internal cutaneous nerve lies internal to the vein, and the venæ comites of the brachial artery ascend along the inner side, to terminate in the axillary vein at the lower border of the subscapularis muscle.

### Branches of the Axillary Artery.

(1) The **superior thoracic** (a. thoracalis suprema, Fig. 629), a small branch which arises from the first part of the axillary at the lower border of the subclavius. It runs downwards and inwards across the first intercostal space, pierces the inner part of the costo-coracoid membrane, and supplies branches to the subclavius, the pectoralis major and minor, and to the serratus magnus and the intercostal muscles; it anastomoses with branches of the suprascapular, the internal mammary, and the acromio-thoracic arteries.

(2) The **acromio-thoracic** (a. thoraco-acromialis, Fig. 629) arises near the upper border of the pectoralis minor, from the second part of the axillary artery. It is a

very short trunk, of considerable size, which passes forwards, pierces the costo-coracoid membrane, and terminates beneath the clavicular portion of the pectoralis major by dividing into four terminal branches—clavicular, pectoral, humeral, and acromial.

(*a*) The **clavicular branch** (ramus clavicularis) is a long slender artery which runs upwards and inwards to the sterno-clavicular joint, anastomosing with the superior thoracic, with branches of the suprascapular, and with the first perforating branch of the internal mammary artery. It supplies the adjacent muscles and the sterno-clavicular articulation.

(*b*) The **pectoral** (ramus pectoralis), or thoracic, is a large branch which descends between the two pectoral muscles, to both of which it gives branches, and it anastomoses with the intercostal and long thoracic arteries.

(*c*) The **humeral branch** (ramus deltoideus) runs outwards to the groove between the pectoralis major and the deltoid, in which it descends by the side of the cephalic vein to the insertion of the deltoid. It anastomoses with the acromial branch and with the anterior circumflex artery, and it gives branches to the pectoralis major and deltoid muscles and to the skin.

(*d*) The **acromial branch** (ramus acromialis) runs upwards and outwards across the tip of the coracoid process to the acromion, where it anastomoses with the last-described branch, with the acromial branches of the suprascapular, and with the posterior circumflex arteries. It gives branches to the deltoid.

(3) The **long thoracic** (a. thoracalis lateralis) arises from the second part of the axillary, and descends along the lower border of the pectoralis minor to anastomose with the intercostal and subscapular arteries, and with the pectoral branch of the acromio-thoracic. It supplies the adjacent muscles, and sends branches to the outer part of the mammary gland; hence it is not infrequently called the **external mammary artery**.

(4) The **alar thoracic** is only occasionally present as a distinct branch, but it is frequently represented by a number of small irregular branches, which may either arise from the axillary or from the thoracic and subscapular branches. It is distributed to the glands and areolar tissue in the axilla.

(5) The **subscapular artery** (a. subscapularis) is the largest branch of the axillary artery. It arises from the third part of the artery, opposite the lower border of the subscapularis, along which it descends to the lower angle of the scapula and to the inner wall of the axillary space. It is accompanied by the second or long subscapular nerve; it supplies the adjacent muscles, and it anastomoses with the posterior scapular, the suprascapular, the long thoracic, and the lateral branches of the intercostal arteries, and gives off one named branch, the dorsalis scapulæ.

The **dorsalis scapulæ artery** (a. circumflexa scapulæ) is frequently larger than the continuation of the subscapular artery. It arises about one and a half inches (37 mm.) from the commencement of the subscapular trunk, and passes backwards into the triangular space between the subscapularis above, the teres major below, and the long head of the triceps externally. Turning round, and usually grooving the axillary border of the scapula, under cover of the teres minor, it enters the infraspinous fossa, where it breaks up into branches which anastomose with branches of the posterior scapular and suprascapular arteries. Whilst it is in the triangular space the dorsal artery gives off an *infrascapular branch* which passes into the subscapular fossa beneath the subscapularis, and terminates by anastomosing with the branches of the posterior and suprascapular arteries. It also gives off in the same situation a descending branch, which runs downwards to the lower angle of the scapula between the teres major and minor muscles, and small branches are given to the deltoid and scapular head of triceps.

(6) The **posterior circumflex** (a. circumflexa humeri posterior) arises from the third part of the axillary artery and passes backwards, accompanied by the circumflex nerve, through an intermuscular cleft, the so-called quadrilateral space, which is bounded by the teres minor and subscapularis above, the teres major below, the long head of the triceps internally, and the humerus externally. It turns round the surgical neck of the humerus under cover of the deltoid muscle, and terminates in numerous branches which supply the deltoid. As a rule it is an artery of large size, only slightly smaller than the subscapular.

**Branches.**—(*a*) **Muscular** to the teres major and minor, the triceps heads, long and external, and the deltoid; (*b*) An **acromial branch,** which ascends to the acromial process, where it anastomoses with the acromial branches of the suprascapular and the acromio-thoracic arteries; (*c*) A **descending branch,** which runs downwards along the external head of the triceps to anastomose with the superior profunda artery; (*d*) **Articular** to the shoulder-joint; (*e*) **Nutrient** to the head of the humerus; (*f*) **Terminal,** which supply a large portion of the deltoid, and anastomose with the anterior circumflex and acromio-thoracic arteries.

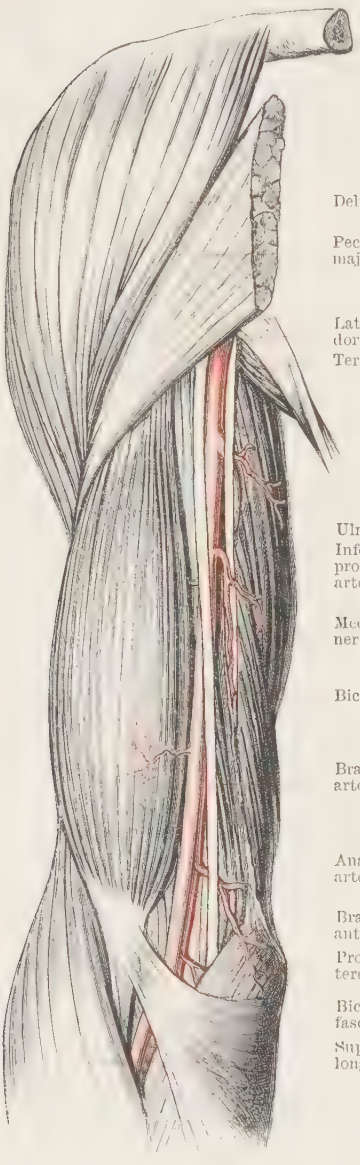

Fig. 630.—The Brachial Artery and its Branches.

(7) The **anterior circumflex artery** (a. circumflexa humeri anterior) is a small branch which is given off from the third part of the axillary close to, or in common with, the posterior circumflex. It passes outwards behind the coraco-brachialis and the two heads of the biceps, round the front of the surgical neck of the humerus, and terminates by anastomosing with the posterior circumflex. At the bicipital groove it gives a well-marked ascending bicipital branch which ascends along the long head of the biceps, supplying the sheath of the tendon, and giving branches to the shoulder-joint. It also gives muscular branches to the adjacent muscles, one of which descends along the tendon of insertion of the pectoralis major.

## THE BRACHIAL ARTERY.

The **brachial artery** (a. brachialis, is the direct continuation of the axillary. It commences at the lower border of the teres major, and terminates in the ante-cubital fossa at the level of the neck of the radius, by dividing into the radial and ulnar arteries.

The general course of the brachial artery is downwards and outwards, along the inner side of the arm. Its position may be indicated on the surface by a line drawn from the lower part of the axillary space at the junction of its anterior and middle thirds to the centre of the bend of the elbow.

**Relations.**—*Posterior.*—It lies successively in front of the long head of the triceps, the musculo-spiral nerve and the superior profunda artery intervening, the internal head of the triceps, the insertion of the coraco-brachialis and the brachialis anticus. *Anterior.*—It is overlapped *in front* by the inner border of the biceps, is crossed at its centre by the median nerve, and in addition is covered by deep and superficial fascia and by skin. In the ante-cubital fossa a thickened portion of the deep fascia, the semilunar or bicipital fascia, separates it from the median basilic vein and the anterior branch of the internal cutaneous nerve, both of which lie in the superficial fascia. *Lateral.*—To the *outer side* it is in relation above with the median nerve, and below with the biceps. To the *inner side* it is in relation in the upper part of its extent with the basilic vein, the internal cutaneous, lesser internal cutaneous, and ulnar nerves, and in the lower part with the median nerve. Two venæ comites, one on each side, accompany the artery, and communications between these pass across the vessel.

### Branches of the Brachial Artery.

(1) The **superior profunda** (a. profunda brachii) is a large branch which arises from the inner and back part of the brachial soon after its commencement. It runs downwards and outwards, with the musculo-spiral nerve, in the musculo-spiral groove, and divides at the back of the humerus into two terminal branches, the anterior and the posterior. Not infrequently this division takes place at a higher level, and the artery appears double. The anterior terminal branch accompanies the musculo-spiral nerve through the external intermuscular septum, and descends between the supinator longus and the brachialis anticus to the front of the external condyle, where it anastomoses with the radial recurrent artery. The posterior terminal branch descends behind the external intermuscular septum, and anastomoses behind the external condyle with the posterior interosseous recurrent artery and with the anastomotic artery.

Whilst they are lying at the back of the humerus one of the terminal branches gives off—(*a*) a slender twig, which descends in the substance of the internal head of the triceps to the back of the elbow, where it anastomoses with the anastomotic artery; (*b*) a nutrient branch, which enters a foramen on the posterior surface of the humerus; and (*c*) an ascending branch, which anastomoses with the descending branch of the posterior circumflex artery.

(2) **Muscular branches** are given to the biceps, coraco-brachialis, brachialis anticus, triceps, and pronator radii teres.

(3) **Nutrient.**—A small artery which arises from the middle of the brachial and enters the nutrient foramen on the inner side of the shaft of the humerus.

(4) The **inferior profunda** (a. collateralis ulnaris superior) is smaller than the superior profunda, with which it sometimes rises by a common trunk; usually, however, it springs from the inner and back part of the middle of the brachial. It runs downwards and backwards, with the ulnar nerve, through the internal intermuscular septum, and then, descending more vertically, reaches the back of the internal condyle of the humerus, where it terminates by anastomosing with the posterior and anterior ulnar recurrent and anastomotic arteries.

(5) The **anastomotic** (a. collateralis ulnaris inferior) rises from the inner side of the brachial artery about two inches (50 mm.) above its termination. It runs inwards behind the median nerve and in front of the brachialis anticus, it then pierces the internal intermuscular septum, and turns outwards between the inner head of the triceps and the posterior surface of the bone to the external condyle. It supplies the adjacent muscles and anastomoses, in front of the internal condyle, with the anterior ulnar recurrent, behind the internal condyle with the posterior ulnar recurrent and the inferior profunda, at the middle of the back of the humerus with a branch of the superior profunda, and behind the external condyle with the posterior terminal branch of the superior profunda and the posterior interosseous recurrent artery.

### The Radial Artery.

The **radial artery** (a. radialis, Figs. 631, 632, and 633) is the smaller of the two terminal branches of the brachial artery, but it is the more direct continuation of the parent trunk. It commences in the ante-cubital fossa opposite the neck of the radius, and terminates in the palm of the hand, by anastomosing with the deep branch of the ulnar artery, and thus completing the deep palmar arch.

The trunk is divisible into **three parts.**

The *first part* lies on the front of the forearm. It runs downwards and somewhat outwards to the apex of the styloid process of the radius. The *second part* curves round the outer side of the wrist and across the back of the trapezium to reach the proximal end of the first interosseus space. The *third part* passes forwards through the first interosseous space to the palm of the hand, where it joins the deep branch of the ulnar artery.

**Relations of the first part.**—*Posterior.*—It passes successively in front of the following structures: the tendon of insertion of the biceps, the supinator brevis, the pronator radii teres, the radial portion of the flexor sublimis digitorum, the flexor longus pollicis, the pronator quadratus, and the anterior ligament of the wrist-joint. *Anterior.*—

The artery is overlapped in the upper half by the anterior border of the supinator longus; in the remainder of its extent it is covered only by skin and fascia. *Lateral.*—To the *outer side* is the brachio-radialis, or supinator longus, and the radial nerve. This latter lies quite near to the artery in its middle third. To the *inner side* is the pronator radii teres above and the flexor carpi radialis below. Two venæ comites, one on each side, accompany the artery.

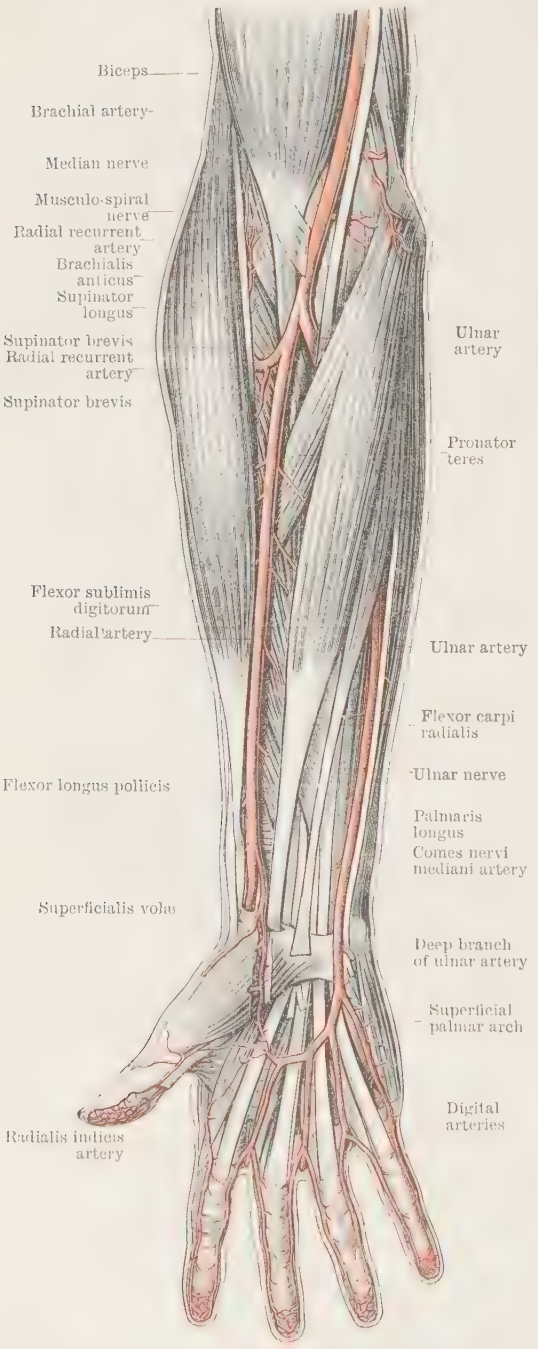

FIG. 631.—SUPERFICIAL DISSECTION OF THE FRONT OF THE FOREARM AND HAND, showing the radial and ulnar arteries and the superficial palmar arch with its branches.

**Branches of the first part.**—(1) The **radial recurrent** (a. recurrens radialis) arises in the ante-cubital fossa. It springs from the outer side of the radial in front of the supinator brevis. It runs outwards, passes between the radial and posterior interosseous nerves, and then ascends to the external condyle of the humerus, where it anastomoses with the anterior terminal branch of the superior profunda. The radial recurrent supplies numerous muscular branches to the supinator longus, the supinator brevis, the extensor carpi radialis longior, and the extensor carpi radialis brevior.

(2) **Muscular branches** (rami musculares) to the muscles on the radial side of the anterior aspect of the forearm.

(3) The **superficialis volæ** (ramus volaris superficialis, Fig. 631) is a slender vessel which arises a short distance above the wrist and runs downwards across the ball of the thumb. It usually pierces the superficial muscles of the thenar eminence, and terminates either in their substance or by uniting with the ulnar artery and completing the superficial palmar arch of the hand.

(4) An **anterior radial carpal branch** (ramus carpeus volaris) passes inwards beneath the flexor tendons and their synovial sheaths, and crosses the anterior carpal ligaments. It anastomoses with the anterior carpal branch of the ulnar artery to form the anterior carpal arch, and it receives communications from the anterior interosseous artery and from the deep palmar arch.

**Relations of the second part.**—As it curves round the outer side and the back of the wrist, the radial artery lies upon the external lateral ligament of the intercarpal joint and upon the back of the trapezium. It is crossed by the extensor ossis metacarpi pollicis, the extensor brevis pollicis, and the extensor longus pollicis; more superficially it is covered by fascia, in which are some filaments of the radial nerve and the commencement of the radial vein, and by skin.

**Branches of the second part.**—(1) **Dorsales Pollicis.**—Two small arteries which run along the borders of the dorsal aspect of the thumb; they supply the skin, tendons, and joints, and anastomose with the palmar digital arteries.

(2) **Dorsalis Indicis.**—A slender artery which runs downwards on the ulnar head of the first dorsal interosseous muscle and along the dorsal aspect of the radial border of the index-finger.

(3) and (4) The **metacarpal** or **first dorsal interosseous** and **posterior radial carpal** arise by a common trunk which crosses beneath the extensor longus pollicis.

(*a*) The metacarpal branch (a. metacarpea dorsalis) descends on the dorsal aspect of the second dorsal interosseous muscle, and divides opposite the heads of the metacarpal bones into two digital branches which supply the adjacent sides of the index and middle fingers. (*b*) The posterior carpal branch (ramus carpeus dorsalis) runs inwards on the dorsal carpal ligaments, and in front of the extensor tendons, to anastomose with the posterior carpal branch of the ulnar artery, and to complete the **dorsal carpal arch** which receives the terminations of the anterior and posterior interosseous arteries. The dorsal carpal arch gives off the **second** and **third dorsal interosseous arteries** (aa. metacarpæ dorsales), which descend on the dorsal aspects of the third and fourth dorsal interosseous muscles as far as the heads of the metacarpal bones, where each divides into two branches (aa. digitales dorsales), for the adjacent sides of the third and fourth and the fourth and fifth fingers respectively.

Each dorsal interosseous artery is connected with the deep palmar arch by a **superior perforating branch** which passes through the upper part of the corresponding interosseous space, and with a digital branch from the superficial palmar arch by an **inferior perforating branch** which passes through the lower part of the space.

**Relations of the third part.**—The third part of the radial artery passes forwards between the two heads of the first dorsal interosseous muscle to reach the palm, where it turns inwards beneath the upper part of the oblique adductor muscle of the thumb, and, after passing through the upper fibres of the tranverse adductor, or between the adjacent borders of the oblique and transverse adductors, it unites with the deep branch of the ulnar artery, completing the deep palmar arch.

**Branches of the third part.**—(1) The **princeps pollicis** (a. princeps pollicis) branch is given off as soon as the radial artery enters the palm. It runs downwards in front of the first metacarpal bone, between the oblique adductor and the opponens pollicis, and under cover of the long flexor tendon, and divides near the lower end of the bone into collateral branches which run along the sides of the thumb and anastomose with the dorsales pollicis arteries.

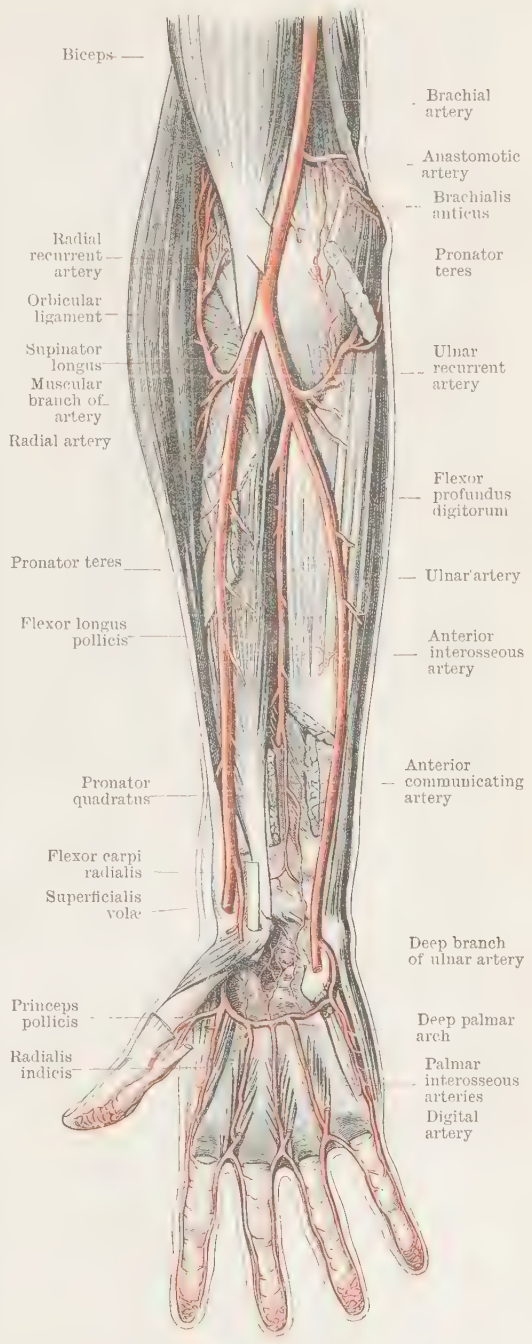

FIG. 632.—DEEP DISSECTION OF THE FRONT OF THE FOREARM AND HAND, showing the radial and ulnar arteries and their branches and the deep palmar arch and its branches.

(2) The **radialis indicis** (a. volaris indicis radialis) is a branch which descends between the ulnar head of the first dorsal interosseous muscle and the transverse adductor of the thumb. It runs along the radial side of the index-finger to its tip, supplying the adjacent tissues; not uncommonly it anastomoses with the superficial palmar arch.

### The Ulnar Artery.

The **ulnar artery** (a. ulnaris, Figs. 631 and 632) is the larger terminal branch, but the less direct continuation of the brachial artery. It commences in the ante-cubital fossa, opposite the neck of the radius, and terminates in the palm of the hand, where it anastomoses with the superficialis volæ to form the superficial palmar arch.

From its origin it runs obliquely downwards and inwards, beneath the muscles arising from the internal condyle, to the junction of the upper and middle thirds of the forearm, where it comes into relation with the ulnar nerve; it then descends vertically, on the radial side of the ulnar nerve, to the wrist, crosses in front of the main part of the annular ligament to the radial side of the pisiform bone, and enters the palm of the hand to form the main part of the superficial palmar arch.

**Relations.**—*Posterior.*—From above downwards it lies in front of the lower part of the brachialis anticus, the flexor profundus digitorum, and the deep portion of the anterior annular ligament. *Anterior.*—In front it is crossed, in the oblique part of its course, by the pronator radii teres, the median nerve, which is separated from the artery by the deep head of the pronator, the flexor sublimis digitorum, the flexor carpi radialis, and the palmaris longus. In the middle third of the forearm it is overlapped by the anterior border of the flexor carpi ulnaris, and in the lower third it is covered by skin and fascia only. A short distance above the wrist the palmar cutaneous branch of the median nerve lies in front of it, and as it crosses the anterior annular ligament, it is bound down by a fascial expansion from the tendon of the flexor carpi ulnaris. Two venæ comites, which frequently communicate with one another, lie one on either side of the artery. *Lateral.*—On the *radial side* there is also, in its lower two-thirds, the flexor sublimis digitorum. On its *ulnar side* there are the flexor carpi ulnaris and the ulnar nerve.

**Branches.**—(1) The **anterior ulnar recurrent** is a small branch which arises in the ante-cubital fossa, frequently in common with the posterior ulnar recurrent. It passes upwards to the front of the internal condyle, under cover of the pronator radii teres, and anastomoses with branches of the anastomotic and inferior profunda arteries.

(2) The **posterior ulnar recurrent branch**, larger than the anterior, arises in the ante-cubital fossa, from the inner side of the ulnar artery, and ascends on the brachialis anticus, and under cover of the muscles which rise from the internal condyle to the back of that prominence, where it passes between the humeral and olecranoid heads of the flexor carpi ulnaris, and anastomoses with the inferior profunda and anastomotic arteries. It gives branches to the adjacent muscles and to the elbow-joint.

(3) The **common interosseous artery** (a. interossea communis), a short trunk which springs from the outer and back part of the ulnar artery in the lower part of the ante-cubital fossa. It passes backwards towards the upper border of the interosseous membrane, and divides into anterior and posterior interosseous branches.

(3*a*) The **anterior interosseous artery** (a. interossea volaris) descends in front of the interosseous membrane, between the adjacent borders of the flexor longus pollicis and the flexor profundus digitorum, to the upper border of the pronator quadratus, where it pierces the interosseous membrane, and continues its descent, first on the posterior surface of the membrane, under cover of the extensor longus pollicis and extensor indicis, and then on the radius, in the groove for the extensor communis digitorum, and it terminates on the back of the carpus in the posterior carpal arch. It is accompanied whilst in front of the interosseous membrane by the anterior interosseous nerve, and after it has pierced the membrane, by the posterior interosseous nerve.

**Branches.**—(*a*) **Nutrient** to the radius and ulna; (*b*) **Muscular** to the adjacent muscles; (*c*) The **anterior communicating**, a slender branch which descends behind the pronator quadratus and in front of the interosseous membrane to anastomose with the anterior carpal arch; (*d*) Small **anastomotic branches** are given off at the back of the forearm to anastomose with the posterior interosseous artery; (*e*) The **comes nervi mediani** (a. mediana) is a long slender branch which rises from the upper part of the artery and descends in the front of the median nerve to the palm, where it anastomoses with recurrent branches of the superficial palmar arch.

(3*b*) The **posterior interosseous trunk** (a. interossea dorsalis) is usually smaller than the anterior interosseous. It passes backwards between the upper border of the interosseous membrane and the oblique ligament, and then between the supinator brevis and the extensor ossis metacarpi pollicis, after which it descends between the superficial and deep muscles on the back of the forearm to the wrist, where it anastomoses with the anterior interosseous artery and with the posterior carpal arch. As it crosses the

extensor ossis metacarpi pollicis it is accompanied by the posterior interosseous nerve, but in the remainder of its course it is separated from the nerve by the deep muscles.

**Branches.**—(*a*) **A posterior interosseous recurrent** (a. interossea recurrens) branch is given off as soon as the posterior interosseous artery has passed beneath the lower border of the supinator brevis. It ascends on the posterior surface of the supinator brevis, under cover of the anconeus, to the back of the external condyle of the humerus, where it anastomoses with the posterior terminal branch of the superior profunda and with branches of the anastomotic artery. (*b*) **Muscular branches** to both superficial and deep muscles on the back of the forearm. (*c*) **Cutaneous branches** to the skin on the back of the forearm and the back of the wrist.

(4) The **anterior ulnar carpal** (ramus carpeus volaris), a small branch given off above the anterior annular ligament; it passes outwards beneath the flexor tendons and their sheaths on the anterior surface of the carpal ligaments, and anastomoses with the anterior carpal branch of the radial to form the anterior carpal arch.

(5) The **posterior ulnar carpal branch** (ramus carpeus dorsalis) arises from the back of the inner side of the ulnar artery just above the pisiform bone. It passes backwards under cover of the flexor and extensor carpi ulnaris muscles to the back of the carpus, where it unites with the posterior carpal branch of the radial to form the posterior carpal arch.

(6) **Profunda** (ramus volaris profundus).—This branch descends between the abductor and flexor brevis minimi digiti, and, turning outwards beneath the flexor brevis, the opponens minimi digiti, and the flexor tendons and their sheaths, joins the termination of the radial artery to complete the deep palmar arch.

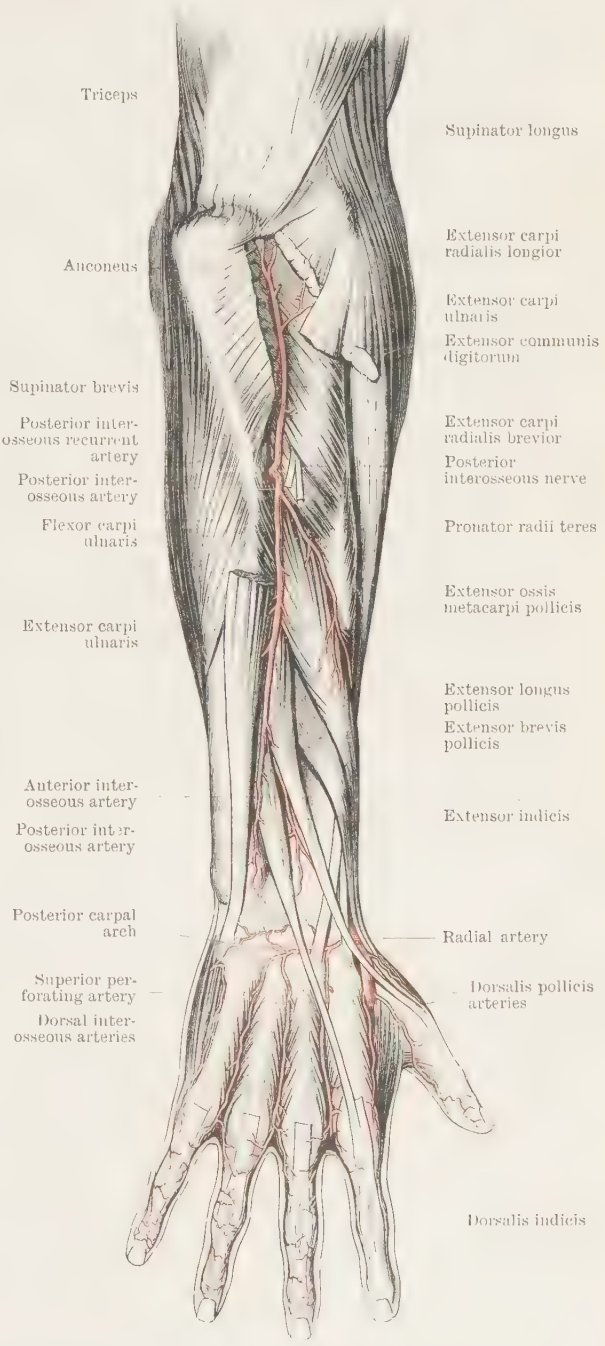

FIG. 633.—THE POSTERIOR INTEROSSEOUS ARTERY AND THE SECOND PART OF THE RADIAL ARTERY, WITH THEIR BRANCHES.

## THE ARTERIAL ARCHES OF THE WRIST AND HAND.

**Anterior Carpal Arch** (Fig. 632).—The anterior carpal arch lies on the front of the carpus behind the flexor tendons and their synovial sheaths. It is formed by the union of the anterior carpal branches of the radial and ulnar arteries, and it receives the communicating branch from the anterior interosseous artery above and recurrent branches from the deep palmar

arch below. The branches of distribution which pass from it supply the ligaments and synovial membranes of the wrist and of the intercarpal and carpo-metacarpal joints.

**Posterior or Dorsal Carpal Arch** (Fig. 633).—This arch lies on the posterior carpal ligaments under cover of the extensor tendons and their sheaths. It is formed by the union of the dorsal carpal branches of the radial and ulnar arteries, and receives the terminations of the anterior and posterior interosseous arteries.

**Branches.**—(*a*) **Articular** to the adjacent articulations. (*b*) **Dorsal interosseous,** two slender branches which run downwards on the third and fourth dorsal interosseous muscles to the clefts of the fingers, where each divides into collateral branches. They communicate near their origins with the deep palmar arch by the superior perforating arteries, and near their terminations with the palmar digital vessels through the inferior perforating arteries. Their collateral terminal branches run downwards on the dorso-lateral aspects of the fingers which bound the third and fourth interosseous spaces, and they anastomose with the collateral digital branches of the palmar digital arteries.

**Superficial Palmar Arch** (arcus volaris superficialis, Fig. 631). This arterial arch includes the terminal portion of the ulnar artery, and is usually completed externally by the superficialis volæ, or sometimes by the radialis indicis, or the princeps pollicis. It extends from the ball of the little finger to the inner border of the superficial head of the flexor brevis pollicis, and reaches as low down as a line drawn across the palm at the level of the lower border of the fully abducted thumb. It is covered by the integuments and the central portion of the palmar fascia, and, on the ulnar side of the palm, by the palmaris brevis, and it is accompanied by venæ comites. It is in contact behind with the flexor brevis and opponens minimi digiti, and with the digital branches of the ulnar and median nerves, as well as with the flexor tendons and the lumbrical muscles.

**Branches.**—**Four digital arteries** (aa. digitales volares communes) arise from the convexity of the arch. The innermost descends along the ulnar border of the little finger, accompanied by the internal digital branch of the ulnar nerve; the outer three pass downwards superficial to the digital nerves, along the middle of the three inner interosseous spaces towards the interdigital clefts, just above which each digital artery divides into **two collateral digital arteries** (aa. digitales volares propriæ), which supply the contiguous sides of the fingers bounding the cleft. As the collateral digital branches descend along the sides of the fingers they lie superficial to the corresponding digital nerves, and supply branches to the joints, to the flexor tendons with their sheaths, and to the skin and subcutaneous tissues on the palmar surface; they also send backwards dorsal branches which anastomose with the dorsal digital arteries and supply the tissues on the dorsal aspects of the second and terminal phalanges. Some of the backwardly-directed branches form a plexus in the matrix of the nail. In the pulp of the finger-tips anastomosing twigs join to form arches from which numerous branches are given off to the skin and subcutaneous fat.

Each of the outer three digital arteries is joined immediately above its division by a palmar interosseous branch from the deep palmar arch and an inferior communicating artery from a dorsal interosseous artery. The innermost digital artery is joined by a branch which comes either from the inner palmar interosseous artery or from the deep palmar arch.

**Deep Palmar Arch** (arcus volaris profundus, Fig. 632).—The deep palmar arch extends from the base of the metacarpal bone of the little finger to the upper end of the first interosseous space, and is formed by the terminal part of the radial artery, anastomosing with the deep branch of the ulnar. It is from half to three quarters of an inch (12 to 18 mm.) above the level of the superficial palmar arch, and it lies deeply in the palm, in contact with the bases of the metacarpal bones and their ligaments and on the origin of the interossei muscles; it is under cover of the flexor tendons and their synovial sheaths.

**Branches.**—(*a*) The **superior perforating** (rami perforantes); three small arteries which pass backwards through the inner three interosseous spaces, and between the origins of the dorsal interossei muscles. They anastomose on the dorsum of the hand with the dorsal interosseous arteries.

(*b*) Small irregular **recurrent branches** pass upwards and unite with the anterior carpal arch.

(*c*) The **articular** to the adjacent articulations.

(*d*) The **palmar interosseous arteries** (aa. metacarpeæ volares) are three vessels which pass downwards on the interosseous muscles of the three inner spaces and under cover of the flexor tendons. They terminate by anastomosing with the palmar digital arteries just before the latter vessels divide into collateral branches.

(*e*) The **communicating,** a small irregular branch which passes inwards between the flexor tendons and the short muscles of the little finger to anastomose with the innermost palmar digital artery.

## BRANCHES OF THE DESCENDING THORACIC AORTA.

The branches given off from the thoracic portion of the descending aorta are distributed chiefly to the walls of the thorax and to the thoracic viscera. They contribute also to the supply of the spinal cord and its membranes, and to that of the vertebral column and of the upper part of the abdominal wall. The branches, which are numerous and for the most part arranged in pairs, are as follows:—

**Parietal.**
- Intercostal.
- Subcostal.
- Diaphragmatic.
- The vas aberrans.

**Visceral.**
- Bronchial.
- Œsophageal.
- Pericardial.
- Mediastinal.

### Parietal Branches of the Descending Thoracic Aorta.

1. **Intercostal Arteries** (a. intercostales). — There are nine pairs of aortic intercostal arteries. They usually arise separately, though not uncommonly a pair may take origin by a common trunk from the back of the aorta, and are distributed to the lower nine intercostal spaces, to the spinal column, to the contents of the spinal canal, and to the muscles and skin of the back. The first three on each side also give branches to the mammary gland. The arteries of opposite sides closely correspond, but, since the aorta in the thoracic region lies on the left side of the spinal column, the right intercostal arteries cross the front of the vertebral column, behind the œsophagus, the thoracic duct, and the vena azygos major, and are longer than the left arteries. In other respects the course of all the aortic intercostal arteries is almost identical. They run outwards and backwards on the sides of the bodies of the vertebræ to the intercostal spaces, passing behind the pleura, and being crossed, opposite the heads of the ribs, by the sympathetic cord. The lower arteries are also crossed by the splanchnic nerves, and those on the left side are in addition crossed by the smaller azygos veins. On reaching an intercostal space each artery runs upwards, sometimes behind, sometimes in front of the corresponding intercostal nerve, to the upper border of the space, along which it is continued in the subcostal groove. It lies at first between the pleura and the posterior intercostal membrane, immediately below the intercostal nerve; it then pierces the intercostal membrane, and runs between it and the external intercostal muscle as far as the angle of the rib, beyond which it is continued forward between the internal and external intercostal muscles. In the subcostal groove the artery lies between the corresponding vein above and the intercostal nerve below, and it terminates in front by anastomosing with an anterior intercostal branch of the internal mammary or of the musculophrenic artery. The lower two intercostal arteries on each side extend beyond their spaces to the abdominal wall, and anastomose with branches of the superior epigastric, subcostal, and lumbar arteries.

**Branches.**—(*a*) **Dorsal** (ramus posterior).—As each artery enters its intercostal space it gives off a posterior or dorsal branch which passes backwards, accompanied by the posterior primary division of a spinal nerve, internal to the superior costo-transverse ligament, between the necks of the ribs which bound the space, and between the adjacent transverse processes, to the vertebral groove, where it divides into internal and external terminal branches. The *internal branch* (ramus cutaneus medialis) passes back-

wards and inwards either over or through the multifidus spinæ, giving branches to the muscles between which it passes and to the vertebral column. The *external branch* (ramus cutaneus lateralis) runs outwards under cover of the longissimus dorsi to the interval between it and the musculus accessorius. It terminates in the skin of the back, after giving branches to the adjacent muscles. A *spinal branch* (ramus spinalis) from each dorsal artery passes through the corresponding intervertebral foramen, and enters the spinal canal, to the contents and walls of which it is distributed. It divides into three branches—neural, post-central, and pre-laminar. The *neural branch* divides into two branches which run inwards on the roots of the spinal nerve, pierce the dura mater and arachnoid, and divide into branches some of which pass to the membranes of the cord, whilst others are continued on to reinforce the dorsal and ventral spinal arteries. The *post-central branch* divides into ascending and descending branches which, anastomosing with similar branches above and below, form a series of vertical arches on the back of the bodies of the vertebræ. The arches of opposite sides are connected by short transverse anastomoses. The *pre-laminar branch* is small, and its ascending and descending branches are distributed in a similar though less regular manner on the posterior wall of the spinal canal.

(*b*) A **collateral branch** springs from the trunk of each intercostal artery near the angle of the rib. It descends to the lower border of the intercostal space, along which it runs forwards to anastomose in front, like the intercostal artery itself, with a separate anterior intercostal branch of the internal mammary or musculo-phrenic artery. The collateral branches of the lower two intercostal arteries on each side are inconstant; when present they are small, and terminate in the abdominal wall.

(*c*) **Muscular branches** (rami musculares) to the adjacent muscles are given off both by the main trunk and its collateral branch.

(*d*) A **lateral cutaneous** (ramus cutaneus lateralis) offset from the intercostal artery accompanies the lateral cutaneous branch of the intercostal nerve.

In addition to the above-named branches the first aortic intercostal on each side anastomoses with the superior intercostal, and may supply the whole or the greater part of the second intercostal space, and the first right aortic intercostal frequently gives origin to the right bronchial artery. The upper three or four aortic intercostals on each side give branches to the mammary gland which anastomose with branches of the long thoracic and internal mammary arteries. Longitudinal anastomoses between adjacent intercostal arteries and their dorsal branches sometimes exist near the necks of the ribs, or near the transverse processes. These longitudinal anastomoses are of considerable morphological interest.

2. The **subcostal arteries** are the last pair of parietal branches given off from the thoracic aorta. They are in series with and are very similar to the aortic intercostal arteries, but are situated below the last ribs. Each runs along the lower border of the twelfth rib in company with the last dorsal nerve. It passes beneath the ligamentum arcuatum externum to the abdomen, and there crosses in front of the quadratus lumborum, and behind the kidney and the adjacent part of the colon. It next pierces the aponeurosis of origin of the transversalis abdominis, and runs between the transversalis and the internal oblique muscles, anastomosing with the lower intercostal arteries, with the lumbar arteries, and with branches of the superior epigastric artery.

3. **Diaphragmatic branches** (aa. phrenicæ superiores) are given off from the lower part of the thoracic aorta. They are small vessels which ramify on the upper surface of the diaphragm, and anastomose with branches of the superior phrenic and musculo-phrenic arteries.

4. The **vas aberrans** is a variable and inconstant branch of the thoracic aorta; it represents the dorsal roots of the fourth and fifth right aortic arches of the embryo. When present it arises from the front and right side of the upper part of the main trunk near the upper bronchial artery, and passes upwards and to the right behind the œsophagus; it frequently anastomoses with the right superior intercostal artery, and it may be enlarged and form the first part of the right subclavian artery.

### Visceral Branches of the Descending Thoracic Aorta.

1. The **bronchial branches** (aa. bronchiales) of the thoracic aortæ are usually two in number—an upper and a lower—and both pass to the left lung. The *upper left bronchial artery* arises from the front of the main trunk opposite the fifth

dorsal vertebra; the *inferior left bronchial artery* usually takes origin near the lower border of the left bronchus. Both vessels are directed downwards and outwards to the back of the bronchus, which they accompany, and, dividing similarly, they follow its ramifications in the lung. They not only supply the walls of the bronchial tubes and the substance of the lungs, but also give branches to the bronchial glands, the pulmonary vessels, the pericardium, and the œsophagus.

As a rule there is only one *right bronchial artery*, and it arises from the first right aortic intercostal artery; but it not uncommonly arises from the upper left bronchial artery, and more rarely it springs directly from the aorta. In its course and distribution it corresponds to the bronchial arteries of the left side.

2. The **œsophageal branches** (aa. œsophageæ) are variable; usually four or five small branches spring from the front of the aorta and pass forwards to the œsophagus, in the walls of which they ramify, anastomosing above with branches of the left bronchial and inferior thyroid arteries, and below with œsophageal branches of the coronary and phrenic arteries.

3. The **pericardial branches** (rami pericardiaci) consist of three or four small irregular vessels which are distributed on the surface of the pericardium.

4. Small **mediastinal branches** (rami mediastinales) pass to the areolar tissue and glands in the posterior mediastinal space, and to the posterior part of the diaphragm.

## BRANCHES OF THE ABDOMINAL AORTA.

The branches of the abdominal portion of the aorta are distributed almost entirely to the walls and contents of the abdominal cavity, but some also supply small branches to the vertebral column, and to the contents of the spinal canal, and others are prolonged into the pelvis. They are divisible into parietal and visceral groups, both of which include paired and single (unpaired) vessels.

- **Parietal.**
  - **Paired.**
    - Inferior phrenic.
    - Lumbar.
    - Common iliac.
  - **Single.** Middle sacral.
- **Visceral.**
  - **Paired.**
    - Suprarenal.
    - Renal.
    - Spermatic or ovarian.
  - **Single.**
    - Cœliac axis.
    - Superior mesenteric.
    - Inferior mesenteric.

### Parietal Branches of the Abdominal Aorta.

1. The **inferior phrenic arteries** (aa. phrenicæ inferiores, Fig. 634) are two in number, and are of small size; they arise, either separately or by a common trunk, from the aorta, immediately below the diaphragm on the under surface of which they are distributed. Diverging from its fellow, each artery runs upwards and outwards on the corresponding crus of the diaphragm—that on the right side passing behind the inferior vena cava, that on the left behind the œsophagus—and just before reaching the central tendon of the diaphragm it divides into internal and external terminal branches. The *internal branch* of each artery runs forward and anastomoses with its fellow of the opposite side, forming an arch, convex forwards, along the front of the central tendon of the diaphragm. Offsets from this arch anastomose with the superior phrenic, musculo-phrenic, and internal mammary arteries. The *external branch* passes outwards towards the lower ribs, and anastomoses with the musculo-phrenic and lower intercostal arteries.

In addition to supplying the diaphragm each inferior phrenic artery frequently gives a **superior capsular branch** to the suprarenal body of its own side, and occasionally small hepatic branches pass through the coronary ligament to the liver. Further, the left artery gives branches to the œsophagus which anastomose with œsophageal branches of the aorta and of the coronary artery, whilst from the artery of the right side minute branches pass to the inferior vena cava.

2. The **lumbar arteries** (aa. lumbales) correspond to the intercostal branches of the thoracic aorta. They are in series with them, their distribution is very similar, and, like the intercostals, they arise, either separately or by common trunks, from the back of the aorta.

There are usually four pairs of lumbar arteries, but occasionally a fifth pair arises from or in common with the middle sacral artery.

From their origins the lumbar arteries pass backwards and outwards on the front and sides of the bodies of the upper four lumbar vertebræ to the intervals between the adjacent transverse processes, beyond which they are continued in the abdominal wall.

They lie on the bodies of the corresponding lumbar vertebræ. In their back-

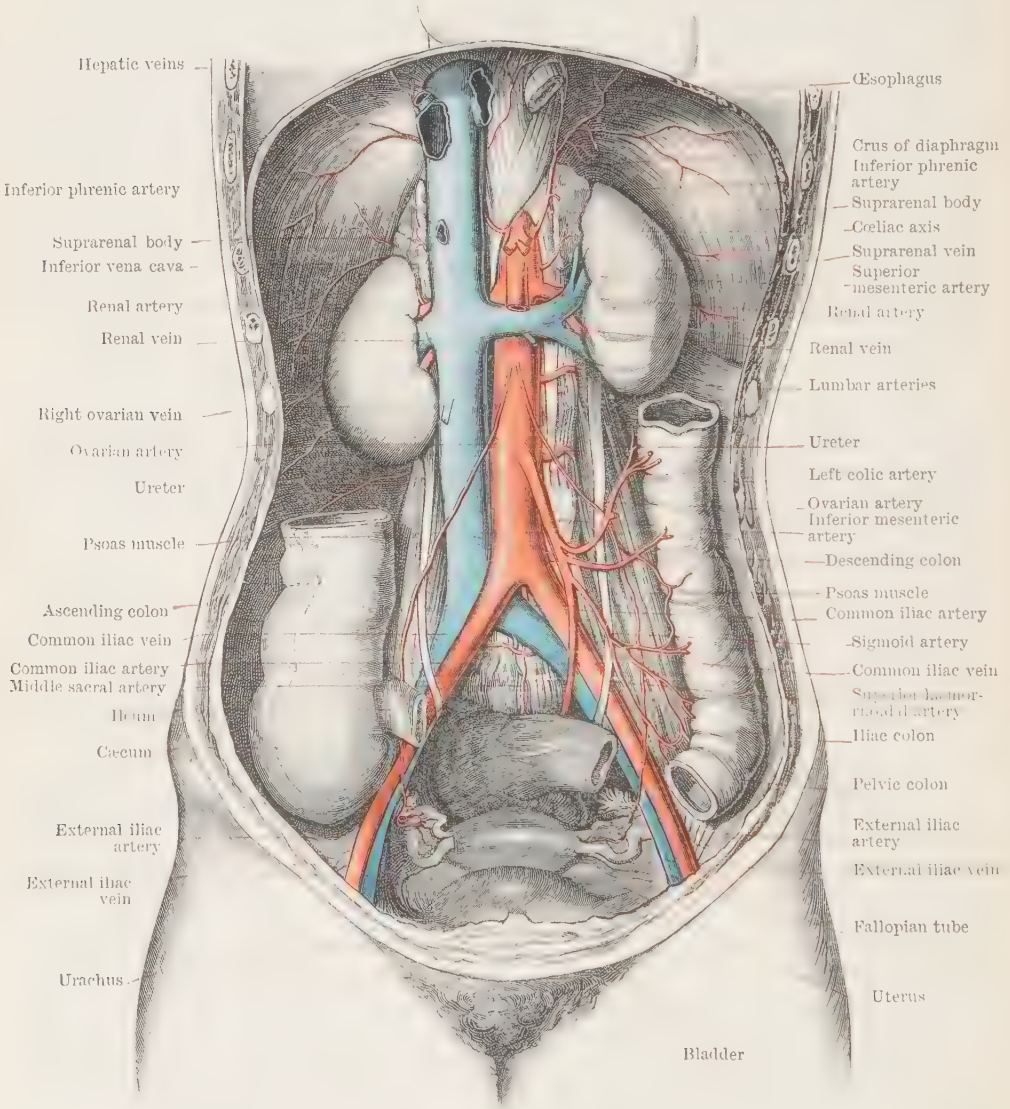

Fig. 634.—The Abdominal Aorta and its Branches.

ward course, and while still in relation with the vertebral bodies, each artery is crossed by the sympathetic cord, and then, after passing internal to and being protected by the fibrous arches from which the muscle arises, it runs behind the psoas muscle and the lumbar plexus. The upper two arteries on each side also pass behind the crura of the diaphragm. Beyond the interval between the transverse processes of the vertebræ each artery turns outwards and crosses the quadratus lumborum—the last usually passing in front of, and the others behind the muscle; it then pierces the aponeurosis of origin of the transversalis, and proceeds forwards in the lateral abdominal wall in the interval between the transversalis and internal oblique

muscles. The lumbar arteries anastomose with one another, with the lower intercostal and subcostal arteries, and with branches of the superior and deep epigastric and of the deep circumflex iliac and ilio-lumbar arteries.

Fine twigs also pass from the lumbar arteries to the extra-peritoneal fat, and anastomose with corresponding branches from the inferior phrenic and ilio-lumbar arteries, and with small branches from the hepatic, renal, and colic arteries, to form the subperitoneal plexus of Turner.

The abdominal aorta lies but little to the left of the middle line, and consequently the right lumbar arteries are scarcely longer than the left. On the right side the arteries, which near their origins lie more in front of the vertebral bodies, pass behind the inferior vena cava, the upper two arteries being separated from this vessel by the right crus of the diaphragm. The upper two right arteries also pass behind the receptaculum chyli and the lower end of the large azygos vein.

**Branches.**—**Dorsal** (ramus dorsalis).—Each lumbar artery gives off, opposite the interval between the vertebral transverse processes, a dorsal branch of considerable size. It is analogous with and distributed like the corresponding branch of an aortic intercostal artery (p. 837). **Muscular branches** are given off, both from the main trunk and its dorsal branch, to the adjacent muscles.

3. The **middle sacral artery** (a. sacralis media, Fig. 634) is a single median vessel. It is commonly regarded as a caudal aorta and as the direct continuation of the abdominal aorta. It is, however, of small size, and almost invariably arises from the back of the aorta about half-an-inch above its bifurcation. It descends in front of the two lower lumbar vertebra and of the sacrum and coccyx, and ends opposite the tip of the last-named bone by anastomosing with the lateral sacral arteries to form a loop from which branches pass to the coccygeal body. In its course it passes at first behind the lower part of the abdominal aorta. Opposite the fifth lumbar vertebra it is crossed by the left common iliac vein, below which it is covered by peritoneum and coils of small intestine as far as the third sacral segment, and in the rest of its extent by the rectum. It is accompanied below by venæ comites, which, however, unite above to form a single middle sacral vein.

Small parietal branches pass transversely outwards on each side to the last lumbar vertebra and to the sacrum. They anastomose with the lateral sacral arteries, and they usually give off small spinal offsets which enter the anterior sacral foramina. Small and irregular visceral branches pass to the rectum and anastomose with the superior and middle hæmorrhoidal arteries.

## COMMON ILIAC ARTERIES.

4. The **common iliac arteries** (aa. iliacæ communes, Figs. 634 and 640) are the terminal branches of the abdominal aorta. They are formed by the bifurcation of the main trunk, and commence opposite the middle of the body of the fourth lumbar vertebra a little to the left of the middle line. Each artery passes downwards and outwards across the bodies of the fourth and fifth lumbar vertebræ and the intervening intervertebral disc, and terminates at the level of the lumbo-sacral articulation and in front of the corresponding sacro-iliac joint by dividing into the internal and external iliac arteries.

The direction of each common iliac is well indicated by a line drawn from the bifurcation of the aorta to a point midway between the symphysis pubes and the anterior superior spine of the ilium.

The angle included between the two diverging trunks is about 60° in the male and about 68° in the female.

The right artery is, for obvious reasons, a little longer than the left; the former is about two inches, and the latter one and three-quarter inches in length.

**Relations.**—*Anterior.*—Both arteries are covered anteriorly by peritoneum, and are separated by it from coils of the small intestine. Communicating branches between the aortic and hypogastric plexuses of the sympathetic pass in front of the arteries, each of which is also crossed anteriorly near its termination by the corresponding ureter.

The left artery is in addition crossed in front by the superior hæmorrhoidal vessels.

*Posterior.*—Behind the artery of each side are the bodies of the fourth and fifth lumbar vertebræ, with the intervertebral disc above the latter, the psoas muscle, the sympathetic cord. These relationships, however, are much closer on the left side than on the right. The right common iliac, except at its lower end, where it is in contact with the psoas, is separated from the structures named by the terminations of the right and left common iliac veins and the commencement of the inferior vena cava. The left common iliac, which is not so separated, lies on the inner border of the psoas. Somewhat deeply placed in the areolar tissue between the psoas and the lumbar vertebræ, the obturator nerve, the lumbo-sacral cord, and the ilio-lumbar artery form posterior relations to the artery of the corresponding side.

*Lateral.*—On both sides of each artery are coils of small intestine. The commencement of the inferior vena cava lies to the outer side of the upper part of the right artery, and on the inner side of this vessel are the right common iliac vein below and the left common iliac vein above. The last-named vein lies on the inner side of the left artery.

### The Paired Visceral Branches of the Abdominal Aorta.

1. **Suprarenal** or **Capsular Arteries** (aa. suprarenales, Fig. 634).—There are three sets of suprarenal arteries—the superior, middle, and inferior. Of these the middle only arise from the aorta direct; the superior spring from the inferior phrenic, and the inferior from the renal arteries.

The middle suprarenal arteries are two small branches which arise, behind the pancreas, from the sides of the aorta, close to the origin of the superior mesenteric artery. They run, one on each side, outwards and upwards upon the crura of the diaphragm, and just above the renal arteries, to the suprarenal bodies to which they are distributed, and they anastomose with the superior and inferior suprarenal arteries.

2. **Renal Arteries** (aa. renales, Fig. 634).—The renal arteries arise, one on each side, from the aorta, about half-an-inch below the origin of the superior mesenteric artery and opposite the second lumbar vertebra.

Both arteries are of large size, and the right, which is a little longer than the left, is frequently slightly lower in position. Each artery runs almost transversely outwards to the hilum of the corresponding kidney. It passes in front of the crus of the diaphragm and of the upper part of the psoas muscle. The left artery lies behind the pancreas; the right vessel passes behind the inferior vena cava, the head of the pancreas, and the second part of the duodenum. The renal vein usually lies below and in front of the artery, but near the kidney the vein not unfrequently occupies a posterior position.

On reaching the hilum of the kidney each artery divides into three branches, two of which pass in front of the pelvis of the ureter, and between it and the renal vein, and the third behind the pelvis. In the renal sinus these primary branches break up into numerous secondary branches which enter the kidney substance between the pyramids.

**Branches.**—The following branches are given off by each renal artery, in addition to the terminal branches :—

(*a*) **Inferior suprarenal** (a. suprarenalis inferior), which passes upwards to the lower part of the suprarenal body.

(*b*) **Ureteral.**—Small branches to the upper part of the ureter, which anastomose with branches of the spermatic or ovarian arteries.

(*c*) **Peri-renal.**—Small branches to the fatty capsule of the kidney, which anastomose with the lumbar arteries.

(*d*) **Glandular offsets**, either from the main trunk or from some of its branches, pass to the renal and lumbar glands.

3. **Spermatic Arteries** (aa. spermaticæ internæ).—The spermatic arteries in the male, and the corresponding ovarian arteries (aa. ovaricæ) in the female, are two long slender vessels, one on the right side and one on the left, which arise from the front of the abdominal aorta, a short distance below the origins of the renal arteries.

Each spermatic artery runs downwards and outwards to the internal abdominal ring; it then traverses the inguinal canal, and consequently takes a downward and inward course. On emerging from the canal, through the external abdominal ring, it enters the scrotum, in which it descends, almost vertically, but in a tortuous

manner, to end immediately above the testicle by dividing into testicular and epididymal branches.

**Relations.**—In the abdominal cavity the arteries lie behind the peritoneum, to which they are closely attached, and in front of the psoas muscles. The right artery is also in front of the inferior vena cava. Each artery descends in front of the ureter, the genito-crural nerve, and the lower end of the external iliac artery of its own side, and is accompanied by two spermatic veins which unite above into a single trunk. The anterior relations differ on the two sides. The right artery lies behind, and is crossed, by the ileo-colic, the right colic, and the terminal branches of the superior mesenteric artery, and by the third part of the duodenum, the termination of the ileum, and the vermiform appendix. The left artery is crossed in front by the left colic and sigmoid branches of the inferior mesenteric artery and by the iliac colon.

At the internal abdominal ring the spermatic artery comes into relation, at its inner side, with the vas deferens. The two structures run together round the outer and anterior aspects of the deep epigastric artery to the inguinal canal.

In the inguinal canal the spermatic artery, along with the other constituents of the spermatic cord, is enclosed in the infundibular and cremasteric fasciæ, the intercolumnar fascia being added at the external abdominal ring. In this part of its course the artery lies in front of the vas deferens, and behind the anterior part of the pampiniform plexus and the spermatic veins which arise from it.

**Branches.**—(*a*) **Ureteral branches**, small in size, are distributed to the middle part of the ureter, anastomosing above with branches from the renal and below with branches from the vesical arteries.

(*b*) **Cremasteric branches**, given off in the inguinal canal and upper part of the scrotum, supply the cremaster muscle, and anastomose with the cremasteric branch of the deep epigastric.

(*c*) **Terminal Branches.**—(i.) The *epididymal branch* runs downwards to the epididymis, which it supplies. It also gives twigs to the vas aberrans, the coni vasculosi, and the tunica vaginalis, and anastomoses with the artery of the vas deferens. (ii.) The *testicular branch* descends on the upper and back part of the testicle, and breaks up into numerous peripheral and central branches. The peripheral branches pass through the tunica albuginea and ramify on its inner surface; they anastomose with one another and with the central branches. The central branches pass through the mediastinum testis and along the surfaces of the septa.

3*a*. The **ovarian arteries** (aa. ovaricæ, Fig. 634) in the female closely correspond to the spermatic arteries in the male. They are, however, much shorter, and, instead of passing through the abdominal wall, descend into the pelvis, where they run between the layers of the broad ligament to terminate between the ovaries and the uterus by anastomosing with the uterine arteries.

**Relations.**—In the upper part of its course the relations of each ovarian artery are like those of the corresponding spermatic artery, but about the level of the anterior superior spine of the ilium each ovarian artery turns inwards, and, crossing the upper part of the external iliac vessels (artery and vein), descends in the anterior border of the fossa ovarii, on the lateral wall of the pelvis, to the broad ligament, where it is placed below the Fallopian tube.

**Branches.**—(*a*) **Ureteral**, to the middle part of the ureter.

(*b*) **Tubal**, to the Fallopian tube, which anastomose with branches of the uterine.

(*c*) **Ligamentous**, to the round ligament, as far as the inguinal canal.

(*d*) **Ovarian branches**, numerous, pass to the hilum of the ovary, and thence to the substance of the organ.

(*e*) A **uterine branch** is formed by the continuation of the trunk to its anastomosis with the uterine branch of the internal iliac.

### The Unpaired or Single Visceral Branches of the Abdominal Aorta.

1. The **cœliac artery** or **cœliac axis** (a. cœliaca, Figs. 634 and 635) arises from the front of the abdominal aorta, immediately below the aortic orifice of the diaphragm and between its crura. It is a short but wide vessel which runs almost horizontally forwards for a distance of about half-an-inch, and then terminates by dividing into three large branches—the coronary or gastric, the hepatic, and the splenic.

**Relations.**—The short trunk extends from the aorta behind the lesser sac of peritoneum, by which it is separated from the stomach, or from the small omentum,

in front. It runs below the Spigelian lobe of the liver, and above the upper border of the pancreas and the splenic vein, and it is surrounded by the solar and cœliac plexuses of the sympathetic; the right semilunar ganglion is to its right side, and the left semilunar ganglion and cardiac end of the stomach are on its left side.

**Branches.**—(*a*) The **coronary** or **gastric artery** (a. gastrica sinistra) is the smallest branch of the cœliac axis. It runs obliquely upwards and to the left, and reaches the smaller curvature of the stomach close to the œsophagus. It then turns sharply forwards, downwards, and to the right, and runs towards the pyloric end of the stomach to anastomose with the pyloric branch of the hepatic artery. In the first part of its course the artery lies behind the lesser sac of the peritoneum; it then passes into the left pancreatico-gastric fold, and is continued between the layers of the small omentum.

**Branches.**—(i.) **Œsophageal** (rami œsophagei).—When the artery reaches the stomach a large

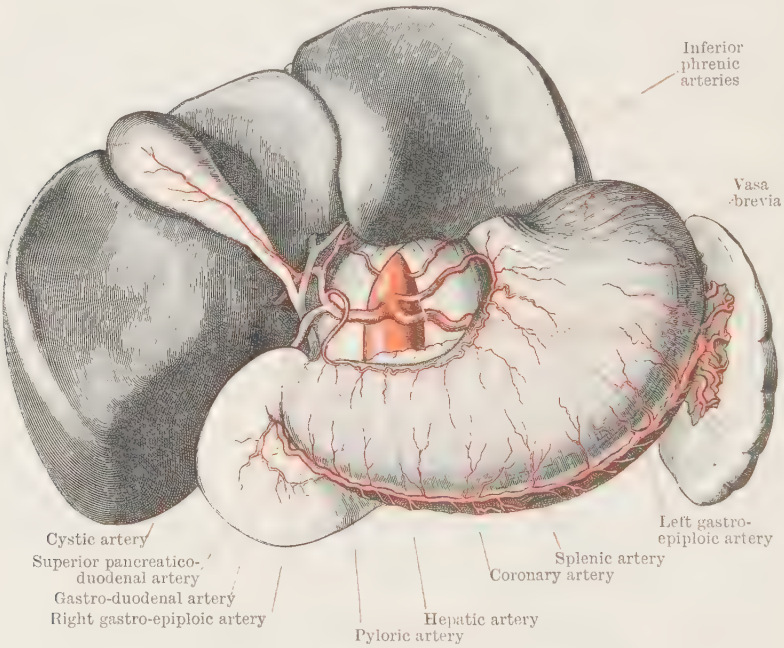

Fig. 635.—The Cœliac Axis and its Branches.

œsophageal branch is given off, which passes upwards on the œsophagus, and gives offsets to it which anastomose with œsophageal branches of the thoracic aorta and with branches of the inferior phrenic. (ii.) **Gastric branches** are distributed to both surfaces of the stomach. They anastomose with branches of the vasa brevia of the splenic, and with branches of the gastro-epiploic arterial arch on the greater curvature of the stomach.

(*b*) The **splenic artery** (a. lienalis, Fig. 635) is the largest branch of the cœliac axis. It runs a more or less tortuous course behind the stomach and the lesser sac of the peritoneum, and along the upper border of the pancreas. It lies in front of the left suprarenal capsule and the upper end of the left kidney, and passes forwards between the two layers of the lieno-renal ligament, where it divides into from five to eight terminal branches (rami lienales) which enter the hilum of the spleen and supply the splenic substance. It is accompanied by the splenic vein, which lies below it.

**Branches.**—(i.) **Pancreatic** (rami pancreatici).—Numerous small branches (pancreaticæ parvæ) are given off to the pancreas. One large branch (pancreatica magna), occasionally present, enters the upper border of the pancreas, about the junction of its middle and left thirds, and runs from left to right in the substance of the pancreas, a little above and behind the pancreatic duct. Both the small and large arteries supply the substance of the pancreas, and anastomose with one another and with branches of the pancreatico-duodenal arteries.

(ii.) The **vasa brevia** (aa. gastricæ breves), or short gastric branches, four or five in number, are given off either from the end of the main vessel or, more commonly, from some of its terminal branches. They pass between the layers of the gastro-splenic omentum to the left end of great curvature of the stomach, and anastomose with the œsophageal, the gastric, and the left gastro-epiploic arteries.

(iii.) The **left gastro-epiploic branch** (a. gastro-epiploica sinistra) arises from the front of the splenic, close to its termination, and passes forwards between the layers of the gastro-splenic omentum to the left end of the great curvature of the stomach, along which it is continued, from left to right, between the layers of the gastro-colic or great omentum. It ends by anastomosing with the right gastro-epiploic artery, and it gives off numerous gastric branches to both surfaces of the stomach, which anastomose with the vasa brevia and with branches of the coronary and pyloric arteries. Long slender omental branches pass to the omentum and anastomose with branches of the colic arteries.

(*c*) The **hepatic artery** (a. hepatica, Fig. 635) runs along the upper border of the head of the pancreas to the right pancreatico-gastric fold of peritoneum, in which it turns forwards to the upper border of the first part of the duodenum. It then passes upwards, between the layers of the small omentum, in front of the portal vein and to the left of the common bile duct, and reaches the transverse fissure of the liver, where it divides into right and left branches.

**Branches.**—(i.) The **pyloric artery** (a. gastrica dextra) is a small branch which arises opposite the upper border of the first part of the duodenum. It descends to the pylorus, running between the layers of the small omentum, and then turns to the left along the smaller curvature of the stomach. It gives branches to both surfaces of the stomach, and terminates by anastomosing with the coronary artery.

(ii.) The **gastro-duodenal artery** (a. gastro-duodenalis).—This branch of the hepatic arises just above the upper border, descends behind, and terminates opposite the lower border of the first part of the duodenum. In its course it lies between the neck of the pancreas and the first part of the duodenum, and it is in front of the portal vein. The common bile duct is on its right side. The vessel ends by dividing into the right gastro-epiploic and the superior pancreatico-duodenal arteries. The **right gastro-epiploic artery** (a. gastro-epiploica dextra) is the larger of the two terminal branches of the gastro-duodenal; it passes from right to left along the greater curvature of the stomach, between the layers of the gastro-colic omentum, and unites with the left gastro-epiploic branch of the splenic artery. From the arterial arch so formed branches pass upwards on both surfaces of the stomach, and anastomose with branches of the pyloric and coronary arteries. Other branches pass downwards to the omentum, and anastomose with branches of the colic arteries. The **superior pancreatico-duodenal artery** (a. pancreatico-duodenalis superior) runs a short course to the right, between the duodenum and the head of the pancreas, and divides into anterior and posterior terminal branches which descend, the former in front of and the latter behind the head of the pancreas, to anastomose with similar branches of the inferior pancreatico-duodenal artery. They supply the head of the pancreas, anastomosing in it with the pancreatic branches of the splenic artery; branches are also given to the second part of the duodenum and to the common bile duct.

(iii.) **Terminal branches.**—The **right hepatic artery** (ramus dexter) passes either in front of or behind the hepatic duct and behind the cystic duct, to the right end of the transverse fissure of the liver, where it divides into two or more branches which enter the substance of the liver and accompany the branches of the portal vein and the hepatic duct. As it crosses just above the junction of the hepatic and cystic ducts, the right hepatic artery gives off a cystic branch. The *cystic artery* (a. cystica) runs downwards and forwards along the cystic duct to the gall-bladder, where it divides into upper and lower branches; the upper passes downwards between the gall-bladder and the under surface of the liver, to both of which it gives offsets; the lower branch is distributed on the under surface of the gall-bladder, between it and the peritoneum. The **left hepatic artery** (ramus sinister) is longer and narrower than the right. It runs to the left end of the transverse fissure, gives one or two branches to the Spigelian lobe, crosses the longitudinal fissure, and breaks up into branches which terminate in the substance of the left lobe of the liver.

2. The **superior mesenteric artery** (a. mesenterica superior, Figs. 634, 636, and 659) springs from the front of the aorta, about half-an-inch below the origin of the cœliac axis and opposite the first lumbar vertebra.

It passes obliquely downwards and forwards, crossing in front of the left renal

vein, the lower part of the head of the pancreas, and the third part of the duodenum; opposite the latter it enters the root of the mesentery, in which it continues to descend, curving obliquely from above downwards and to the right, to the right iliac fossa, and crossing in this part of its course obliquely in front of the aorta, the lower part of the inferior vena cava, the right ureter, and the right psoas muscle. At its origin it lies behind the neck of the pancreas and the splenic vein; where it passes in front of the duodenum it is crossed anteriorly by the transverse colon, and in the lower part of its extent it is concealed by coils of small intestine.

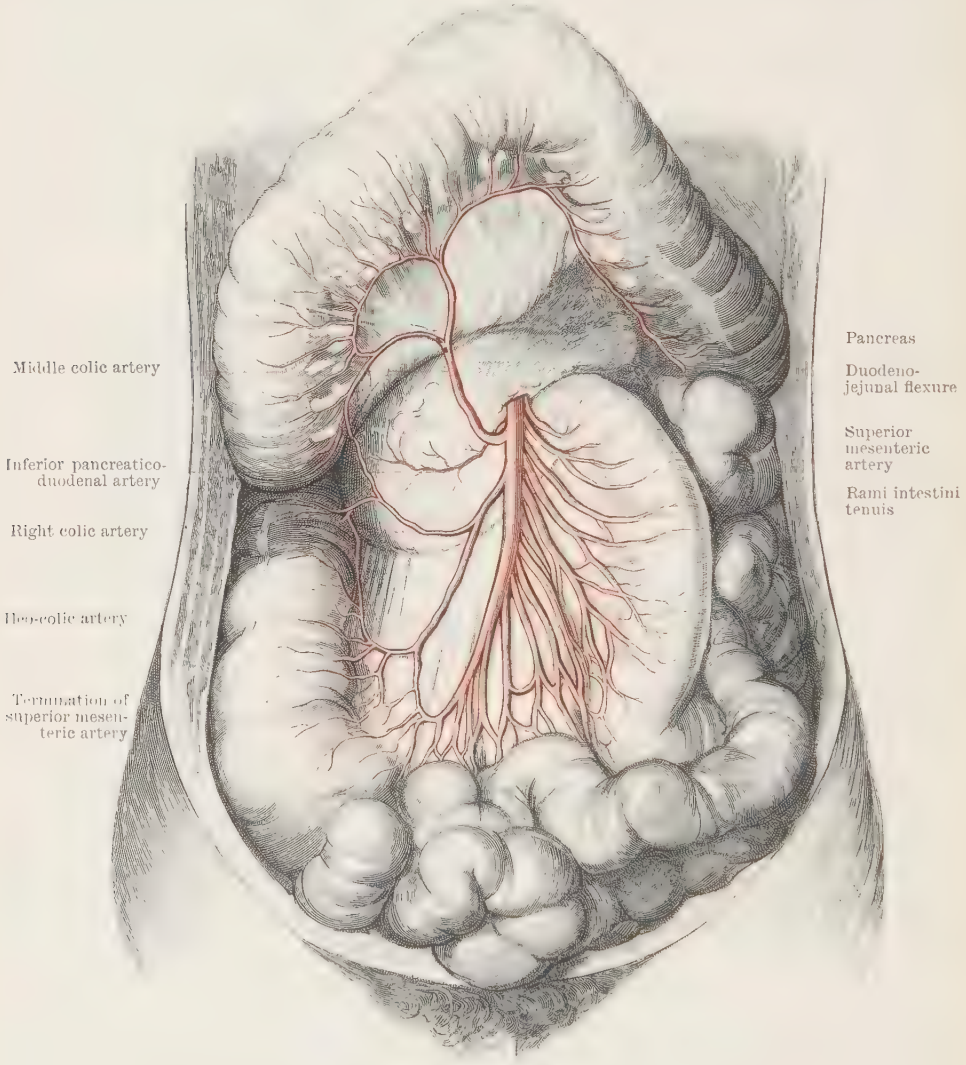

FIG. 636.—THE SUPERIOR MESENTERIC ARTERY AND ITS BRANCHES.

**Branches.**—It gives off numerous branches which supply the duodenum and the pancreas in part, the whole of the small intestine below the duodenum, and the large intestine nearly as far as the splenic flexure.

The branches are as follows:—

(*a*) **Rami intestini tenuis** (aa. intestinales), or branches to the small intestine, varying from ten to sixteen in number; they spring from the convexity of the superior mesenteric artery, and pass obliquely forwards and downwards between the layers of the mesentery, each dividing into two branches which anastomose with adjacent branches to form a series of arcades from which secondary branches are given off. This process of division and union is repeated three or four times; thus four or five tiers of arches are

formed, from the most distal of which terminal branches are given off to the walls of the jejunum and ileum. Branches from the successive arcades are also given off to the mesenteric glands. The terminal branches anastomose together in the walls of the gut, forming a vascular network which communicates above with the inferior pancreatico-duodenal artery and below with the terminal branch of the superior mesenteric trunk. The vascular loops and branches are accompanied by corresponding veins, lymphatics, and nerves.

(*b*) The **inferior pancreatico-duodenal artery** (a. pancreatico-duodenalis inferior). It arises either from the trunk of the superior mesenteric, at the upper border of the third part of the duodenum, or from the first of the rami intestini. It runs to the right, between the head of the pancreas and the third part of the duodenum, and terminates by dividing into two branches, anterior and posterior, which ascend, the former in front and the latter behind the head of the pancreas; they supply the head of the pancreas, the second and third parts of the duodenum, and they anastomose with the similar branches of the superior pancreatico-duodenal artery.

(*c*) The **middle colic artery** (a. colica media) is a large branch which springs from the front of the superior mesenteric as it enters the root of the mesentery. It runs downwards and forwards in the transverse mesocolon, and terminates by dividing into two branches, right and left, which anastomose respectively with the right and left colic arteries, forming arcades from which secondary and tertiary loops are derived, the terminal branches being distributed to the walls of the transverse colon.

(*d*) The **right colic artery** (a. colica dextra) springs from the right or concave side of the superior mesenteric, either alone or in the form of a common trunk which divides into right and ileo-colic branches. It runs to the right, behind the peritoneum on the posterior wall of the abdomen, and in front of the right psoas, the ureter, and the spermatic or ovarian vessels, towards the ascending colon, near which it divides into an ascending and a descending branch. The former passes upwards, and anastomoses in the transverse mesocolon with the middle colic artery. The latter descends to anastomose with the upper branch of the ileo-colic, and from the loops thus formed branches are distributed to the walls of the ascending colon and the beginning of the transverse colon.

(*e*) The **ileo-colic artery** (a. ileo-colica) arises by a common trunk with the right colic, or separately from the right side of the superior mesenteric, and passes downwards and outwards, behind the peritoneum, towards the lower part of the ascending colon, where it terminates by dividing into an ascending branch which anastomoses with the lower branch of the right colic, and a descending branch which communicates with the colic terminal branches of the superior mesenteric trunk.

(*f*) **Terminal.**—The lower end of the superior mesenteric artery divides into five branches—(i.) ileal, (ii.) appendicular, (iii.) anterior ileo-cæcal, (iv.) posterior ileo-cæcal, and (v.) colic.

The **ileal branch** (a. ilea) turns upwards and to the left in the lowest part of the mesentery, and anastomoses with the rami intestini. The **appendicular branch** (a. appendicularis) passes behind the terminal portion of the ileum, and through the meso-appendix to the vermiform process, upon which it ends. The **anterior ileo-cæcal** crosses the front of the ileo-cæcal junction in a fold of peritoneum; the **posterior ileo-cæcal** crosses the ileo-cæcal junction posteriorly, and the **colic** runs upwards to the ascending colon. The ileo-cæcal branches supply the walls of the cæcum, and, like the colic branch, anastomose with branches of the ileo-colic artery.

3. The **inferior mesenteric artery** (a. mesenterica inferior, Fig. 634) arises from the front and towards the left side of the aorta an inch and a half above the bifurcation; it passes downwards and slightly outwards, lying behind the peritoneum and on the front of the left psoas muscle, to the upper and outer border of the left common iliac artery, where it becomes the superior hæmorrhoidal.

**Branches.**—(*a*) The **left colic artery** (a. colica sinistra) arises from the left side of the inferior mesenteric near its origin. It runs upwards and to the left towards the splenic flexure of the colon, where it divides into ascending and descending branches. The ascending branch crosses in front of the lower end of the left kidney, passes between the layers of the transverse mesocolon, and, turning inwards, terminates by joining the left branch of the middle colic artery. The descending branch passes downwards behind the peritoneum to the inner side of the descending colon to unite with the superior sigmoid artery, and from the loops thus formed branches are distributed to the descending colon.

In the whole of its course the left colic artery lies behind the peritoneum, and on the posterior abdominal wall; it crosses in front of the left psoas and the left ureter.

(*b*) The **sigmoid branches** (aa. sigmoideæ), usually two in number, arise from the convexity of the inferior mesenteric, and pass downwards and outwards to the iliac colon. They lie behind the peritoneum, and in front of the psoas, the ureter, and the upper part of the iliacus. They terminate by dividing into branches which anastomose with the left colic above and with branches of the superior hæmorrhoidal below, forming a series of arches from which branches are distributed to the lower part of the descending colon, the iliac colon, and the pelvic colon.

(*c*) The **superior hæmorrhoidal artery** (a. hæmorrhoidalis superior) is the direct continuation of the inferior mesenteric. It enters the mesentery of the pelvic colon, crosses the front of the left common iliac artery, descends into the pelvis as far as the third piece of the sacrum, or in other words the junction between the pelvic colon and the rectum, and divides into two branches which pass downwards on the sides of the rectum. Half-way down the rectum each of the two terminal branches of the superior hæmorrhoidal artery divides into two or more branches which pass through the muscular coats and terminate in the submucous tissue, where they divide into numerous small branches which pass vertically downwards, anastomosing with each other, with offsets from the middle hæmorrhoidal branches of the internal iliac arteries, the inferior hæmorrhoidal branches of the internal pudic arteries, and with branches from the middle sacral artery.

The superior hæmorrhoidal artery supplies the mucous membrane of the pelvic colon and the rectum and the muscular coats of the pelvic colon.

## THE INTERNAL ILIAC ARTERY.

The **internal iliac** or **hypogastric artery** (a. hypogastrica, Figs. 634, 637, and 640) in the fœtus is the direct continuation of the common iliac trunk. It supplies numerous branches to the pelvis, runs upwards on the anterior abdominal wall to the umbilicus, and is prolonged as the umbilical artery to the placenta. One of its pelvic branches—the sciatic—is at first the main artery of the inferior extremity, but subsequently another branch is given off which becomes the chief arterial trunk of the lower limb. This branch is the external iliac artery; it soon equals and ultimately exceeds the internal iliac in size, and it is into these two vessels that the common iliac appears to bifurcate.

When the placental circulation ceases and the umbilical cord is severed, the part of the internal iliac trunk which extends from the pelvis to the umbilicus atrophies, and is afterwards represented almost entirely by a fibrous cord, known as the obliterated hypogastric artery. It is only at its proximal end that the atrophied part remains pervious, and here it forms the commencement of the superior vesical artery; accordingly, the permanent internal iliac artery is a comparatively short vessel. Owing to the arrangement of some of its branches it appears to end in an anterior and a posterior division, the former of which is to be regarded as the continuation of the vessel to the obliterated hypogastric, whilst the latter is simply a common stem of origin for some of the branches.

With this explanation the internal iliac artery may be described in the usual manner.

It arises from the common iliac opposite the lumbo-sacral articulation, and descends into the pelvis, to terminate, as a rule, opposite the upper border of the great sciatic notch, in two divisions—anterior and posterior—from each of which branches of distribution are given off. The artery measures about one and a half inches in length, and is the inner of the two terminal branches of the common iliac artery.

**Relations.**—*Anterior.*—The artery on each side is covered in front and internally by peritoneum, under which the corresponding ureter descends along the anterior border of the artery. The ilio-pelvic colon crosses from the front to the inner side of the left artery, and the terminal part of the ileum bears the same relation to the right artery.

*Posterior* to it are the internal iliac vein and the commencement of the common iliac vein; behind these is the lumbo-sacral cord and the sacrum.

*Lateral.*—On its outer side the external iliac vein separates it from the psoas muscle above, whilst below this is the obturator nerve, embedded in a mass of fat which intervenes between the internal iliac artery and the side wall of the pelvis. On its inner side it is crossed by some of the tributaries of the internal iliac vein, and is covered by peritoneum.

**Branches.**—The internal iliac artery supplies the greater part of the pelvic wall and viscera, and its branches are also distributed to the buttock and thigh and to the external organs of generation.

All the branches may be given off separately from a single undivided parent

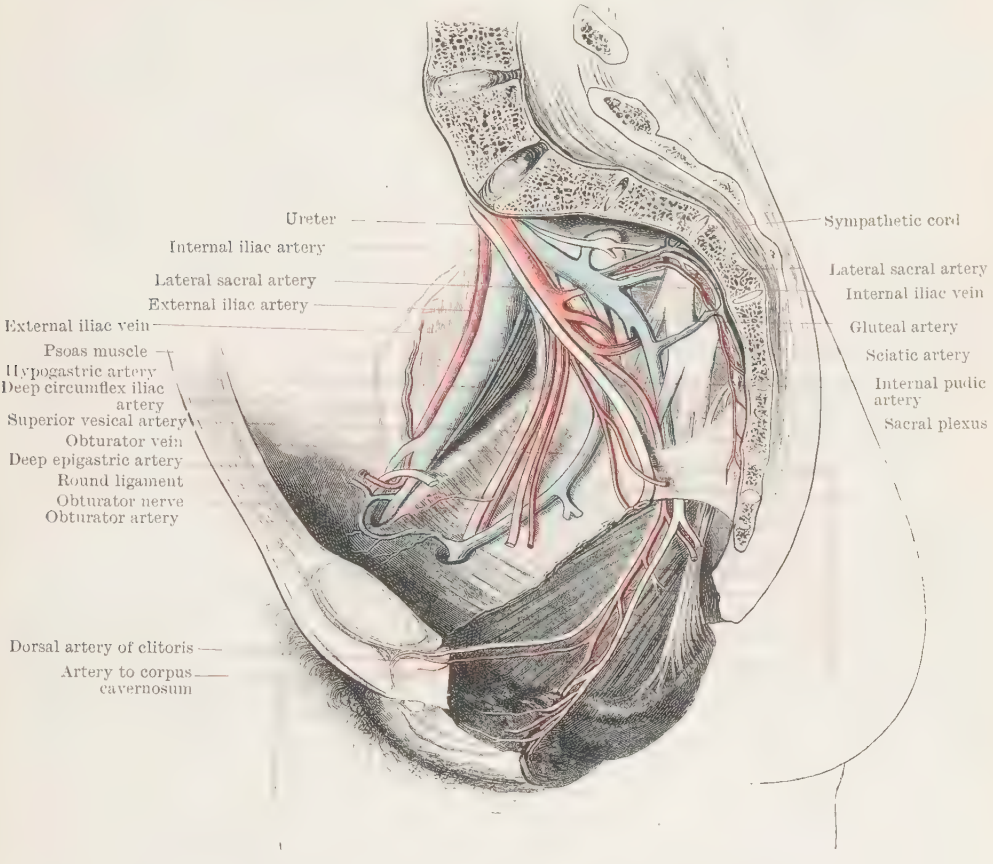

FIG. 637.—THE INTERNAL ILIAC ARTERY AND ITS BRANCHES IN THE FEMALE.

10. Artery to bulb.

trunk, but as a rule they arise in two groups corresponding to the two divisions in which the artery under these circumstances appears to end.

- **Posterior division**
  - **parietal**
    - Ilio-lumbar
    - Lateral sacral
    - Gluteal
- **Anterior division**
  - **parietal**
    - Obturator
    - Sciatic
    - Internal pudic
  - **visceral**
    - Superior vesical
      - (Obliterated hypogastric)
    - Middle vesical
    - Inferior vesical
    - Middle hæmorrhoidal.

In the female the inferior vesical is replaced by a vaginal branch, and an additional branch, the uterine, is given off.

### Branches of the Posterior Division.

The posterior terminal division gives off the ilio-lumbar and lateral sacral arteries, and is continued as the gluteal artery. No visceral branches are derived from this division.

1. **Ilio-lumbar Artery** (a. ilio-lumbalis).—This vessel runs upwards and outwards across the brim of the pelvis to the iliac fossa. It passes in front of the sacro-iliac articulation, between the lumbo-sacral cord and the obturator nerve, and behind either the lower part of the common or the upper part of the external iliac vessels and the psoas and iliacus muscles.

In the iliac fossa it anastomoses with branches of the deep circumflex iliac and obturator arteries. It also gives off offsets to the iliacus, and supplies a large nutrient branch to the ilium. A **lumbar branch** (ramus lumbalis) ascends behind the psoas to the crest of the ilium. It supplies the psoas and quadratus lumborum, and anastomoses with the lumbar and deep circumflex iliac arteries; it also gives off a *spinal branch* which enters the intervertebral foramen between the fifth lumbar vertebra and the sacrum, and is distributed like the spinal branches of the lumbar and aortic intercostal arteries.

2. **Lateral Sacral Arteries** (aa. sacrales laterales).—There is sometimes only a single lateral sacral artery on each side; more commonly there are two, superior and inferior.

Both branches run downwards and inwards on the front of the sacrum. The inferior passes in front of the pyriformis and the sacral nerves, and descends on the outer side of the sympathetic cord to the coccyx where it terminates by anastomosing with the middle sacral. The superior branch only reaches as far as the first or the second anterior sacral foramen, and then it enters the sacral canal. It anastomoses with the lower branch and with the middle sacral artery. Transverse branches are given off by the lateral sacral arteries to the pyriformis, and to the sacral nerves. Spinal offsets are also given off, which pass through the anterior sacral foramina to the sacral canal; they supply the membranes of the cord, the roots of the sacral nerves, and the filum terminale, and anastomose with other spinal arteries. They then pass backwards through the posterior sacral foramina, and anastomose on the back of the sacrum with branches of the gluteal and sciatic arteries.

3. **Gluteal Artery** (a. glutæa superior, Figs. 637 and 643).—After giving off the ilio-lumbar and lateral sacral branches, the posterior division of the internal iliac is continued as the gluteal artery. This is a large vessel which pierces the pelvic fascia, passes backwards between the lumbo-sacral cord and the first sacral nerve, and leaves the pelvis through the upper part of the great sciatic foramen. It runs above the pyriformis muscle to the buttock, immediately on reaching which it terminates, between the adjacent borders of the pyriformis and gluteus medius muscles and beneath the gluteus maximus, by dividing into superficial and deep branches.

(*a*) The **superficial branch** divides at once into numerous branches, some of which supply the gluteus maximus, whilst others pass through it, near its origin, to the overlying skin. The branches freely anastomose with branches of the sciatic, internal pudic, internal circumflex, deep circumflex iliac, and lateral sacral arteries.

(*b*) The **deep terminal branch**, accompanied by the superior gluteal nerve, runs forwards between the gluteus medius and minimus, and, after giving a nutrient branch to the ilium, subdivides into upper and lower branches. The *upper branch*, running forwards along the origin of the gluteus minimus from the middle curved line of the ilium, passes beyond the anterior margins of the gluteus medius and minimus to anastomose, under cover of the tensor fasciæ femoris, with the ascending branch of the external circumflex artery. It also anastomoses with the circumflex iliac artery, and it supplies muscular branches to the adjacent muscles. The *lower branch* passes more directly forwards, across the gluteus minimus, towards the trochanter major, along with the branch of the superior gluteal nerve which supplies the tensor fasciæ femoris. It supplies the glutei muscles, and anastomoses with the ascending branch of the external circumflex artery.

Before leaving the pelvis the gluteal artery gives **muscular branches** to the pelvic

diaphragm and the obturator internus, small **neural branches** to the roots of the sacral plexus, and **nutrient branches** to the hip-bone.

### Branches of the Anterior Division of the Internal Iliac Artery.

The anterior division gives off both parietal and visceral branches, and is continued as the hypogastric artery, which for the greater part of its extent is obliterated. The parietal branches are the obturator, the pudic, and the sciatic. The visceral branches include the superior, middle and inferior vesical, and the middle hæmorrhoidal arteries in the male. Similar visceral branches are also given off in the female, but the inferior vesical is replaced by the vaginal artery, and an additional branch, the uterine artery, is also given off.

### Visceral Branches.

1. The **superior vesical artery** (a. vesicalis superior) arises from the anterior division of the internal iliac. It divides into numerous branches which supply the upper part of the bladder, anastomosing with the other vesical arteries, and it also gives small branches to the urachus, and often to the lower part of the ureter. It may in addition give off the middle vesical artery, and not unfrequently the long slender artery to the vas deferens arises from one of its branches.

2. **Obliterated Hypogastric Artery.**—Atrophy of that portion of the internal iliac artery, which extends from the side of the bladder to the umbilicus (a. umbilicalis), has already been referred to. It is complete between the umbilicus and the true origin of the superior vesical artery, but between this origin and the apparent ending of the internal iliac in its two divisions the atrophy is incomplete, and the lumen of the vessel, though greatly diminished in size, remains, and is looked upon as the first part of the superior vesical artery. Strictly speaking, the first of these two parts only constitutes the "obliterated hypogastric" (ligamentum umbilicale laterale). It is a fibrous cord which runs forwards and upwards towards the apex of the bladder, whence it ascends on the posterior surface of the anterior abdominal wall and on the outer side of the urachus to the umbilicus. As it passes along the wall of the pelvis it is under cover of the peritoneum, and it is crossed by the vas deferens in the male, and by the round ligament in the female.

3. The **middle vesical artery** is usually given off behind the superior vesical. It is distributed to the posterior surface of the bladder as low down as the base; and to the vesiculæ seminales.

4. The **inferior vesical artery** (a. vesicalis inferior) is a very constant branch which runs inwards upon the upper surface of the levator ani to the base of the bladder. It also gives branches to the seminal vesicles, the vas deferens, the lower part of the ureter and the prostate, and it anastomoses with its fellow of the opposite side, with the other vesical arteries, and with the middle hæmorrhoidal artery.

The **artery to the vas** (a. deferentialis), which not unfrequently arises from the superior vesical, is a long slender vessel which runs downwards to the vas and vesicula seminales, and is then continued with the vas deferens to the testicle, where it anastomoses with the spermatic artery. It also anastomoses with the cremasteric branch of the deep epigastric artery.

5. The **middle hæmorrhoidal artery** (a. hæmorrhoidalis media) is an irregular branch which arises either directly from the anterior division of the internal iliac or from the inferior vesical branch; more rarely it springs from the internal pudic artery. It runs inwards, and is distributed to the muscular coats of the rectum; it also gives branches to the prostate, the seminal vesicle, and the vas deferens, and it anastomoses with its fellow of the opposite side, with the inferior vesical, and with the superior and inferior hæmorrhoidal arteries.

6. The **vaginal artery** (a. vaginalis) in the female usually corresponds to the inferior vesical in the male; in which case it arises from the anterior division of the internal iliac, either independently or in common with the uterine artery.

Occasionally both inferior vesical and uterine vessels are present, and not uncommonly the vaginal artery is represented by several branches.

The vaginal arteries run downwards and inwards on the floor of the pelvis to the sides of the vagina, and divide into numerous branches which ramify on its anterior and posterior walls. The corresponding branches of opposite sides anastomose and form anterior and posterior longitudinal vessels, the so-called azygos arteries. They also anastomose above with the cervical branches of the uterine artery, and below with the perineal branches of the internal pudic. In addition to supplying the vagina, small branches are given to the bulb of the vestibule, to the base of the bladder, and to the rectum.

7. The **uterine artery** (a. uterina) arises from the anterior division of the internal iliac, either separately or in common with the vaginal or middle hæmorrhoidal arteries. It runs inwards and slightly forwards, upon the upper surface of the levator ani, to the lower border of the broad ligament, between the two layers of which it passes inwards, and arches above the ureter about three-quarters of an inch from the uterus. It passes above the lateral fornix of the vagina to the side of the neck of the uterus, and is then directed upwards, until it almost reaches the fundus, just below which, however, it turns outwards beneath the isthmus of the Fallopian tube and anastomoses with the ovarian artery. It supplies the uterus, the upper part of the vagina, the inner part of the Fallopian tube, and gives branches to the round ligament of the uterus. It anastomoses with its fellow of the opposite side, and with the vaginal, the ovarian, and the deep epigastric arteries.

### Parietal Branches of the Anterior Division of the Internal Iliac.

1. The **obturator artery** (a. obturatoria, Figs. 637 and 640) runs forwards and downwards along the lateral wall of the true pelvis, just below its brim, to the obturator foramen, through the upper part of which it passes. It terminates immediately on entering the thigh by dividing into internal and external terminal branches, which skirt round the margin of the obturator foramen beneath the obturator externus muscle. It is accompanied in the whole of its course by the obturator nerve and vein, the former being above it and the latter below.

To its outer side is the pelvic fascia, which intervenes between it and the upper part of the obturator internus muscle, whilst on its inner side it is covered by peritoneum; between the peritoneum and the artery is the ureter. When the bladder is distended it also comes into close relation with the anterior part of the artery. In the female the ovarian vessels and the broad ligament are on the inner side of the obturator artery.

**Branches.**—All the branches except the terminal are given off before the artery leaves the pelvis. They include:—(*a*) **Muscular branches** to the obturator internus, levator ani and ilio-psoas muscles. (*b*) A **nutrient branch** to the ilium, which passes beneath the ilio-psoas muscle, supplies the bone, and anastomoses with the ilio-lumbar artery. (*c*) A **vesical branch**, or branches, pass inwards to the bladder beneath the lateral false ligament. (*d*) A **pubic branch** (ramus pubicus), which ascends on the back of the pubes, and anastomoses with its fellow of the opposite side and with the pubic branch of the deep epigastric, is given off just before the artery leaves the pelvis. In its upward course it may pass either on the outer or inner side of the external iliac vein, whilst not unfrequently it runs on the inner side of the crural ring. In the latter case it is important in relation to femoral hernia; and this importance is emphasised when, as sometimes happens, the obturator artery arises as an enlarged pubic branch of the deep epigastric artery instead of from the internal iliac. (*e*) **Terminal.**—The *internal terminal branch* (ramus anterior) runs forwards, and the *external* (ramus posterior) backwards round the margin of the obturator foramen. They lie on the obturator membrane, and under cover of the obturator externus. They anastomose together at the lower margin of the foramen, and both give off offsets which anastomose with the internal circumflex artery, and twigs of supply to the adjacent muscles. The external branch also gives an acetabular branch to the hip-joint, which passes upwards, through the cotyloid notch on the inner side of the transverse ligament, to supply the ligamentum teres and the head of the femur.

2. **Internal Pudic Artery** (a. pudenda interna, Figs. 637 and 638).—The internal pudic artery arises from the anterior division of the internal iliac close to the origin of the sciatic artery, which slightly exceeds it in size. It runs downwards and backwards in front of the pyriformis muscle and the sacral plexus, from both of which it is separated by the pelvic fascia, and on the outer side of the rectum to the lower part of the great sciatic foramen. In this course it pierces the pelvic fascia, passes between the pyriformis and coccygeus muscles, and leaves the pelvis to enter the buttock in company with the corresponding veins, the sciatic vessels and nerves, the pudic nerve, and the nerve to the obturator internus. In the buttock it lies, under cover of the gluteus maximus, on the spine of the ischium, between the pudic nerve and the nerve to the obturator internus, the former being internal to it. It next passes through the small sciatic foramen

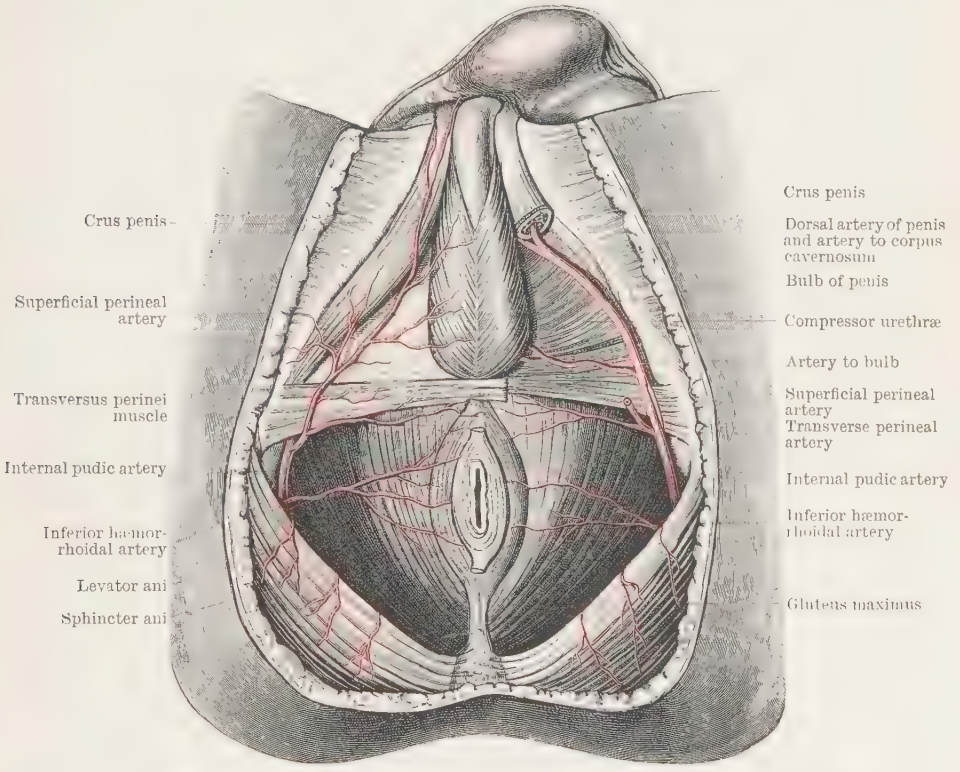

Fig. 638.—The Perineal Distribution of the Internal Pudic Artery in the Male.

and enters the perineum, in the anterior part of which it terminates by dividing into the artery of the corpus cavernosum and the dorsal artery of the penis.

In the first part of its course in the perineum the artery lies in the outer fascial wall of the ischio-rectal fossa, where it is enclosed in the space known as Alcock's canal. This, which is situated about one and a half inches above the lower margin of the tuberosity of the ischium, contains also the pudic veins and the terminal parts of the pudic nerve, viz. the dorsal nerve of the penis which lies above the artery, and the perineal division which lies below the vessel. From the ischio-rectal fossa the internal pudic is continued forwards between the two layers of the triangular ligament of the urethra, and close to the ramus of the pubis. About half-an-inch below the subpubic ligament it turns somewhat abruptly forwards, pierces the anterior layer of the triangular ligament, and immediately divides into its terminal branches, viz. the artery of the corpus cavernosum and the dorsal artery of the penis. The division sometimes takes place whilst the artery is still between the layers of the triangular ligament.

**Branches.**—*In the pelvis* it gives small branches to the neighbouring muscles and to the roots of the sacral plexus.

*In the buttock.*—(*a*) **Muscular branches** are given to the adjacent muscles. (*b*) **Anastomotic branches** unite with branches of the gluteal, sciatic and internal circumflex arteries.

*In the ischio-rectal fossa.*—(*c*) The **inferior hæmorrhoidal artery** (a. hæmorrhoidalis inferior) pierces the inner wall of Alcock's canal, and runs obliquely forwards and inwards. It soon divides into two or three main branches, which, sometimes arising separately, pass across the space to the anal passage. The artery anastomoses in the walls of the anal passage with its fellow of the opposite side, and with the middle and superior hæmorrhoidal arteries; it also anastomoses with the transverse perineal arteries, and it supplies cutaneous twigs to the region of the anus, and others which turn round the lower border of the gluteus maximus to supply the lower part of the buttock.

(*d*) The **superficial perineal artery** (a. perinei) arises in the anterior part of the ischio-rectal fossa, pierces the base of the triangular ligament, and divides into long slender branches (aa. scrotales posteriores in the male, labiales posteriores in the female) which are continued forwards in the urethral triangle, beneath the superficial perineal fascia, to the scrotum. It anastomoses with its fellow of the opposite side, with the transverse perineal and the external pudic arteries, and it supplies the muscles and subcutaneous structures of the urethral triangle.

(*e*) The **transverse perineal artery** is a small branch which arises either from the internal pudic or from its superficial perineal branch. It runs inwards along the base of the triangular ligament to the central point of the perineum, where it anastomoses with its fellow of the opposite side, with the superficial perineal branch, and with the inferior hæmorrhoidal arteries. It supplies the sphincter ani, the bulbo-cavernosus or sphincter vaginæ, and the anterior fibres of the levator ani.

*In the urethral triangle.*—(*f*) The **artery to the bulb** (a. bulbi urethræ), a branch which is usually of relatively large size, is given off between the layers of the triangular ligament. It runs transversely inwards along the posterior border of the compressor urethræ, and then turning forwards a short distance from the outer side of the urethra, it pierces the anterior layer of the triangular ligament and enters the substance of the bulb. It passes onwards in the corpus spongiosum to the glans, where it anastomoses with its fellow and with the dorsal arteries of the penis.

It supplies the compressor urethræ muscle, Cowper's gland, the corpus spongiosum, and the penile part of the urethra. In the female this artery supplies the bulb of the vestibule.

(*g*) The **artery of the corpus cavernosum** (a. profunda penis in the male; a. profunda clitoridis in the female) is usually the larger of the two terminal branches. Immediately after its origin it enters the crus penis, and runs forwards in the corpus cavernosum, which it supplies.

(*h*) The **dorsal artery of the penis** (a. dorsalis penis in the male; a. dorsalis clitoridis in the female) passes forwards between the layers of the suspensory ligament, and runs along the dorsal surface of the penis with the dorsal nerve immediately to its outer side, whilst it is separated from its fellow of the opposite side by the median deep dorsal vein. It supplies the superficial tissues on the dorsal aspect of the penis, sends branches into the corpus cavernosum to anastomose with the artery to the corpus cavernosum, and its terminal branches enter the glans penis, where they anastomose with the arteries to the bulb. It also anastomoses with the external pudic branches of the femoral.

3. **Sciatic Artery** (a. glutæa inferior, Figs. 637 and 639).—The sciatic artery arises, usually distinct from the pudic artery, but sometimes in common with it, from the anterior division of the internal iliac. It descends a little behind and external to the pudic vessels, pierces the pelvic fascia, runs backwards between the first and second, or second and third sacral nerves, and passing between the pyriformis and coccygeus muscles, leaves the pelvis through the lower part of the great sciatic foramen, and enters the buttock just below the pyriformis. In the buttock it descends behind and to the inner side of the great sciatic nerve beneath the gluteus maximus, and behind the obturator internus, the two gemelli, the quadratus femoris, and upper part of the adductor magnus muscles, to the upper part of the thigh.

Below the lower border of the gluteus maximus the artery is comparatively superficial, and having given off its largest branches, it descends as a long slender vessel with the small sciatic nerve.

**Branches.**—*In the pelvis.*—Small and irregular branches supply the adjacent viscera

and muscles and the sacral nerves; they anastomose with branches of the internal pudic and lateral sacral arteries.

*In the buttock.*—(*a*) **Muscular branches** are given off to the muscles of the buttock and to the upper parts of the hamstring muscles. They anastomose with the pudic, internal circumflex, and obturator arteries. (*b*) The **coccygeal branch** arises immediately after the artery leaves the pelvis. It runs inwards, pierces the great sacro-sciatic ligament and the gluteus maximus, and ends in the soft tissues over the back of the lower part of the sacrum and of the coccyx. It gives several branches to the gluteus maximus, and anastomoses with branches of the gluteal and lateral sacral arteries. (*c*) An **anastomotic branch** passes transversely outwards, over or under the great sciatic nerve, towards the great trochanter of the femur. It anastomoses with branches of the gluteal, pudic, internal and external circumflex, and the first perforating arteries, taking part in the formation of the so-called "crucial anastomosis." (*d*) **Cutaneous branches**, accompanying twigs of the small sciatic nerve, pass round the lower border of the gluteus maximus muscle to the integument. (*e*) The **comes nervi ischiatici** (a. comitans n. ischiadici) is a long slender branch which runs down on the surface, or in the substance of the great sciatic nerve. It supplies the nerve, and anastomoses with the perforating arteries and with the termination of the profunda.

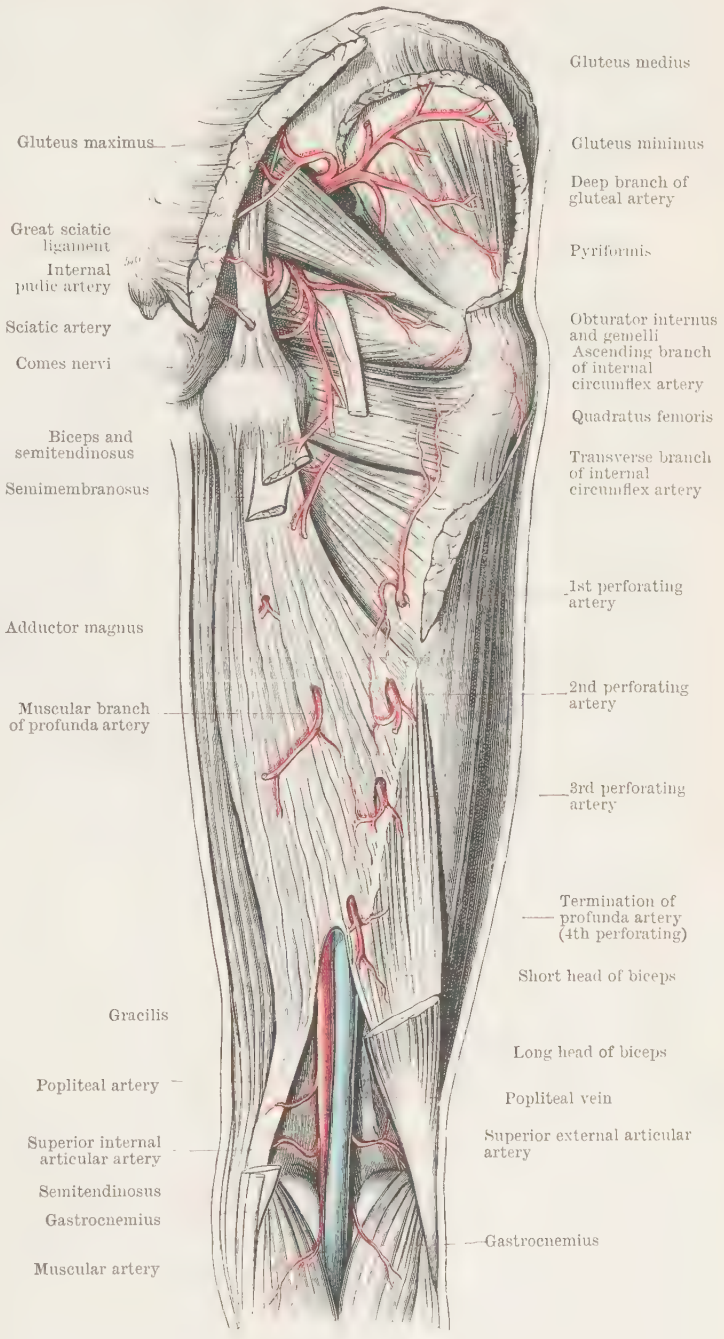

FIG. 639.—THE ARTERIES OF THE BUTTOCK AND THE BACK OF THE THIGH AND KNEE.

## ARTERIES OF THE LOWER EXTREMITY.

The main artery of each lower limb is continued from the corresponding common iliac artery. It descends as a single trunk as far as the lower border of the popliteus, and ends there by dividing into the anterior and posterior tibial arteries. Distinctive names are, however, applied to different parts of the artery, corresponding to the several regions through which it passes. Thus in the abdomen it is called the **external iliac artery**, in the upper two-thirds of the thigh it receives the name of the **femoral artery**, whilst its lower part, which is situated on the flexor aspect of the knee, is termed the **popliteal artery**.

### THE EXTERNAL ILIAC ARTERY.

The **external iliac artery** (a. iliaca externa) extends from a point opposite the sacro-iliac joint at the level of the lumbo-sacral articulation to a point beneath Poupart's ligament, midway between the anterior superior spine of the ilium and the symphysis pubis, where it becomes the femoral artery. Its length is about three and a half inches (87 to 100 mm.), and in the adult it is usually somewhat larger than the internal iliac artery.

It runs downwards, outwards, and forwards along the brim of the pelvis, resting upon the iliac fascia, which separates it above from the inner border, and below from the anterior surface of the psoas muscle, and it is enclosed with its accompanying vein in a thin fascial sheath.

**Relations.**—*Anterior.*—It is covered in front by peritoneum, which separates it on the left side from the pelvic colon, iliac colon, and coils of small intestine, and on the right side from the terminal portion of the ileum, and sometimes from the vermiform appendix. The ureter, descending behind the peritoneum, sometimes crosses the front of the artery near its origin, and in the female the ovarian vessels cross the upper part of the artery. Near its lower end the artery is crossed anteriorly by the genital branch of the genito-crural nerve and by the deep circumflex iliac vein. In the male this part of the artery is also crossed by the vas deferens, and in the female by the round ligament of the uterus. Several iliac lymphatic glands lie in front and at the sides of the external iliac artery, and almost invariably one of these is directly in front of its termination.

*Posterior.*—The iliac fascia and psoas muscle lie behind the artery. Near its upper end the obturator nerve is also posterior to the vessel.

*Lateral.*—Externally is the genito-crural nerve; internally, and on a somewhat posterior plane, is the external iliac vein.

**Branches.**—In addition to small branches to the psoas muscle and to the lymphatic glands, two named branches of considerable size spring from the external iliac artery, viz. the deep epigastric and the deep circumflex iliac.

(1) The **deep epigastric artery** (a. epigastrica inferior, Figs. 637 and 640) arises immediately above Poupart's ligament from the front of the external iliac. Curving forward from its origin it lies in the extra-peritoneal fat, it turns round the lower border of the peritoneal sac, and runs upwards and inwards along the inner side of the internal abdominal ring and along the outer border of Hesselbach's triangle; it then pierces the transversalis fascia, passes over the semilunar fold of Douglas and enters the sheath of the rectus abdominis. For a short distance it ascends behind the rectus, but it soon penetrates the substance of the muscle, and breaks up into branches which anastomose with terminal offsets of the superior epigastric branch of the internal mammary artery and with the lower intercostal arteries. At the internal abdominal ring in the male the vas deferens, the spermatic vessels, and the genital branch of the genito-crural nerve hook round the front and outer side of the artery, the vas deferens turning inwards behind it; whilst in the female the round ligament of the uterus and the genital branch of the genito-crural nerve occupy the corresponding positions.

**Branches.**—(*a*) **Muscular branches** which spring mainly from the outer side of the artery supply the rectus, the pyramidalis, the transversalis, and the oblique muscles of the abdominal wall, and anastomose with branches of the deep circumflex iliac, the

lumbar, and the lower intercostal arteries. (*b*) **Cutaneous branches** which pass from the front of the deep epigastric pierce the rectus abdominis and the front part of its sheath, and terminate in the subcutaneous tissues of the anterior abdominal wall, where they anastomose with corresponding branches of the opposite side and with branches of the superficial epigastric artery. (*c*) The **cremasteric branch** (a. spermatica externa in the male, a. ligamenti teretis uteri in the female) is small. It descends through the inguinal canal and anastomoses with the external pudic and superficial perineal arteries, and in the male with the spermatic artery also. In the male it accompanies the spermatic cord, supplying its coverings, including the cremaster. In the female it runs with the round

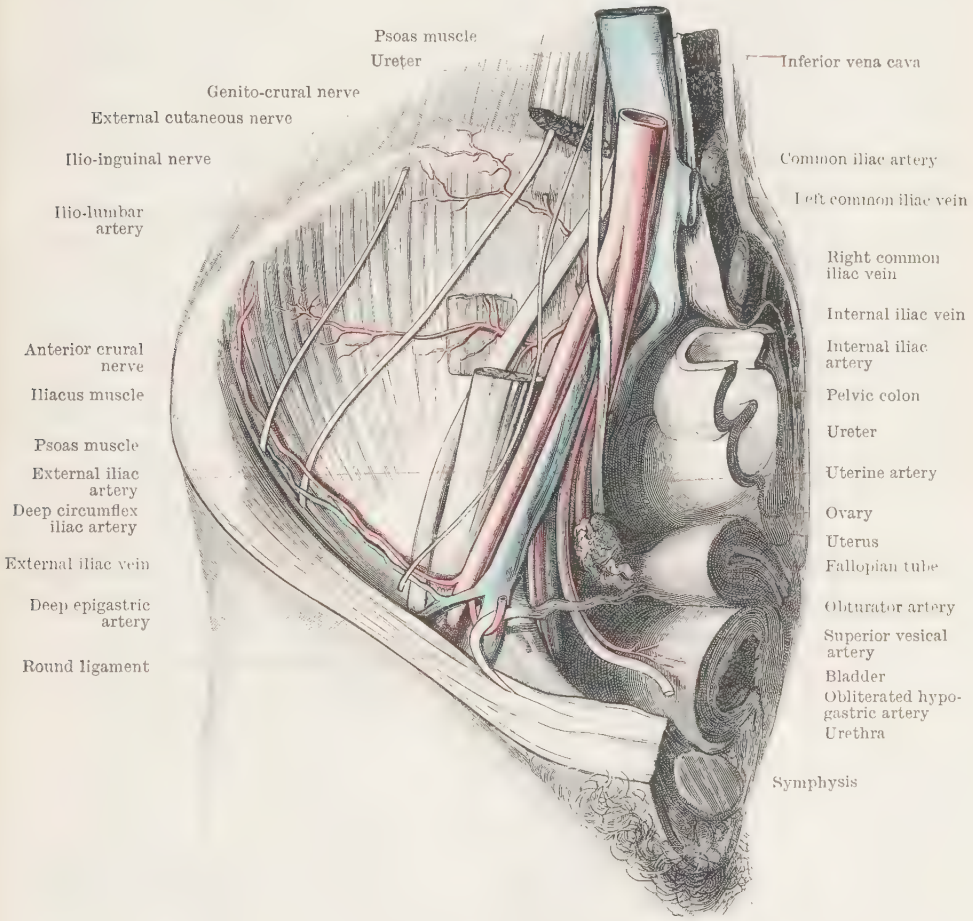

FIG. 640.—THE ILIAC ARTERIES AND VEINS IN THE FEMALE.

ligament. (*d*) The **pubic branch** (ramus pubicus) descends either on the outer or the inner side of the crural ring to anastomose with the pubic branch of the obturator artery; it also anastomoses with its fellow of the opposite side. Sometimes when the obturator branch of the internal iliac artery is absent, the pubic branch of the deep epigastric artery enlarges and becomes the obturator artery, which descends to the obturator foramen either on the outer or the inner side of the crural ring. In the latter case the artery may be injured in the operation for the relief of a strangulated femoral hernia.

(2) The **deep circumflex iliac artery** (a. circumflexa ilium profunda, Figs. 637 and 640) springs from the outer side of the external iliac artery, usually a little below the deep epigastric, and immediately above Poupart's ligament. It runs outwards and upwards to the anterior superior spine of the ilium. In this part of its course it lies just above the lower border of Poupart's ligament, and is enclosed in a fibrous canal formed by the union of the transversalis and iliac fasciæ. A little beyond the anterior superior spine it pierces the transversalis abdominis, and

is continued backwards between the transversalis and the internal oblique, to terminate by anastomosing with branches of the ilio-lumbar artery.

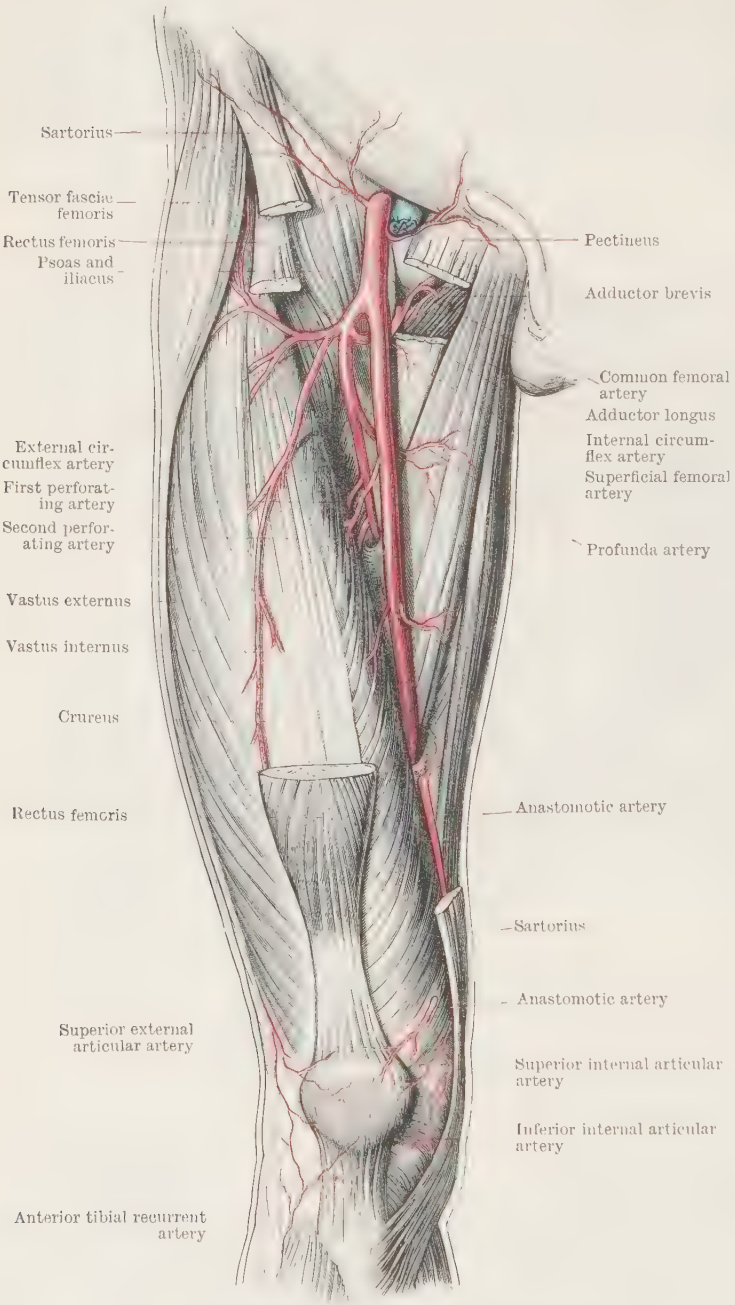

FIG. 641.—THE FEMORAL ARTERY AND ITS BRANCHES.

**Branches.** — (*a*) **Muscular** to the upper parts of the sartorius and the tensor fasciæ femoris, and to the muscles of the abdominal wall. One of the latter branches is frequently of considerable size; it pierces the transversalis muscle a short distance in front of the anterior superior spine of the ilium, and ascends vertically between the transversalis and the internal oblique, anastomosing with the lumbar and epigastric arteries. (*b*) **Cutaneous branches** pierce the internal and external oblique muscles. They terminate in the skin over the crest of the ilium, and they anastomose with the gluteal, the superficial circumflex iliac and the ilio-lumbar arteries.

## THE FEMORAL ARTERY.

The **femoral artery** (a. femoralis, Figs. 641 and 642) continues the external iliac into the thigh. It commences at the lower border of Poupart's ligament, and, descending through the upper two-thirds of the thigh, terminates at the opening in the adductor magnus. At one time it was customary to speak of the first one and a half inches, as far as the origin of the profunda branch, as the common femoral, and to say that it divided into the superficial and deep femoral branches, of which the former was the direct continuation of the common trunk. The morphology and development of the vessel gives no support for such terminology, and it should be discontinued.

**Course.**—Its general direction is indicated by a line drawn from the point of

origin midway between the anterior superior spine of the ilium and the symphysis pubis to the adductor tubercle, the thigh being flexed and rotated outwards.

In its upper half the femoral artery lies in Scarpa's triangle, and is comparatively superficial; at the apex of the triangle it passes beneath the sartorius, enters Hunter's canal, and is thus more deeply placed.

At its entry into Scarpa's triangle both the artery and its vein are enclosed, for a distance of one and a quarter inches, in a funnel-shaped fascial sheath formed of the fascia transversalis in front and the iliac fascia behind. This is called the **femoral sheath**; it is divided by septa, running from front to back, into three compartments, the outer of which is occupied by the femoral artery and genito-crural nerve. The middle contains the femoral vein, and the internal compartment constitutes the crural canal.

**Relations.**—In *Scarpa's triangle* the femoral artery is covered by skin and fascia, by superficial inguinal lymphatic glands and small superficial vessels. The anterior part of the femoral sheath and the cribriform fascia are in front of the upper part of the artery, and the fascia lata is in front of the lower part. Near the apex of the triangle the artery is crossed by the internal cutaneous nerve, and not infrequently by a tributary of the internal saphenous vein. Behind, it is in relation, from above downwards, with the posterior part of the femoral sheath, the pubic portion of the fascia lata and the psoas, the pectineus, and the upper part of the adductor longus muscles. The nerve to the pectineus passes between the artery and the psoas; the femoral vein and the profunda artery and vein intervene between it and the pectineus, and the femoral vein also separates it from the adductor longus.

The femoral vein which lies behind the artery in the lower part of Scarpa's triangle passes to its inner side above, but is separated from the artery by the outer septum of the femoral sheath. On the outer side of the artery is the anterior crural nerve above; lower down the internal saphenous nerve and the nerve to the vastus internus are continued on the outer side. The crural branch of the genito-crural nerve is in front and to the outer side above, and runs for a short distance in the femoral sheath.

In *Hunter's canal* the artery has behind it the adductor longus and the adductor magnus, whilst in front and to the outer side is the vastus internus. The femoral vein is also behind the artery, but lies to its outer side below and to its inner side above. Superficial to the artery is the fascial roof of the canal, upon which is the sub-sartorial plexus of nerves and the sartorius muscle. The internal or long saphenous nerve enters Hunter's canal with the artery, and runs first on its outer side, then in front, and lastly on its inner side.

**Branches.**—The femoral artery gives off the following branches:—

(1) Superficial branches.
  (*a*) The superficial external pudic.
  (*b*) The superficial epigastric.
  (*c*) The superficial circumflex iliac.
(2) Muscular.
(3) The deep external pudic.
(4) The profunda.
(5) The anastomotica magna.

(*a*) The **superficial circumflex iliac** (a. circumflexa ilium superficialis) springs from the front of the femoral artery just below Poupart's ligament. It pierces the femoral sheath and the fascia lata, external to the saphenous opening, and runs in the superficial fascia as far as the anterior superior spine of the ilium. It supplies the outer set of inguinal glands and the skin of the groin, and it sends branches through the fascia lata which anastomose with the deep circumflex iliac and supply the upper parts of the sartorius and tensor fasciæ femoris muscles.

(*b*) The **superficial epigastric artery** (a. epigastrica superficialis) arises near the preceding. It pierces the femoral sheath and the cribriform fascia, and passes upwards and inwards between the superficial and deep layers of the superficial fascia of the abdominal wall towards the umbilicus. It supplies the inguinal glands and the integument, and anastomoses with its fellow of the opposite side, with the deep epigastric, and with the superficial circumflex iliac and superficial external pudic arteries.

(*c*) The **superficial external pudic artery** (a. pudenda externa superficialis) also

springs from the front of the femoral artery, and, after piercing the femoral sheath and the cribriform fascia, runs upwards and inwards towards the spine of the pubis, where it crosses superficial to the spermatic cord. It supplies the integument of the lower part of the abdominal wall, the root of the dorsum of the penis in the male, and the region of the mons Veneris in the female, and it anastomoses with its fellow of the opposite side, the deep external pudic, the dorsal artery of the penis, and the superficial epigastric arteries.

(2) **Muscular branches** are distributed to the pectineus and the adductor

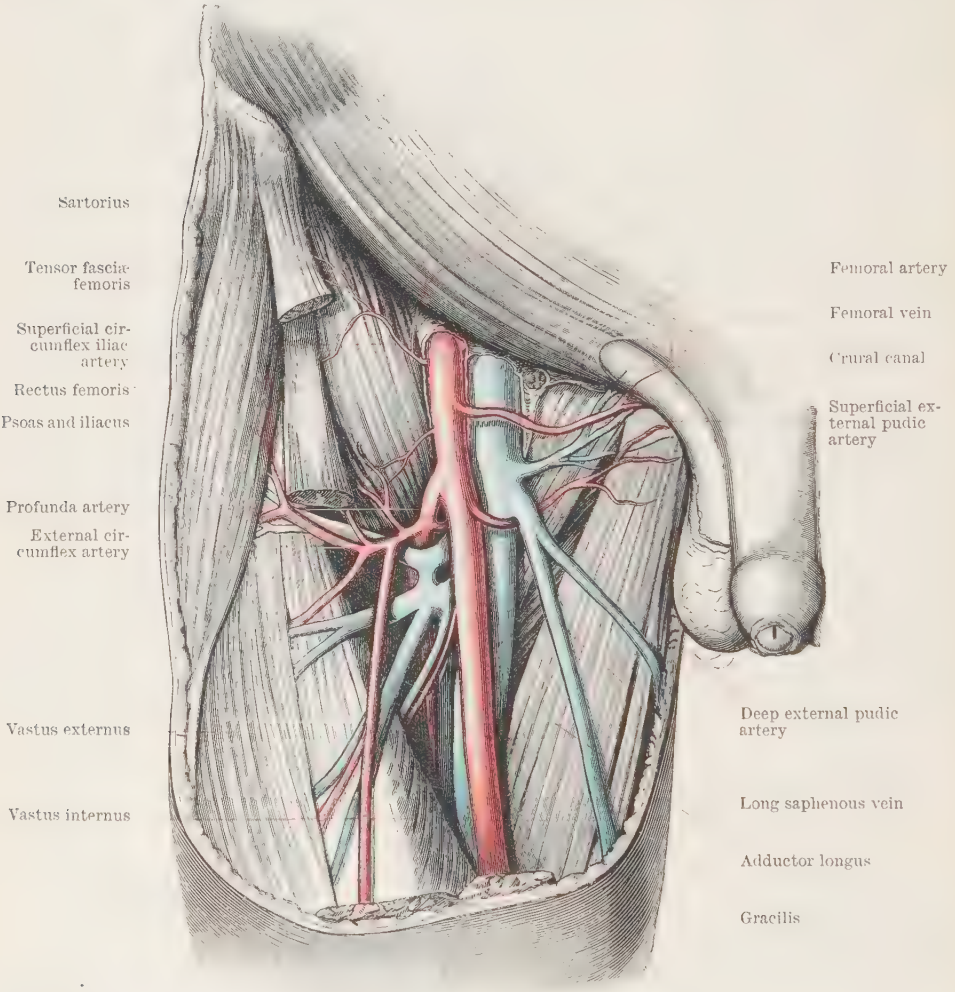

Fig. 642.—The Femoral Vessels in Scarpa's Triangle.

muscles on the inner side, and to the sartorius and the vastus internus on the outer side.

(3) The **deep external pudic artery** (a. pudenda externa profunda) rises from the inner side of the femoral. It runs inwards, across the front of the pectineus, and in front of or behind the adductor longus, to the inner side of the thigh; it then pierces the deep fascia, and terminates in the scrotum, where it anastomoses with the superficial perineal and superficial external pudic arteries, and with the cremasteric branch of the deep epigastric artery.

(4) The **profunda artery** (a. profunda femoris, Fig. 640) is the largest branch of the femoral artery. It arises about an inch and a half below Poupart's ligament, from the outer side of the femoral artery. Curving backwards and inwards, it passes behind the latter vessel, and runs downwards, close to the inner aspect of

the femur, to the lower third of the thigh, where it perforates the adductor magnus and passes to the back of the thigh. Its termination is known as the fourth perforating artery. As the profunda descends it lies in front of the iliacus, the pectineus, the adductor brevis, and the adductor magnus. It is separated from the femoral artery by its own vein, by the femoral vein, and by the adductor longus muscle behind which it passes.

**Branches.**—(*a*) **Muscular branches** are given off from the profunda both in Scarpa's triangle, and whilst it lies between the adductor muscles; many of them terminate in the adductors, others pass through the adductor magnus, and terminate in the hamstrings, where they anastomose with the transverse branch of the internal circumflex and with the upper muscular branches of the popliteal artery.

(*b*) The **external circumflex artery** (a. circumflexa femoris lateralis, Figs. 641 and 642) springs from the outer side of the profunda, or occasionally from the femoral artery above the origin of the profunda. It runs outwards across the front of the iliacus, and between the superficial and deep branches of the anterior crural nerve, to the outer border of Scarpa's triangle; then, passing behind the sartorius and the rectus femoris, it terminates by dividing into three terminal branches—the ascending, the transverse, and the descending. Before its termination it supplies branches to the muscles mentioned and to the upper part of the crureus.

(i.) The **ascending terminal branch** (ramus ascendens) runs upwards and outwards, behind the rectus femoris and the tensor fasciæ femoris, along the anterior intertrochanteric line, to the anterior borders of the gluteus medius and minimus, between which it passes to anastomose with the deep branches of the gluteal artery. It supplies twigs to the neighbouring muscles, anastomoses with the gluteal, the deep circumflex iliac, and the transverse branch of the external circumflex arteries, and, as it ascends along the anterior intertrochanteric line, gives off a branch which passes between the two limbs of the Y-shaped ligament into the hip-joint. (ii.) The **transverse terminal branch** is small; it runs outwards between the crureus and the rectus femoris, passes into the substance of the vastus externus, winds round the femur, and anastomoses with the ascending and descending branches, with the perforating branches of the profunda, and with the sciatic and internal circumflex arteries. (iii.) The **descending terminal branch** (ramus descendens) runs downwards behind the rectus and along the anterior border of the vastus externus accompanied by the nerve to the latter muscle. It anastomoses with the transverse branch, with twigs of the inferior perforating arteries, with the anastomotic branch of the femoral, and with the superior external articular branch of the popliteal artery.

(*c*) The **internal circumflex artery** (a. circumflexa femoris medialis, Fig. 641) springs from the inner and back part of the profunda, at the same level as the external circumflex, and runs backwards, through the floor of Scarpa's triangle, passing between the psoas and the pectineus; crossing the upper border of the adductor brevis it is continued backwards beneath the neck of the femur, and passes between the adjacent borders of the obturator externus and the adductor brevis to the upper border of the adductor magnus, where it divides into two terminal branches, a transverse and an ascending.

**Branches.**—(i.) An **articular branch** (ramus acetabuli) is given off as the artery passes beneath the neck of the femur. It ascends to the cotyloid notch where it anastomoses with twigs from the posterior branch of the obturator artery, and it sends branches into the cotyloid cavity and along the ligamentum teres to the head of the femur. (ii.) **Muscular branches** are given off to the neighbouring muscles. The largest of these branches usually rises immediately before the termination of the artery, it descends on the anterior aspect of the adductor magnus and anastomoses with the muscular branches of the profunda artery. (iii.) The **ascending terminal branch** (ramus profundus) passes upwards and outwards, between the obturator externus and the quadratus femoris to the digital fossa of the femur, where it anastomoses with branches of the gluteal and the sciatic arteries. (iv.) The **transverse terminal branch** (ramus superficialis) runs backwards between the lower border of the quadratus femoris and the upper border of the adductor magnus to the hamstring muscles. It anastomoses in front of the lower part of the gluteus maximus with the sciatic and first perforating arteries and with the transverse branch of the external circumflex, and in the substance of the hamstrings with the muscular branches of the profunda.

(*d*) The **perforating arteries** (Fig. 643), including the terminal branch of the profunda, are four in number. They curve backwards and outwards round the posterior aspect of the femur, lying close to the bone, in front of well-marked tendinous arches, which interrupt the continuity of muscular attachments; their terminal branches enter the vastus externus and anastomose in its substance with each other, with the descending branch of the external circumflex, with the anastomotic, and with the superior external articular branch of the popliteal.

The **first perforating artery** (a. perforans prima) pierces the insertions of the adductors brevis and magnus, and some of its branches anastomose in front of the gluteus maximus with the sciatic, with the transverse branch of the internal circumflex, and with the transverse branch of the external circumflex, forming what is known as the crucial anastomosis.

The **second perforating artery** (a. perforans secunda) pierces the adductors brevis and magnus, and then passes between the gluteus maximus and the short head of the biceps into the vastus externus. It anastomoses with its fellows above and below, and with the internal circumflex and the upper muscular branches of the popliteal artery.

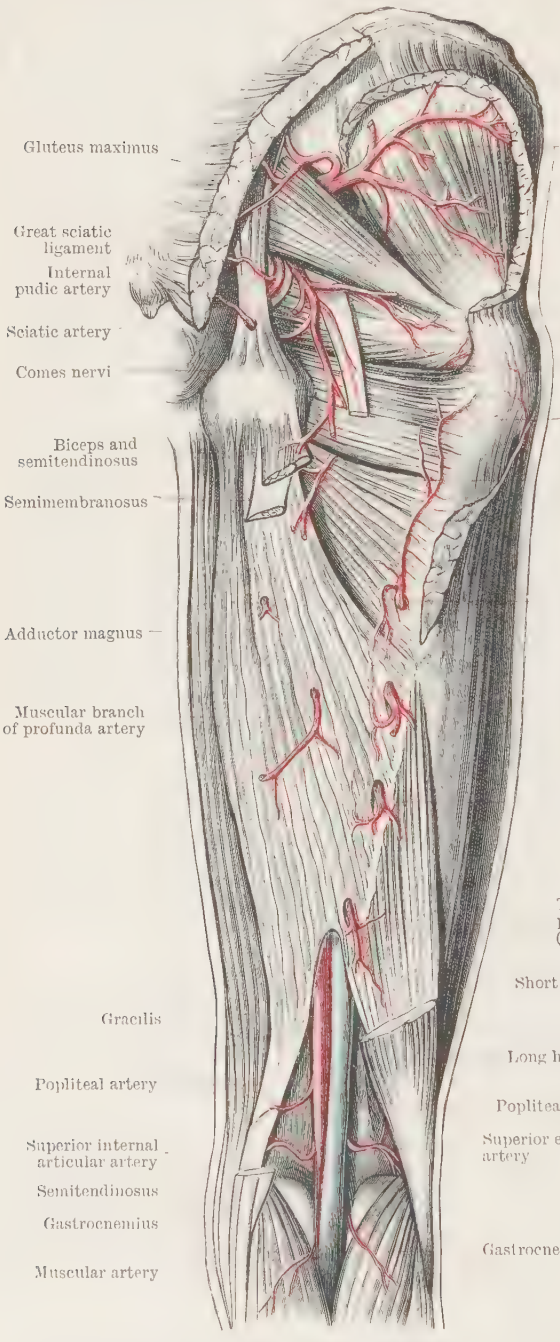

FIG. 643.—THE ARTERIES OF THE BUTTOCK AND THE BACK OF THE THIGH AND KNEE.

The **third** (a. perforans tertia) and **fourth perforating arteries** pass through the adductor magnus and the short head of the biceps into the vastus externus. Their anastomoses are similar to those of the second perforating.

A **nutrient branch** (a. nutricia femoris) to the femur is given off either from the second or third perforating artery, usually the former; an additional nutrient branch may also be supplied by the first or fourth perforating arteries.

(5) The **anastomotic** (a. genu suprema) arises near the termination of the femoral artery in the lower part of Hunter's canal, and divides almost immediately into a superficial and a deep branch; indeed, very frequently the two branches arise separately from the femoral trunk.

(*a*) The **superficial branch** (ramus saphenus) passes through the lower end of Hunter's canal with the long saphenous nerve, and appears superficially on the inner side of the knee between the gracilis and the sartorius. It gives twigs to the integument of the upper and inner part of the leg, and it anastomoses with the inferior internal articular artery. (*b*) The **deep branch** (ramus musculo-articularis) descends in the substance of the vastus internus along the anterior aspect of the tendon of the adductor magnus. It anastomoses with

the superior internal articular artery, and it sends branches outwards, one on the surface of the femur and another along the upper border of the patella, to anastomose with the descending branch of the external circumflex, the inferior perforating artery, the superior external articular, and the anterior tibial recurrent.

## THE POPLITEAL ARTERY.

The **popliteal artery** (a. poplitea) is the direct continuation of the femoral. It commences at the upper and inner part of the popliteal space, under cover of the semimembranosus, and terminates at the lower border of the popliteus muscle, and on a level with the lower part of the tubercle of the tibia, by dividing into the anterior and the posterior tibial arteries.

From its origin the artery descends, with an outward inclination, to the interspace between the condyles of the femur, whence it is continued vertically downwards to its termination.

**Relations.**—*Anterior.*—It is in contact in front and from above downwards with the popliteal surface of the femur, the posterior ligament of the knee-joint, and the fascia covering the posterior surface of the popliteus.

*Posterior.*—The artery is overlapped behind by the outer border of the semimembranosus above; it is crossed about its middle by the popliteal vein and the internal popliteal nerve, the vein intervening between the artery and the nerve; whilst in the lower part of its extent it is overlapped by the adjacent borders of the two heads of the gastrocnemius, and is crossed by the nerves to the soleus and popliteus and by the plantaris muscle.

*Lateral.*—On its outer side it is in relation above with the internal popliteal nerve and the popliteal vein, then with the outer condyle of the femur, and below with the outer head of the gastrocnemius and with the plantaris.

On the inner side it is in relation above with the semimembranosus, in the middle with the inner condyle of the femur, and below with the internal popliteal nerve, the popliteal vein, and the internal head of the gastrocnemius. Popliteal lymphatic glands are arranged irregularly around the artery.

**Branches.**—(1) **Muscular branches** are given off in two sets, upper and lower.

The upper muscular branches are distributed to the lower parts of the hamstring muscles, in which they anastomose with branches of the profunda artery.

The lower muscular, or sural, arteries (aa. surales) enter the upper parts of the gastrocnemius, the plantaris, the soleus, and the popliteus muscles, and they anastomose with branches of the posterior tibial artery and the lower articular arteries.

(2) The **articular branches** are five in number—viz. upper and lower external, upper and lower internal, and an azygos branch.

(*a*) The **superior external articular artery** (a. genu superior lateralis) passes outwards above the external condyle, behind the femur and in front of the biceps tendon, into the vastus externus, where it anastomoses with the anastomotic, the descending branch of the external circumflex, and the lowest perforating artery; it also sends branches downwards to anastomose with the inferior external articular and with the anterior tibial recurrent.

(*b*) The **superior internal articular artery** (a. genu superior medialis) passes inwards above the internal condyle, behind the femur, and in front of the tendon of the adductor magnus, into the vastus internus. It anastomoses with branches of the anastomotic and of the superior external articular artery.

(*c*) The **inferior external articular artery** (a. genu inferior lateralis) runs outwards across the popliteus muscle and in front of the plantaris and the external head of the gastrocnemius; then turning forwards, it is joined by the inferior external articular nerve, and passes to the inner side of the external lateral ligament. It terminates by anastomosing with its fellow of the opposite side and with the superior external articular and anterior tibial recurrent arteries.

(*d*) The **inferior internal articular artery** (a. genu inferior medialis) passes inwards below the inner tuberosity of the tibia, along the upper border of the popliteus and in front of the internal head of the gastrocnemius, to the inner side of the knee, where it turns forwards between the bone and the internal lateral ligament, and terminates anteriorly by anastomosing with its fellow of the opposite side, with the recurrent branch of the anterior tibial artery, and with the superior internal articular artery.

(*e*) The **azygos articular artery** (a. genu media) passes directly forwards from the front

of the popliteal artery, pierces the central part of the posterior ligament of the knee-joint, and enters the intercondylar space. It supplies branches to the crucial ligaments and to the synovial membrane, and is accompanied by the azygos articular branch of the internal popliteal nerve, and sometimes by the genicular branch of the obturator nerve.

(3) **Cutaneous branches** are distributed to the skin over the popliteal space. One of these, the *superficial sural artery*, descends in the middle line of the back of the calf along with the external saphenous nerve.

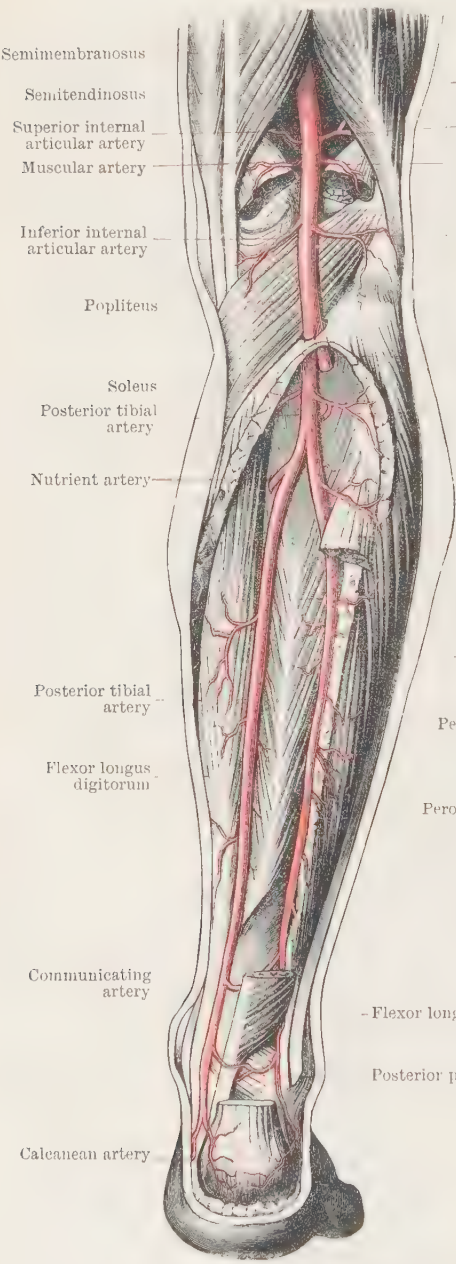

FIG. 644.—THE POPLITEAL AND POSTERIOR TIBIAL ARTERIES AND THEIR BRANCHES.

## THE POSTERIOR TIBIAL ARTERY.

The **posterior tibial artery** (a. tibialis posterior), the larger of the two terminal branches of the popliteal, commences at the lower border of the popliteus and terminates midway between the tip of the inner malleolus and the most prominent part of the heel, at the lower border of the internal annular ligament. It ends by dividing into the internal and the external plantar arteries, which pass onwards to the sole of the foot.

The artery runs downwards and inwards on the back of the leg between the superficial and deep layers of muscles, and covered by the deep intermuscular fascia which intervenes between them.

**Relations.**—*Anterior.*—It is in contact in front, and from above downwards, with the tibialis posticus, the flexor longus digitorum, the posterior surface of the tibia, and the posterior ligament of the ankle-joint.

*Posterior.* — The artery is crossed about an inch and a half below its origin by the posterior tibial nerve. Elsewhere it is in contact with the intermuscular fascia, which binds down the deep layer of muscles. More superficially the upper half of the artery is covered by the fleshy parts of the soleus and gastrocnemius muscles, between which is the plantaris; the lower half of the artery is much nearer the surface, and is only covered by skin and fascia, except at its termination, where it lies beneath the internal annular ligament and the origin of the abductor hallucis.

*Lateral.*—The artery is accompanied by two venæ comites, one on either side. The posterior tibial nerve lies at first on the inner side of the vessel, then crosses behind it, and is continued down on its outer side. In the last part of its course the artery is separated

from the internal malleolus by the tendons of the tibialis posticus and the flexor longus digitorum, whilst the tendon of the flexor longus hallucis lies behind and external to it.

**Branches.**—The posterior tibial gives off numerous branches, the largest of which, the peroneal, forms one of the chief arteries of the leg. The branches include—

(1) Two large **muscular branches** which are distributed to the soleus, the tibialis posticus, the flexor longus digitorum, and the flexor longus hallucis. They anastomose with the deep sural branches of the popliteal artery and the lower internal articular artery.

(2) The **medullary branch** (a. nutricia tibiæ), the largest of the medullary group of arteries, springs from the upper part of the posterior tibial, pierces the tibialis posticus, and enters the medullary foramen on the posterior surface of the tibia. In the interior of the bone it divides into ascending and descending branches, the former passing upwards towards the head of the bone, and the latter downwards towards the lower extremity. Before entering the tibia the medullary artery gives small muscular branches.

(3) A **communicating branch** (ramus communicans) unites the posterior tibial to the peroneal artery about an inch above the inferior tibio-fibular articulation. It passes behind the shaft of the tibia and in front of the flexor longus hallucis.

(4) **Cutaneous branches** are distributed to the skin of the inner and posterior part of the leg.

(5) An **internal malleolar branch** (a. malleolaris posterior medialis) is distributed to the internal surface of the inner malleolus, anastomosing with a corresponding branch of the anterior tibial artery.

(6) The **peroneal artery** (a. peronæa, Fig. 644) is the largest branch of the posterior tibial. It arises about an inch below the lower border of the popliteus, curves outwards across the upper part of the tibialis posticus to the postero-internal border of the fibula, along which it descends to the lower part of the interosseous space, and it terminates about an inch above the ankle-joint by dividing into anterior and posterior terminal branches.

As the peroneal artery passes outwards from its origin it lies behind the tibialis posticus, and is covered posteriorly by the deep intermuscular fascia and by the soleus. As it descends along the postero-internal border of the fibula it lies in a fibrous canal between the tibialis posticus in front and the flexor longus hallucis behind. The peroneal artery is accompanied by two venæ comites, and is crossed in front and behind by communicating branches between them.

**Branches.**—(*a*) **Muscular branches** are distributed to the soleus, tibialis posticus, flexor longus hallucis, and peroneal muscles. Some pass through the interosseous membrane and supply the anterior muscles of the leg.

(*b*) A **medullary branch** (a. nutricia fibulæ) enters the medullary foramen of the fibula.

(*c*) A **communicating branch** (a. communicans) passes across the back of the lower end of the shaft of the tibia, about an inch above the inferior tibio-fibular articulation, to anastomose with the posterior tibial artery.

(*d*) The **terminal branches** are: (i.) The anterior terminal branch or *anterior peroneal artery* (ramus perforans), which passes forwards between the lower border of the interosseous membrane and the interosseous inferior tibio-fibular ligament, and runs in front of the ankle to the dorsum of the foot, where it anastomoses with the external malleolar branch of the anterior tibial artery and with the tarsal branch of the dorsalis pedis; it also supplies branches to the inferior tibio-fibular articulation, to the ankle-joint, and to the peroneus tertius.

(ii.) The posterior terminal branch (ramus calcaneus lateralis), or *posterior peroneal artery*, passes downwards behind the inferior tibio-fibular articulation and external malleolus to the outer side of the heel and the foot. It supplies the ankle, the inferior tibio-fibular articulation, and the calcaneo-astragaloid joint, and anastomoses with the internal calcaneal branch of the external plantar artery, and with the tarsal and metatarsal branches of the dorsalis pedis.

### Plantar Arteries.

(7) The **internal** and **external plantar arteries** are the terminal branches of the posterior tibial artery. They arise beneath the origin of the abductor hallucis muscle, midway between the tip of the internal malleolus and the most prominent part of the inner side of the os calcis.

**Internal Plantar Artery** (a. plantaris medialis).—This is the smaller of the two terminal branches of the posterior tibial artery. It passes forwards along the inner side of the foot, in the interval between the abductor hallucis and the flexor brevis digitorum, to the head of the first metatarsal bone, where it terminates by uniting with the plantar digital branch of the dorsalis hallucis, which is distributed to the inner side of the great toe. In its course forwards it gives branches to the adjacent muscles and articulations, and to the subjacent skin; it also gives three

digital branches which anastomose at the roots of the inner three interdigital clefts, with the princeps hallucis branch of the dorsalis pedis and with the inner two digital branches from the plantar arch. Some of the cutaneous branches of the internal plantar artery anastomose, round the inner border of the foot, with the inner cutaneous branches of the dorsalis pedis artery.

**External Plantar Artery** (a. plantaris lateralis).—This artery, the larger of the two terminal branches of the posterior tibial artery, runs forwards and outwards, first between the flexor brevis digitorum and the accessorius and then in the interval between the flexor brevis digitorum and the abductor minimi digiti, to the inner side of the base of the fifth metatarsal bone, where it turns abruptly inwards; it then passes across the bases of the metatarsal bones and the origins of the interossei, and above the oblique adductor of the great toe, to the outer side of the base of the first metatarsal bone, where it terminates by anastomosing with the dorsalis pedis artery. The last part of the artery is convex forwards and forms the plantar arch, which is completed by the dorsalis pedis.

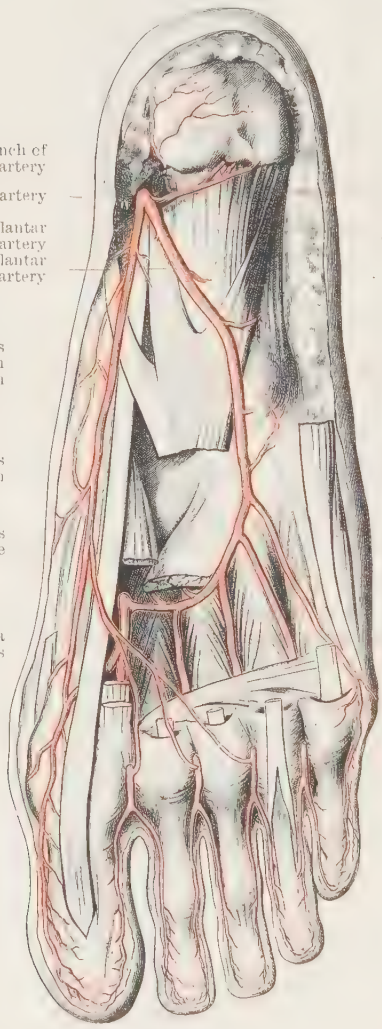

FIG. 645.—THE PLANTAR ARTERIES AND THEIR BRANCHES.

**Branches.** — Between its origin and the base of the fifth metatarsal the external plantar artery gives off (*a*) the **internal calcaneal branch**, which is distributed to the skin and the subcutaneous tissue of the heel.

(*b*) **Muscular branches** to the abductor hallucis, flexor brevis digitorum, accessorius, and abductor minimi digiti.

(*c*) **Cutaneous branches** to the skin of the outer side of the foot.

Between the base of the fifth metatarsal bone and the first interosseous space it forms the **plantar arch** (arcus plantaris), and gives off (*d*) four **digital branches** (aa. metatarsæ plantares); (*e*) three **posterior perforating arteries** (rami perforantes) to the dorsal interosseous arteries; and (*f*) **articular branches** to the tarsal joints.

The **outermost digital branch** runs along the outer side of the little toe, supplying the skin, joints, and the flexor tendons with their synovial sheaths. The **inner three digital branches** run forwards on the plantar surfaces of the interossei, the inner two lying dorsal to the oblique adductor of the great toe, and all three passing dorsal to the transverse adductor. At the bases of the interdigital clefts the three inner digital arteries divide into collateral branches (aa. digitales plantares) which run along the plantar aspect of adjacent toes, and supply skin, joints, and the flexor tendons and sheaths. Opposite the last phalanx of each toe the digital arteries anastomose.

The **posterior perforating arteries** are three in number; they pass dorsalwards through the three outer interosseous spaces, between the heads of the dorsal interosseous muscles, and terminate by uniting with the dorsal interosseous branches of the metatarsal artery.

**Anterior perforating branches** which communicate with the dorsal interosseous arteries are given off from two or three of the digital arteries just before they divide.

The **articular branches** are numerous and irregular; they supply the joints and ligaments of the tarsus on its plantar aspect.

## The Anterior Tibial Artery.

The **anterior tibial artery** (a. tibialis anterior), the smaller of the two terminal divisions of the popliteal, commences opposite the lower border of the popliteus muscle, and terminates in front of the ankle, where it is continued into the dorsal artery of the foot.

**Course and Relations.**—From its origin at the back of the leg the artery passes forwards to the front, between the two uppermost slips of the tibialis posticus and above the upper border of the interosseous membrane. It then descends resting, in the upper two-thirds of its course, upon the anterior surface of the interosseous membrane and, subsequently, on the shaft of the tibia and the anterior ligament of the ankle-joint. In the upper third of the anterior compartment of the leg it lies between the extensor longus digitorum externally and the tibialis anticus internally; in the middle third it is between the extensor longus hallucis and the tibialis anticus; in the lower third the extensor longus hallucis crosses in front of the artery and reaches its inner side, and the last part of the vessel lies between the tendon of the extensor longus hallucis and the innermost tendon of the extensor longus digitorum.

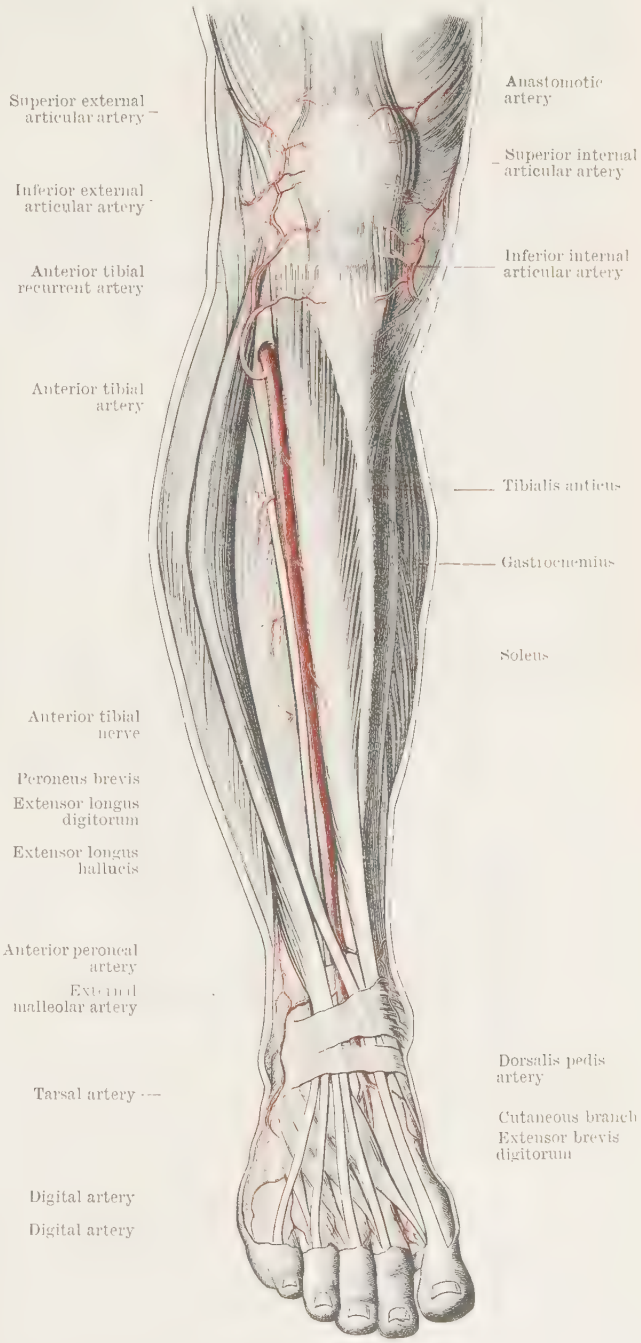

Fig. 646.—The Anterior Tibial Artery and its Branches.

The anterior tibial nerve is at first well to the outer side of the artery, but it soon passes in front of the vessel, and it lies in front of the artery in its middle

third; lower down the nerve is usually found on the outer side again, and at the ankle it intervenes between the artery and the innermost tendon of the extensor longus digitorum.

Two venæ comites, with numerous intercommunications, accompany the artery.

Obviously the anterior tibial artery is, at least in its upper part, deeply placed; moreover, its lateral muscular boundaries overlap it. In the greater part of its extent it is, however, easily accessible from the surface; and beyond being crossed by the nerve and tendon, as already described, is only covered, in addition, by skin, fascia, and the anterior annular ligament.

**Branches.**—Close to its origin the artery gives off superior fibular and posterior tibial recurrent branches; after it reaches the front of the leg it gives off anterior tibial recurrent, muscular, cutaneous, internal malleolar, and external malleolar branches.

(1) The **superior fibular branch** is a small vessel which may arise separately from the anterior tibial artery, or by a common stem with the posterior tibial recurrent; occasionally it springs from the lower end of the popliteal artery, or from the posterior tibial. It runs upwards and outwards behind the neck of the fibula and through the fibres of the soleus, and it terminates in branches which supply the soleus, the peroneus longus, and the skin of the upper and outer part of the leg. It anastomoses with the inferior external articular artery.

(2) The **posterior tibial recurrent branch** (a. recurrens tibialis posterior), also small, and not always present, runs upwards in front of the popliteus muscle to the back of the knee-joint. It anastomoses with the inferior articular branches of the popliteal, and gives branches to the popliteus muscle and the superior tibio-fibular articulation.

(3) The **anterior tibial recurrent branch** (a. recurrens tibialis anterior) arises from the anterior tibial artery in front of the interosseous membrane. It runs upwards and inwards, between the upper part of the tibialis anticus and the outer tuberosity of the tibia, accompanied by the recurrent articular branch of the external popliteal nerve, and after supplying the tibialis anticus and the superior tibio-fibular articulation it pierces the deep fascia of the leg; it is connected with the anastomoses round the knee-joint formed by the articular branches of the popliteal artery, the descending branch of the external circumflex artery, and the anastomotic artery.

(4) The **muscular branches** are distributed to the muscles of the front of the leg, and a few small branches also pass backwards to the deep surface of the tibialis posticus muscle.

(5) The **cutaneous branches** supply the skin of the front of the leg.

(6) The **internal malleolar branch** (a. malleolaris anterior medialis) arises from the lower part of the anterior tibial artery, and is smaller than its companion on the outer side. It runs inwards, beneath the tibialis anticus tendon, ramifies over the internal malleolus, anastomosing with branches of the posterior tibial artery, and is distributed to the skin and to the ankle-joint.

(7) The **external malleolar branch** (a. malleolaris anterior lateralis), more constant and larger than the internal, passes outwards beneath the extensor longus digitorum and peroneus tertius towards the external malleolus. It anastomoses with the anterior peroneal and tarsal arteries, and supplies the ankle-joint and the adjacent articulations.

**Dorsalis Pedis Artery** (a. dorsalis pedis).—The dorsal artery of the foot is the direct continuation of the anterior tibial; it commences opposite the front of the ankle-joint, and extends to the posterior extremity of the first interosseous space, where it passes to the plantar aspect of the foot, and, anastomosing with the termination of the external plantar artery, completes the plantar arch.

It is covered superficially by skin and fascia, including the inferior part of the anterior annular ligament, and it is crossed, just before it reaches the first interosseous space, by the innermost tendon of the extensor brevis digitorum. It rests upon the anterior ligament of the ankle, the head of the astragalus, the astragalo-navicular ligament, the dorsum of the navicular bone, the dorsal naviculo-cuneiform and the inter-cuneiform ligaments between the internal and middle cuneiform bones. On its outer side is the internal terminal branch of the anterior tibial nerve, which intervenes between it and the extensor brevis digitorum and innermost tendon of the extensor longus digitorum. On its inner side it is in relation with the tendon of the extensor proprius hallucis. Two venæ comites, one on each side, accompany the artery.

As it passes through the base of the first interosseous space it lies between the two heads of the first dorsal interosseous muscle, and in the sole of the foot it is dorsal to the flexor brevis hallucis.

**Branches.**—On the dorsum of the foot the dorsalis pedis artery gives off cutaneous branches, the tarsal branch, the metatarsal branch, and the dorsalis hallucis or first dorsal interosseous. In the sole of the foot, and before it unites with the external plantar artery, it gives off the princeps hallucis.

(1) **Cutaneous branches,** two or three in number, are distributed to the skin on the dorsum and inner side of the foot; they anastomose with branches of the internal plantar artery.

(2) The **tarsal branch** (a. tarsea lateralis) is given off opposite the head of the astragalus; it runs outwards beneath the extensor brevis digitorum, supplying that muscle and the tarsal joints, and anastomoses with branches of the anterior peroneal, metatarsal, and external plantar arteries, and with the external malleolar artery.

(3) The **metatarsal artery** (a. arcuata) arises opposite the internal cuneiform bone. It runs outwards on the bases of the metatarsal bones, beneath the long and short extensor tendons, supplies the extensor brevis, and anastomoses with branches of the tarsal and external plantar arteries. It gives off three **dorsal interosseous arteries** (aa. metatarseæ dorsales) which run downwards on the muscles which occupy the three outer interosseous spaces to the clefts of the toes, where each divides into two *collateral digital branches* (aa. digitales dorsales) for the adjacent sides of the toes bounding the cleft to which it goes. The outer side of the little toe receives a branch from the outermost dorsal interosseous artery. Each dorsal interosseous artery gives off a *posterior perforating branch* which passes through the posterior part of the interosseous space, between the heads of the dorsal interosseous muscle, to anastomose with the plantar arch, and an *anterior perforating branch*, which descends through the anterior part of the space to anastomose with the corresponding plantar digital artery.

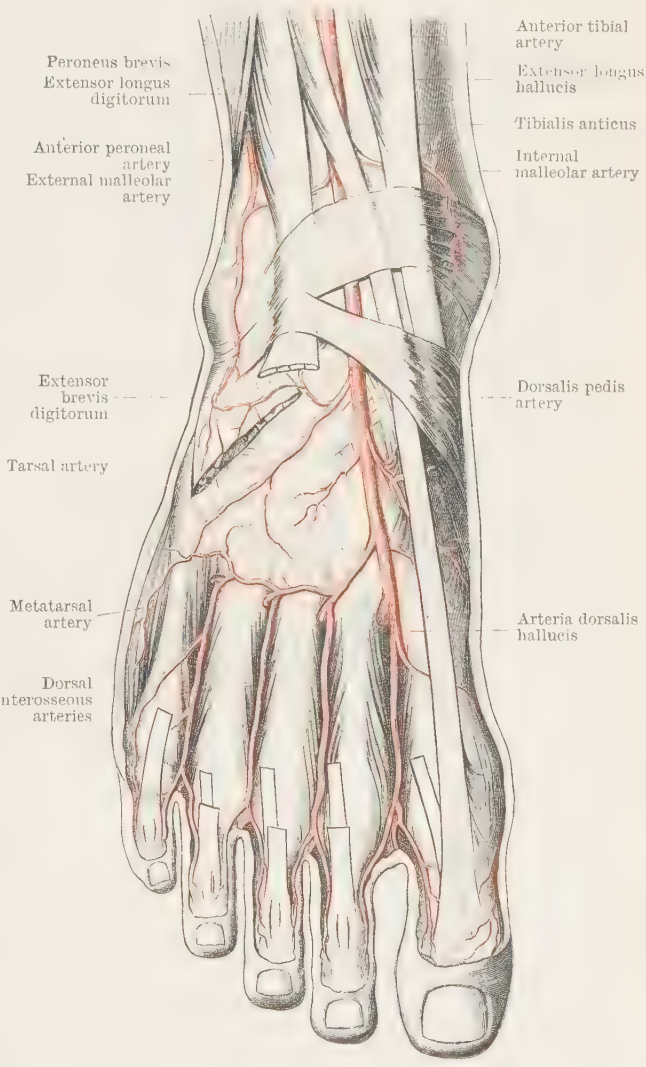

FIG. 647.—THE DORSALIS PEDIS ARTERY AND ITS BRANCHES.

(4) The **dorsalis hallucis artery** (first dorsal interosseous) is continued forwards from the dorsal artery of the foot, and runs on the dorsal surface of the first dorsal interosseous muscle. It ends by dividing into collateral dorsal digital branches for the adjacent sides of the first and second toes. Before it divides it usually gives off a dorsal digital branch which passes beneath the tendon of the extensor hallucis to the inner side of the great toe.

(5) The **princeps hallucis** (plantar digital artery) springs from the termination of

the dorsalis pedis in the sole of the foot; it runs forwards in the plantar part of the first interosseous space, and divides, at the interdigital cleft, into collateral digital branches for the supply of the adjacent sides of the first and second toes on their plantar aspects. Before its division it supplies a plantar digital branch to the inner side of the great toe.

## THE VEINS.

Veins commence at the terminations of the capillaries. They converge towards the heart, and unite with one another to form larger and still larger vessels, until finally seven large trunks are formed which open into the auricles of the heart. Three of these, the **superior vena cava**, the **inferior vena cava**, and the **coronary sinus**, belong to the *systemic circulation*; they contain venous blood, and open into the right auricle. The remaining four belong to the *pulmonary circulation;* they return arterialised blood from the lungs, and open into the left auricle.

In addition to the systemic and pulmonary veins, there is also a third group of veins, constituting the **portal system**, in which blood from the abdominal part of the alimentary canal, and from the spleen and pancreas, is conveyed to the liver. The portal system is further peculiar in that it both begins and ends in capillaries. From its terminal capillaries in the liver the hepatic veins arise, and as these open into the inferior vena cava the blood of the portal system is finally poured into the general systemic circulation. The hepatic veins also receive blood supplied to the liver by the hepatic arteries.

### PULMONARY VEINS.

The terminal **pulmonary veins** (v. pulmonales, Figs. 613 and 620), two on each side, open into the left auricle of the heart. Their tributaries arise in capillary plexuses in the walls of the pulmonary alveoli. By the union of the smaller veins larger vessels are formed which run along the anterior aspects of the bronchial tubes, and, uniting together, ultimately form a single efferent vessel in each lobe, which passes into the root of the lung. Thus there are five main pulmonary veins, but, immediately after entering the root of the lung, the vessels from the upper and middle lobes of the right lung join together, and so only four terminal pulmonary veins open into the left auricle of the heart. Neither the main stems nor their tributaries possess valves.

**Relations.**—In the root of the lung the upper pulmonary vein on each side lies below and in front of the pulmonary artery. The lower pulmonary vein on each side is in the lowest part of the root, and it is placed much farther back than the upper vein.

On the right side the upper pulmonary vein passes behind the superior vena cava, and the lower behind the right auricle. They both terminate in the upper and back part of the left auricle close to the interauricular septum.

On the left side both upper and lower pulmonary veins cross the front of the descending aorta, and they terminate in the upper and back part of the left auricle near its left border.

All four pulmonary veins perforate the fibrous layer of the pericardium, and receive partial coverings of the serous layer before they enter the auricle.

### SYSTEMIC VEINS.

The systemic veins return blood to the right auricle of the heart through the superior vena cava, the inferior vena cava, and the coronary sinus. The two first-named receive blood from the veins of the body and limbs and from most of the abdominal and pelvic viscera. The coronary sinus receives blood from the veins of the walls of the heart alone.

**General arrangement.**—The veins of the body wall and limbs form two groups —(1) the superficial veins; (2) the deep veins.

The **superficial veins**, which commence in the capillaries of the skin and subcutaneous tissues, lie in the superficial fascia, and are very numerous. They

frequently anastomose with one another, and they also communicate with the deep veins, in which, after piercing the deep fascia, they terminate. They may or may not accompany superficial arteries.

The **deep veins** accompany arteries, and are known as *venæ comites*. The large arteries have only one accompanying vein, but with the medium-sized and small arteries there are usually two venæ comites, which freely anastomose with each other by short transverse branches of communication.

**Visceral veins** usually accompany the arteries which supply viscera in the head, neck, thorax, and abdomen. As a rule there is only one vein with each visceral artery, and, with the exception of those which enter into the formation of the portal system, they terminate in the deep systemic veins.

## THE CORONARY SINUS AND THE VEINS OF THE HEART.

The **coronary sinus** (sinus coronarius, Fig. 613) is a short, but relatively wide, venous trunk which receives the majority of the veins of the heart. It lies in the inferior portion of the auriculo-ventricular sulcus, between the left auricle and the left ventricle, and it is covered superficially by some of the muscular fibres of the auricle.

It terminates in the lower and back part of the right auricle, between the orifice of the inferior vena cava on the right, and the right auriculo-ventricular orifice in front; an imperfect valve, consisting of one or two cusps, called the **valve of Thebesius**, is situated at the opening of the sinus into the auricle.

The apertures of all the tributaries of the coronary sinus, except that of the oblique vein, are provided with valves, which, however, are frequently incompetent.

**Tributaries.**—(1) The **great cardiac** or **left coronary vein** (v. cordis magna, Fig. 614) commences at the apex of the heart. It ascends in the anterior interventricular sulcus to the auriculo-ventricular groove; it then turns to the left, and, passing round the left margin of the heart into the postero-inferior part of the auriculo-ventricular groove, terminates in the left extremity of the coronary sinus. It receives tributaries from the walls of both ventricles and from the wall of the left auricle. It also receives the *left marginal vein*, which commences at the lower extremity of the left margin of the heart, along which it ascends to its termination.

(2) **Small cardiac** or **right coronary vein** (v. cordis parva).—This vein is very variable; as a rule it commences at the right margin of the heart in the auriculo-ventricular sulcus, passes to the left, and terminates in the coronary sinus near its right end. It receives tributaries from the walls of the right auricle and the right ventricle; one from the latter, the *right marginal vein*, ascends along the right margin of the heart, and sometimes opens directly into the right auricle.

(3) The **oblique vein of Marshall** (v. obliqua atrii sinistri, Fig. 613) is a small venous channel which descends obliquely on the posterior wall of the left auricle and terminates in the coronary sinus. Its orifice is not provided with a valve. It is of special interest, inasmuch as it represents the left superior vena cava of some other mammals, and is developed from the left duct of Cuvier.

(4) The **inferior interventricular, inferior cardiac**, or **middle cardiac vein** (v. cordis media), commences at the apex of the heart, and, passing backwards in the inferior interventricular sulcus, terminates in the right end of the coronary sinus. It receives tributaries from the inferior parts of the walls of both ventricles.

**Veins of the heart which do not end in the coronary sinus.**—(*a*) The *anterior cardiac veins* (vv. cordis anteriores) are two or three small vessels which ascend on the anterior wall of the right ventricle to the auriculo-ventricular groove, where they either end separately in the right auricle or terminate in the commencement of the small cardiac vein. (*b*) The *venæ minimæ cordis*.—A number of small veins which commence in the substance of the walls of the heart, and terminate directly in its cavities, principally in the auricles; some few, however, open into the ventricles.

## THE SUPERIOR VENA CAVA AND ITS TRIBUTARIES.

The **superior vena cava** (Figs. 619 and 620) returns the blood from the head and neck, the upper extremities, the thoracic wall, and a portion of the upper part

of the posterior wall of the abdomen. It is formed, at the lower border of the first right costal cartilage, by the union of the two innominate veins, and it descends, with a slight convexity to the right, to the level of the third right costal cartilage, where it opens into the upper and back part of the right auricle. It is about three inches (7·5 cm.) long; in the lower half of its extent it is enclosed within the fibrous layer of the pericardium, and it is covered in front and laterally by the serous layer.

**Relations.**—It is overlapped *in front* by the margins of the right lung and pleural sac and by the ascending aorta. The lung and pleura intervene between it and the second and third costal cartilages, the internal intercostal muscles in the first and second intercostal spaces, and the internal mammary vessels. It is in relation *behind* with the right vagus nerve, the vena azygos major, the right bronchus, the right pulmonary artery, and the upper right pulmonary vein. On its *left side* are the commencement of the innominate artery and the ascending portion of the aorta, whilst on the *right side* it is in close relation with the right pleura, the phrenic nerve and comes nervi phrenici vessels intervening.

**Tributaries.**—In addition to the two innominate veins, by the union of which it is formed, the superior vena cava only receives one large tributary, viz. the vena azygos major; but several small pericardial and mediastinal veins open into it.

### The Azygos Veins.

The **vena azygos major** (v. azygos, Fig. 660) commences either from the back of the inferior vena cava, at the level of the right renal vein, or as the direct upward continuation of an anastomosing channel which connects together the lumbar veins of the right side, and which is known as the *right ascending lumbar vein.* The great azygos vein ascends through the aortic orifice of the diaphragm, and is continued upwards through the posterior mediastinum. In the upper part of its course, it first passes behind and then arches forwards above the root of the right lung to its termination in the posterior part of the superior vena cava, immediately before the latter vessel pierces the pericardium. It frequently possesses imperfect valves.

**Relations.**—*In the abdomen* it lies on the bodies of the upper lumbar vertebræ, behind the right crus of the diaphragm and the inferior vena cava, and to the right side of the thoracic duct.

*In the thorax* it lies on the bodies of the lower eight dorsal vertebræ, the intervening discs, and the anterior common ligament, and it crosses in front of the right aortic intercostal arteries. In the lower part of the posterior mediastinum it is covered in front by the right pleura and lung; at a higher level it is overlapped by the right margin of the œsophagus, and immediately before its termination it is crossed by the root of the right lung.

On its right side it receives the right posterior intercostal veins. On its left side it is in relation, in the greater part of its extent, with the thoracic duct and, as it arches forwards over the root of the lung, with the right vagus nerve. About the level of the seventh dorsal vertebra it receives the vena azygos minor superior, whilst at the level of the eighth dorsal vertebra the vena azygos minor inferior opens into it.

In addition to the left azygos veins it receives the right posterior intercostal veins, except that from the first space but including the right superior intercostal vein, the right subcostal vein, and, through the ascending lumbar vein, the upper right lumbar veins. It also receives the right bronchial veins and some small œsophageal, pericardial, and mediastinal tributaries.

The **vena azygos minor superior** (v. hemi-azygos accessoria) is formed by the union of the fourth, fifth, sixth, and seventh left posterior intercostal veins. It lies in the posterior mediastinum on the left sides of the bodies of the fifth, sixth, and seventh dorsal vertebræ, and crosses the spine from left to right opposite the body of the seventh dorsal vertebra, passing behind the aorta, œsophagus, and thoracic duct; it terminates in the vena azygos major. It receives the left bronchial veins, some small posterior mediastinal veins also open into it, and it communicates with the left superior intercostal vein.

The **vena azygos minor inferior** (v. hemi-azygos) commences in the epigastric region. At its origin it is connected either with the left ascending lumbar vein or with the left renal vein. After piercing the left crus of the diaphragm it ascends on the left sides of the

bodies of the lower dorsal vertebræ, and opposite the eighth dorsal vertebra it turns to the right, crosses the front of the spine behind the aorta, œsophagus, and thoracic duct, and terminates in the vena azygos major. As it ascends in the posterior mediastinum it lies internal to the sympathetic cord, behind the roots of the splanchnic nerves, and superficial to the lower left intercostal arteries. Through the left ascending lumbar vein it receives blood from the upper lumbar veins of the left side; the lower four posterior intercostal veins, the left subcostal vein, and small mediastinal tributaries also terminate in it.

Not infrequently the upper and lower minor azygos veins unite, opposite the seventh or eighth dorsal vertebra, to form a common trunk which terminates in the azygos major.

The **bronchial veins** do not quite correspond to the bronchial arteries, and they are not found on the walls of the smallest bronchi. On each side the tributaries run in front of and behind the bronchial tubes to the root of the lung, where they unite, as a rule, into two small trunks; those of the right side open into the vena azygos major, and those of the left into the vena azygos minor superior, or into the left superior intercostal vein. On both sides they are joined by tracheal and posterior mediastinal veins. Some few small bronchial veins, including most of those from the smaller tubes, open into the pulmonary veins.

**Intercostal Veins.**—There are two sets of intercostal veins (vv. intercostales), the anterior and the posterior.

The **anterior intercostal veins** are tributaries of the internal mammary or of the musculo-phrenic veins, and are described with those vessels (p. 874).

The **posterior intercostal veins** (Fig. 660) are eleven in number on each side. A single vein runs in each intercostal space; it is situated in the subcostal groove above the corresponding artery.

On the right side the posterior intercostal vein of the first space accompanies the superior intercostal artery across the front of the neck of the first rib, and terminates in the vertebral or innominate vein. The second, third, and fourth intercostal veins of the right side unite together to form a common trunk, the **right superior intercostal vein** (v. intercostalis suprema dextra), which terminates by joining the vena azygos major. The fifth to the eleventh posterior intercostal veins of the right side open separately in the vena azygos major.

On the left side the first posterior intercostal vein follows a course similar to that taken by the corresponding vein on the right side, and terminates in the left vertebral or innominate vein. The second, third, and fourth posterior intercostal veins of the left side unite to form the **left superior intercostal vein** (v. intercostalis suprema sinistra), which runs from behind forwards along the left and anterior aspect of the aortic arch. It passes obliquely between the left vagus and phrenic nerves, crosses the root of the left subclavian artery, and ends in the lower part of the left innominate vein. The fifth, sixth, seventh, and eighth posterior intercostal veins of the left side terminate in the vena azygos minor superior, and the ninth, tenth, and eleventh in the vena azygos minor inferior.

Each posterior intercostal vein is provided with valves, both at its termination and along its course, which prevent the blood flowing towards the anterior aspect of the thoracic wall. Its tributaries are derived from the adjacent muscles and bones, and a short distance from its termination it receives a dorsal tributary which passes forwards to it between the transverse processes of the vertebræ. This dorsal vessel is formed by the union of small veins which issue from the muscles of the back, from the anterior and posterior spinal plexuses which lie respectively in front of the bodies and behind the arches of the vertebræ, and by venous channels which issue through the intervertebral foramina; the latter vessels commence in the spinal canal, where they are connected with the anterior and posterior spinal veins.

### The Innominate Veins.

The **innominate** or **brachio-cephalic veins** (vv. anonymæ dextra et sinistra Figs. 619 and 620), two in number, right and left, return blood from the head and neck, the upper extremities, the upper part of the posterior wall of the thorax, the anterior wall of the thorax, and the upper part of the anterior wall of the abdomen. Each innominate vein commences behind the sternal end of the clavicle of the corresponding side, and is formed by the union of the internal jugular and subclavian veins; the two innominate veins terminate by uniting together, at the lower border of the cartilage of the first rib on the right side, to form the superior

vena cava. To reach this point the left vein has to pass from left to right behind the manubrium sterni, and it is therefore about three times as long as the right vein. The innominate veins do not possess valves.

The **right innominate vein** is a little more than one inch (3 cm.) in length. It descends almost vertically to the lower border of the first costal cartilage, and terminates in the superior vena cava.

**Relations.**—It is in relation in front with the sternal end of the clavicle and the sterno-hyoid and sterno-thyroid muscles. It partly overlaps the innominate artery, which lies to its left side, and it is in front of the right vagus nerve and the posterior part of the upper end of the right pleural sac. The phrenic nerve and the accompanying vessels run along its right side, and intervene between it and the right pleural sac.

**Tributaries.**—In addition to the veins by the union of which it is formed, the right innominate vein receives the right vertebral and internal mammary veins, and sometimes the right inferior thyroid vein and the first right posterior intercostal vein. The right lymphatic duct also opens into it.

The **left innominate vein** passes from left to right, with a slight obliquity downwards, behind the upper part of the manubrium sterni, to the lower border of the first right costal cartilage, where it terminates in the superior vena cava. It is a little less than three inches long (6 to 7·5 cm.)

**Relations.**—It is covered in front, in the greater part of its extent, by the sterno-hyoid and sterno-thyroid muscles, but at its right extremity it is slightly overlapped by the right pleura, and in the middle line the remains of the thymus gland intervene between it and the posterior surface of the sternum. It rests posteriorly upon the left subclavian artery, the left phrenic, and the left vagus nerves, the left superior cardiac branch of the sympathetic, the inferior cervical branch of the left vagus, the left common carotid artery, the trachea, and the innominate artery.

Its lower border is in relation with the arch of the aorta, and on its upper border it receives the inferior thyroid vein of one or both sides.

**Tributaries.**—It receives the vertebral, internal mammary, inferior thyroid, and superior intercostal veins of its own side, the first left posterior intercostal vein, and some pericardial, thymic, anterior bronchial, and anterior mediastinal veins. Sometimes the right inferior thyroid vein joins it, but usually this vessel terminates in the right innominate vein or in the commencement of the superior vena cava.

The thoracic duct opens into it just at the angle of junction of the internal jugular and subclavian veins.

**Internal mammary veins** (vv. mammariæ internæ).—Each internal mammary artery is accompanied by venæ comites; they commence by the union of the venæ comites of the superior epigastric and musculo-phrenic arteries, between the sixth costal cartilage and the triangularis sterni, and at the upper part of the thorax they fuse into a single vessel which enters the superior mediastinum and ends in the innominate vein of the same side.

The tributaries of the internal mammary veins are—(*a*) The **venæ comites** of the **superior epigastric** and **musculo-phrenic arteries**, which in their turn receive tributaries which correspond with the branches of the arteries they accompany. (*b*) Six **anterior perforating veins** which accompany the corresponding arteries, one lying in each of the upper six intercostal spaces. (*c*) Twelve **anterior intercostal veins** from the upper six intercostal spaces, two veins lying in each space with the corresponding branches of the internal mammary artery. (*d*) Small and irregular **pleural**, **muscular**, **mediastinal**, and **sternal veins**.

The internal mammary veins are provided with numerous valves which prevent the blood from flowing downwards.

**Superior epigastric veins** (vv. epigastricæ superiores).—The venæ comites of the superior epigastric artery receive tributaries from the substance of the rectus abdominis, the sheath of the muscle, and the superjacent skin and fascia; they pass with the artery, between the sternal and costal origins of the diaphragm, and terminate in the internal mammary veins.

**Musculo-phrenic veins.**—The venæ comites of the musculo-phrenic artery commence in the abdomen, pass through the diaphragm with the artery, and terminate in the internal mammary veins. They receive as tributaries the anterior intercostal veins of the seventh, eighth, and ninth intercostal spaces, and small venules from the substance of the diaphragm.

**Vertebral Veins** (vv. vertebrales).—These correspond only to the extra-cranial parts of the vertebral arteries. Each commences by the union of offsets from the intraspinal venous plexuses, and, issuing from the spinal canal, passes across the posterior arch of the atlas with the vertebral artery to the foramen in the transverse process of the atlas. It then descends through the foramina in the cervical transverse processes, and breaks up into a plexus of venous channels which surround the artery. At the lower part of the neck these channels unite to form a single trunk which issues from the foramen in the transverse process of the sixth cervical vertebra, and descends, in the interval between the longus colli and scalenus anticus muscles, to terminate in the upper and back part of the innominate vein, where it possesses a uni- or bi-cuspidate valve.

**Relations.**—In the first part of its course the vein lies in the suboccipital triangle. The second, plexiform portion, is in the canal formed by the foramina in the transverse processes of the cervical vertebræ, and, with the artery which it surrounds, lies in front of the trunks of the cervical spinal nerves. The third part, in the root of the neck, is between the longus colli and scalenus anticus muscles, in front of the first part of the vertebral artery, and behind the internal jugular vein.

**Tributaries.**—In addition to the offsets from the intraspinal venous plexuses by the union of which it is formed, each vertebral vein receives the following tributaries:—(*a*) Small vessels which issue from the muscles, ligaments, and bones of the deeper parts of the neck, and the lower and back part of the head. (*b*) Offsets from the intraspinal venous plexuses which pass out of the spinal canal by the intervertebral foramina. (*c*) The **anterior deep cervical** or **anterior vertebral vein**, a vessel which is formed by the union of tributaries which issue from a venous plexus which lies in front of the bodies and on the roots of the transverse processes of the cervical vertebræ. This vessel accompanies the ascending cervical artery, and terminates in the lower part of the vertebral vein, immediately after the latter has issued from the foramen in the sixth cervical transverse process. (*d*) The **posterior deep cervical** (v. cervicalis profunda) or **posterior vertebral vein**; this commences in the suboccipital triangle from a venous plexus with which the vertebral and occipital veins communicate. It descends behind the transverse processes of the cervical vertebræ in company with the profunda cervicis artery, turns forwards at the root of the neck, between the transverse processes of the sixth and seventh cervical vertebræ or between the latter and the neck of the first rib, and opens into the vertebral vein. It receives blood from the muscles, ligaments, and bones of the back of the neck. (*e*) The **posterior intercostal vein** from the first intercostal space sometimes opens into it.

Occasionally the venous plexus round the vertebral artery ends below in two terminal trunks, anterior and posterior, instead of one. In these cases the second terminal vessel lies behind the lower part of the vertebral artery, passes through the foramen in the transverse process of the seventh cervical vertebra, and turns forwards on the outer side of the artery to join the anterior trunk, thus forming a common terminal vein which ends in the usual manner.

**Inferior Thyroid Veins** (vv. thyreoideæ inferiores).—Each inferior thyroid vein commences by the union of a series of tributaries which issue from the isthmus and the corresponding lateral lobe of the thyroid body. The two veins descend along the front of the trachea into the superior mediastinum, where the right inferior thyroid vein terminates in the junction of the two innominate veins, and the left in the upper part of the left innominate vein; or the two veins unite to form a single trunk, which usually ends in the left innominate vein, but occasionally in the right. In their descent through the neck the inferior thyroid veins frequently anastomose together, and sometimes these anastomoses are so frequent and irregular that a venous plexus is formed in front of the lower cervical portion of the trachea.

## VEINS OF THE HEAD AND NECK.

**Internal jugular veins** (Figs. 620 and 650).—Each internal jugular vein (v. jugularis interna) commences in the posterior compartment of the jugular foramen, as the direct continuation of the lateral sinus, and terminates behind the sternal part of the clavicle by uniting with the subclavian vein of the same side to form the innominate vein.

At its commencement it is dilated, forming the bulb of the jugular vein, and in this situation it lies behind and somewhat to the outer side of the internal carotid artery and the last four cranial nerves. As it descends it accompanies first the internal and then the common carotid artery; inclining forwards during its descent, it gradually passes from its original position, behind and to the outer side of the internal carotid artery, and lies more completely to the outer side of the internal and common carotid arteries, and indeed somewhat overlaps the latter in front. This is more especially the case on the left side, for both internal jugular veins trend slightly towards the right as they descend; consequently at the root of the neck the right vein is separated from the right common carotid artery by a small interval filled by areolar tissue, whilst the left vein is more directly in front of the corresponding common carotid artery.

Within an inch of its lower extremity each internal jugular vein is provided with a valve, which, however, is frequently incompetent. It consists of one, two, or three cusps.

**Relations.**—The vein lies in front of the transverse processes of the cervical vertebræ, the rectus capitis lateralis, rectus capitis anticus major, and scalenus anticus muscles, the ascending cervical artery, which runs upwards in the interval between the attachments of the two latter muscles, and the phrenic nerve; the suprascapular and the transverse cervical arteries intervene between it and the scalenus anticus. At the root of the neck the vein lies in front of the first part of the subclavian artery and the origins of the vertebral artery and the thyroid axis, and on the left side it is in front of the terminal part of the thoracic duct.

On the inner side of the internal jugular vein, immediately below the skull, are the internal carotid artery and the last four cranial nerves; in the rest of its extent it is in relation internally either with the internal or the common carotid artery, whilst to its inner side and somewhat posteriorly, between it and the large arteries, lies the vagus nerve.

Each internal jugular vein is covered in the whole of its length by the sterno-mastoid muscle; near its upper end it is crossed by the posterior belly of the digastric, whilst in its lower half, in addition to the sterno-mastoid, the omo-hyoid, the sterno-hyoid, and the sterno-thyroid muscles are superficial to it. Just below the transverse process of the atlas, and under cover of the sterno-mastoid, the vein is crossed on its outer side by the spinal accessory nerve and by the occipital artery; about the middle of its course it is also crossed by the communicans cervicis nerve, and near its lower end by the anterior jugular vein; the latter vessel, however, is separated from it by the sterno-hyoid and sterno-thyroid muscles. Superficial to the vein are numerous deep cervical lymphatic glands.

**Tributaries.**—(*a*) The **inferior petrosal sinus**, which joins it near its commencement. (*b*) **Pharyngeal branches** from the venous plexus on the wall of the pharynx. (*c*) The **common facial vein**, which receives the facial vein and its tributaries. (*d*) The **lingual veins** (vv. linguales), small venæ comites, which commence chiefly in the sublingual and dorsalis linguæ veins, and accompany the first and second parts of the lingual artery. (*e*) The **ranine vein**, which commences beneath the tip of the tongue, and accompanies at first the two terminal parts of the lingual artery, and afterwards the hypoglossal nerve. (*f*) The **superior thyroid vein** (v. thyreoidea superioris), which accompanies the corresponding artery. (*g*) The **middle thyroid vein**, which passes backwards from the lateral lobe of the thyroid body and crosses the middle of the outer aspect of the common carotid artery. (*h*) The **occipital vein** (v. occipitalis) occasionally terminates in the internal jugular vein. In many cases, however, it ends in the suboccipital plexus, which is drained by the vertebral and deep cervical veins (see p. 875).

The **common facial vein** (v. facialis communis) is formed by the union of the **facial vein** (v. facialis anterior) with the anterior division, or terminal branch, of a venous trunk which lies in substance of the parotid gland, and which is called the **temporo-maxillary vein** (v. facialis posterior). It accompanies the first part of the facial artery in the carotid triangle, passes between the sterno-mastoid, and terminates in the anterior border of the internal jugular vein. Just before it disappears beneath the sterno-mastoid, the common facial vein frequently gives off a large branch, which descends along the anterior border of the sterno-mastoid to the suprasternal fossa, where it joins the anterior jugular vein.

The **facial vein** (v. facialis anterior, Fig. 648) commences at the inner angle of the orbit in the angular vein, which is formed by the union of the supra-orbital and frontal

veins. It passes downwards and backwards on the face, from the inner angle of the orbit to the lower and anterior part of the masseter muscle, which it crosses, lying in the same plane as the facial artery, but following a much straighter course. After crossing the lower border of the jaw it passes across the submaxillary triangle, superficial to the submaxillary gland, and separate from the facial artery, which here lies in a deeper plane, and it terminates a short distance below the angle of the jaw by uniting with the anterior division of the temporo-maxillary vein to form the common facial vein.

The facial vein receives tributaries corresponding with all the branches of the facial artery, except the ascending palatine and the tonsillar, which have no accompanying veins, the blood from the region which they supply being returned for the most part through the pharyngeal plexus. The facial vein also communicates with the pterygoid plexus which surrounds the external pterygoid muscle by means of an anastomosing channel, called the **deep facial vein**, which passes backwards between the masseter and buccinator muscles into the zygomatic fossa.

The **inferior thyroid veins** have already been described (see p. 875).

**Subclavian Veins.**—The subclavian vein (v. subclavia) of each side is the direct continuation of the main vein of the upper extremity, the axillary vein; but through its tributary, the external jugular vein, it also receives blood both from the superficial and deep parts of the head and neck.

From its commencement at the outer border of the first rib it runs inwards below and in front of the corresponding artery, from which it is separated by the lower part of the scalenus anticus muscle, and it terminates behind the sternal end of the clavicle, in the innominate vein of the corresponding side. As it passes inwards it forms a slight curve, the convexity of which is directed upwards.

Each subclavian vein possesses a single bicuspid valve which is situated immediately on the distal side of the opening of the external jugular vein.

**Relations.**—The subclavian vein is in relation in front with the posterior layer of the costo-coracoid membrane, which separates it from the subclavius muscle, and the nerve to the subclavius, and with the back of the sternal end of the clavicle, from which it is partly separated, however, by the fibres of the sterno-hyoid and sterno-thyroid muscles.

It is closely attached in front to the posterior surface of the costo-coracoid membrane, consequently it is expanded when the clavicle is moved forwards, a condition of affairs which constitutes a distinct danger when operations are being performed in the neighbourhood of the vein, for in the event of the vessel being wounded, forward movement of the clavicle may cause air to be sucked into the vein with fatal results.

Behind the vein, and on a higher plane, are the first and third parts of the subclavian artery, but it is separated from the second part by the scalenus anticus. To the inner side of the anterior scalene the posterior relations of the vein, in addition to the subclavian artery, are the upper part of the internal mammary artery, the phrenic nerve, and the cervical portion of the pleura.

It rests upon the upper surface of the first rib.

**Tributaries.**—Whilst the subclavian vein is the direct continuation of the axillary vein, and receives the blood from the upper extremity, it has, as a general rule, only one named tributary, viz. the external jugular vein.

The **external jugular vein** (v. jugularis externa, Fig. 648) is formed on the superficial surface of the sterno-mastoid muscle, a little below and behind the angle of the jaw, by the union of the posterior auricular vein with the posterior terminal branch of the *temporo-maxillary vein*. After its formation the external jugular vein descends, with a slight obliquity backwards, to the anterior part of the subclavian portion of the posterior triangle of the neck, where it pierces the deep fascia, and, after crossing in front of the third part of the subclavian artery, terminates in the subclavian vein.

Whilst on the surface of the sterno-mastoid muscle it is covered by the superficial fascia and platysma muscle, and it lies parallel with, and slightly in front of, the great auricular nerve; after crossing the transverse cervical nerve it reaches the posterior border of the sterno-mastoid, where it receives a tributary called the **posterior external jugular vein**, which commences in the superficial tissues of the upper and back part of the neck, and runs downwards and forwards across the roof

of the upper part of the posterior cervical triangle to its termination in the external jugular vein.

As the external jugular vein pierces the deep cervical fascia in the subclavian triangle, its wall is closely attached to the margin of the opening through which it passes, and as it is crossing in front of the third part of the subclavian artery it is joined by the suprascapular, transverse cervical, and anterior jugular veins.

There are usually two valves in the lower part of the vein—one, which is generally incompetent, at its termination, and a second at a higher level

**Tributaries.**—In addition to the posterior auricular vein and the posterior division

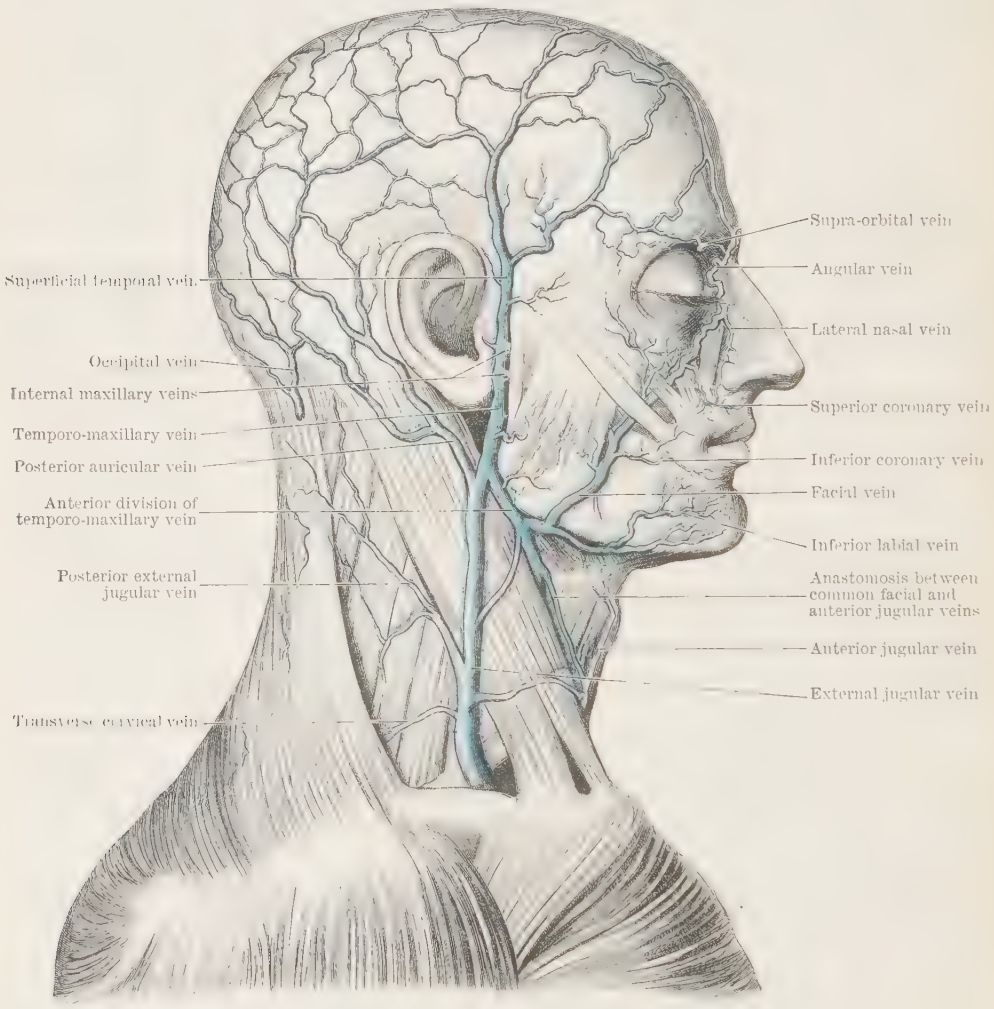

FIG. 648.—SUPERFICIAL VEINS OF THE HEAD AND NECK.

of the temporo-maxillary vein by which it is formed, the external jugular vein receives the posterior external jugular vein, which has already been described, the transverse cervical and suprascapular veins from the region of the shoulder, and the anterior jugular vein. Occasionally the cephalic vein also opens into it.

The **posterior auricular vein** (v. auricularis posterior, Fig. 648) receives tributaries from the posterior parts of the parietal and temporal regions and from the inner surface of the pinna. It is considerably larger than the posterior auricular artery, which it only accompanies in the scalp. At the base of the scalp it leaves the artery and descends in the superficial fascia, over the upper part of the sterno-mastoid, to open into the commencement of the external jugular vein.

The posterior division of the **temporo-maxillary vein** (see p. 880).

The **transverse cervical** and **suprascapular veins** accompany the corresponding arteries; not infrequently they open directly into the subclavian vein.

The **anterior jugular vein** (v. jugularis anterior) commences over the anterior belly of the digastric muscle, and is formed by the union of small veins from the lower lip and the submental region. It descends in the superficial fascia, at a variable distance from the middle line, and perforates the superficial layer of the deep fascia just above the inner end of the clavicle. It there enters the space above the manubrium sterni, which lies between the first and second layers of the deep cervical fascia, and which is called Burns's space, where, after anastomosing with its fellow of the opposite side and receiving a communication from the facial vein, it turns outwards, between the sterno-mastoid superficially and the sterno-hyoid, sterno-thyroid, and scalenus anticus muscles deeply, to terminate at the outer border of the latter muscle in the external jugular vein.

### The Veins of the Scalp.

The veins which drain the blood from the superficial parts of the scalp are the frontal, the supra-orbital, the superficial temporal, the posterior auricular, and the occipital. The blood from the deeper part of the scalp, in the region of the temporal fossa on each side, passes into the deep temporal veins, which are tributaries of the pterygoid plexus.

The **frontal** (v. frontalis) and **supra-orbital veins** (v. supra-orbitalis) receive blood from the inner and front part of the scalp. They unite together, near the upper and inner angle of the orbit, to form the *angular vein*; before the union is effected the supra-orbital vein sends a branch backwards through the supra-orbital notch into the orbital cavity, where it terminates in the ophthalmic vein, and as this branch passes through the notch it receives the frontal diploic vein (p. 881).

The **superficial temporal vein** (v. temporalis superficialis) receives tributaries from the outer part of the frontal region, from the greater part of the superficial area of the temporal region, and from the anterior part of the parietal region. It passes downwards, across the posterior root of the zygoma, into the parotid gland, where it unites with the internal maxillary vein to form the temporo-maxillary trunk.

The **posterior auricular vein** (v. auricularis posterior) drains the posterior portions of the temporal and parietal areas of the scalp. It runs downwards across the mastoid portion of the temporal bone, and terminates in the external jugular vein.

The **occipital vein** (v. occipitalis, Fig. 648) receives tributaries from the inner and posterior part of the parietal region and from the occipital region. As a rule it pierces the occipital origin of the trapezius, and, passing deeply into the suboccipital triangle, terminates in a plexus of veins which is drained by the vertebral and deep cervical veins. It sometimes communicates with the external jugular vein, and occasionally an offset from it accompanies the corresponding artery and ends in the internal jugular vein.

It generally receives the mastoid emissary vein; one of its tributaries receives the parietal emissary vein, and occasionally an emissary vein from the torcular Herophili opens into it.

### The Veins of the Orbit, the Nose, and the Pterygo-maxillary Region.

The veins of these three regions are closely associated together; for although the orbital blood is returned for the most part to the cavernous sinus by the ophthalmic vein, the latter vein is closely connected with the pterygoid plexus which lies in the pterygo-maxillary region.

**Veins of the Orbit.**—The veins of the orbit correspond, with the exception of the frontal vein, with the branches of the ophthalmic artery, and they gradually converge, as they pass backwards in the orbit, until they form two main trunks, an upper (v. ophthalmica superior) and a lower (v. ophthalmica inferior); these terminate, separately or by a single trunk, in the anterior end of the cavernous sinus, to which they pass through the foramen lacerum anterius, and between the two heads of the external rectus muscle.

The superior ophthalmic vein communicates, at the internal angle of the orbit,

with the angular vein, and the inferior ophthalmic vein communicates through the spheno-maxillary fissure with the pterygoid plexus.

**Veins of the Nose.**—The veins of the walls of the nasal cavity end partly in the ethmoidal tributaries of the superior ophthalmic vein, partly in the septal affluent of the superior coronary and in the lateral nasal veins, both of which are tributaries of the facial vein; but the majority of the veins of the nose, both from the septal and outer walls, join together to form a spheno-palatine vein which passes through the spheno-palatine foramen and the spheno-maxillary fossa, and terminates in the pterygoid plexus.

**Pterygoid Plexus and the Internal Maxillary Vein.**—The **pterygoid plexus** (plexus pterygoideus) of veins lies in the zygomatic and pterygoid fossæ. It covers the inner surface of the internal pterygoid muscle, and surrounds the external pterygoid. It receives tributaries which correspond with and accompany the branches of the internal maxillary artery—viz. spheno-palatine, pterygo-palatine, vidian, infra-orbital, posterior superior dental, posterior palatine, buccal, two or three deep temporal, pterygoid, masseteric, and inferior dental veins, and the vena comites of the middle meningeal artery. It communicates superiorly with the cavernous sinus through the foramen ovale, anteriorly with the inferior ophthalmic vein through the spheno-maxillary fissure, and between the masseter and the buccinator with the facial vein by the deep facial anastomosing branch. It also communicates posteriorly and internally, on the inner side of the internal pterygoid, with the pharyngeal plexus, and it terminates posteriorly in the internal maxillary vein.

The **internal maxillary vein** is a short vessel which accompanies the first part of the internal maxillary artery, between the spheno-mandibular ligament and the neck of the lower jaw; it enters the parotid gland, and terminates by uniting with the superficial temporal vein to form the temporo-maxillary trunk. Occasionally the internal maxillary vein is double.

The **temporo-maxillary vein** (v. facialis posterior) is a short trunk which is formed in the upper part of the parotid gland, behind the neck of the jaw, by the union of the superficial temporal and internal maxillary veins. As it descends it lies superficial to the external carotid artery, and it is crossed by the cervico- and temporo-facial branches of the facial nerve. It terminates at the lower part of the parotid gland by dividing into posterior and anterior divisions. The posterior division passes backwards, perforates the deep cervical fascia, and unites on the upper part of the sterno-mastoid muscle with the posterior auricular vein to form the external jugular vein. The anterior division passes downwards and forwards into the carotid triangle, where it terminates in the common facial vein.

## VENOUS SINUSES AND VEINS OF THE CRANIUM AND OF ITS CONTENTS.

The venous channels met with in the cranial walls and cranial cavity are:—

(1) The diploic veins (vv. diploicæ), which lie in the cancellous tissue between the outer and inner tables of the cranial bones.

(2) The meningeal veins, which accompany the meningeal arteries in the outer layer of the dura mater.

(3) The veins of the brain, which lie between the folds of pia mater and in the subarachnoid space.

(4) The cranial venous sinuses, channels which are situated between the outer and inner layers of the dura mater; they receive the blood from the terminal cerebral veins.

### Diploic and Meningeal Veins.

The **diploic veins** (vv. diploicæ) are anastomosing spaces in the cancellous tissue of the flat bones of the skull; they are lined by endothelium. The number of efferent vessels which emerge from these spaces is not constant, but usually there are at least four—viz. a frontal, two temporal, anterior and posterior, and an occipital.

The **frontal diploic vein** (v. diploica frontalis) is one of the most constant; it drains the anterior part of the frontal bone, and, passing through a small aperture in the upper margin of the supraorbital notch, terminates in the supraorbital vein.

The **anterior temporal diploic vein** (v. diploica temporalis anterior) drains the posterior part of the frontal bone and the anterior part of the parietal bone; it pierces the great wing of the sphenoid, and terminates either in the spheno-parietal sinus or in the anterior deep temporal vein.

The **posterior temporal diploic vein** (v. diploica temporalis posterior) drains the posterior part of the parietal bone; it runs downwards to the posterior inferior angle of the parietal bone, and terminates in the lateral sinus, to which it passes either through a foramen in the inner table of the parietal bone or through the mastoid foramen.

The **occipital diploic vein** (v. diploica occipitalis) is usually the largest of the

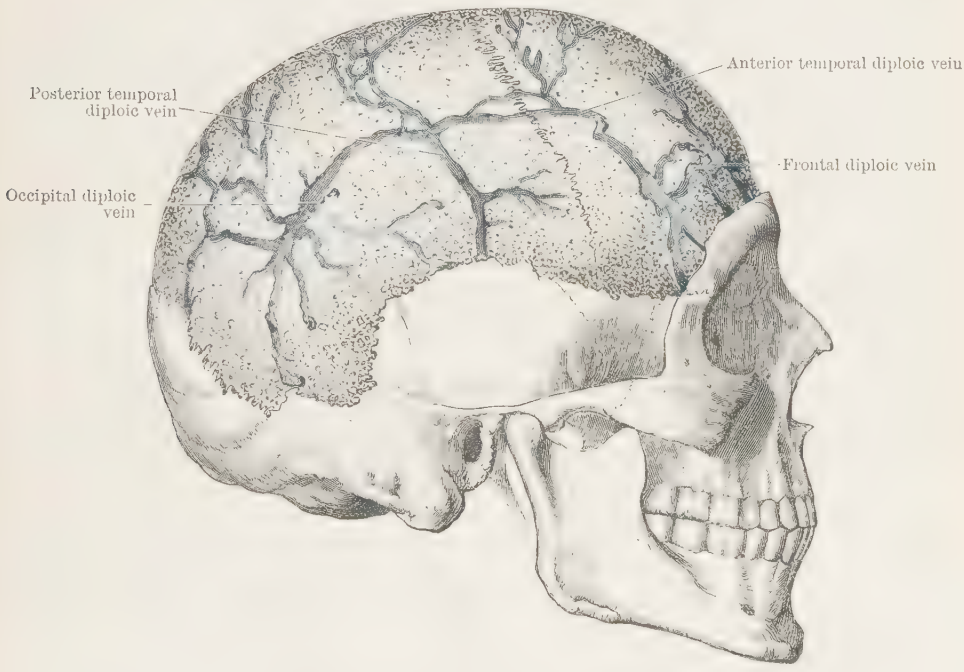

Fig. 649.—The Veins of the Diploë.

series; it drains the occipital bone, and terminates either externally in the occipital vein or internally in the lateral sinus.

The **meningeal veins** (v. meningeæ) commence in two capillary plexuses, a deep and a superficial. The deep plexus is a wide-meshed network in the inner layer of the dura mater. Its efferent vessels terminate in the superficial plexus. The superficial plexus lies in the outer layer of the dura mater. It consists of numerous vessels of uniform calibre which frequently anastomose together, and terminate in two sets of efferents; of these, one set ends in the cranial blood sinuses, and the other accompanies the meningeal arteries. The efferent meningeal veins are peculiar, inasmuch as they do not increase in size as they approach their terminations, and they are irregular in their relations to the arteries; as a rule the middle meningeal arteries alone possess two venæ comites, the other meningeal arteries usually having only one accompanying vein.

## Veins of the Brain.

The veins of the brain include the veins of the cerebrum, of the mid-brain, of the cerebellum, of the pons, and of the medulla oblongata. They do not possess valves.

**Veins of the Cerebrum** (vv. cerebri).—The cerebral veins are arranged in two groups, (*a*) the deep and (*b*) the superficial.

The deep veins issue from the substance of the brain. The superficial veins lie upon its surface in the pia mater and the subarachnoid space. The terminal trunks of both sets pierce the arachnoid membrane and the inner layer of the dura mater, and open into the cranial venous sinuses.

(*a*) The **deep cerebral veins** are the choroid veins, the veins of the corpora striata, the veins of Galen, and the inferior striate veins.

Each **choroid vein** (v. chorioidea) is formed by the union of tributaries which issue from the choroid plexus in the descending horn of a lateral ventricle. It ascends along the lateral border of the velum interpositum, and passes forwards in the outer border of that fold of pia mater to the foramen of Monro, where it receives efferents from the choroid plexus of the third ventricle, and ends by uniting with the vein of the corpus striatum to form the vein of Galen.

The **vein of the corpus striatum**, on each side, is formed by the union of tributaries which issue from the corpus striatum and from the optic thalamus. It runs forwards between these bodies, in a groove in the floor of the lateral ventricle, and, after receiving tributaries from the walls of the anterior horn of the ventricle, including the septum lucidum, it terminates at the apex of the velum interpositum, where it joins the choroid vein to form the vein of Galen.

The **veins of Galen** are three in number—a right and a left vein, and the vena magna Galeni.

Each lateral vein of Galen commences at the apex of the velum interpositum, near the foramen of Monro, by the union of the vein of the corpus striatum with the choroid vein. The two veins run backwards between the layers of the velum, and terminate beneath the splenium of the corpus callosum by uniting to form the vena magna Galeni.

The tributaries which enter each vein, after its formation, are the basilar vein, the efferent veins from the choroid plexus of the third ventricle, and veins from the posterior part of the corpus callosum, the pineal body, the corpora quadrigemina, and the walls of the posterior cornu of the lateral ventricle.

The **vena magna Galeni** (v. cerebri magna [Galeni]) passes backwards and slightly upwards from its origin, and ends in the anterior extremity of the straight sinus. In addition to the two veins of Galen, by the union of which it is formed, it receives tributaries from the posterior parts of the callosal convolutions, from the inner and tentorial surfaces of the occipital lobes of the brain, and from the upper surface of the cerebellum.

An **inferior striate vein** descends on each side from the substance of the corpus striatum, and, after passing through the anterior perforated space, ends in the basilar vein (p. 883), which, as already stated, is a tributary of the corresponding lateral vein of Galen.

(*b*) The **superficial cerebral veins** are more numerous and of larger calibre than the cerebral arteries. They lie upon the surface of the cerebrum, they drain blood from the cerebral cortex, and they are divisible into two sets, the superior and the inferior.

The **superior cerebral veins** (vv. cerebri superiores), twelve or more in number, lie in the pia mater and subarachnoid space on the upper and outer aspect of the cerebral hemispheres. They run inwards to the margin of the longitudinal fissure, where they receive tributaries from the inner surface of the hemispheres, and they terminate in the superior longitudinal sinus. The anterior veins of this set are small and run transversely inwards, but the posterior are large and run obliquely forwards and inwards; they are embedded for some distance in the wall of the sinus, and their orifices are directed forwards against the blood stream.

The **inferior cerebral veins** (vv. cerebri inferiores) lie on the lower and outer aspects of the cerebral hemispheres; they run downwards and inwards, and terminate in the sinuses which lie at the base of the skull—viz. the cavernous, the superior petrosal, and the lateral sinuses. One of these veins, the **superficial Sylvian vein**, runs along the posterior horizontal limb and stem of the fissure of Sylvius to the

cavernous sinus; occasionally it is united by an anastomotic loop, known as the **great anastomotic vein** of Trolard, with the superior longitudinal sinus, and sometimes by the **posterior anastomotic vein** with the lateral sinus.

The **anterior cerebral vein** of each side lies in the great longitudinal fissure, and accompanies the corresponding anterior cerebral artery; it receives tributaries from the corpus callosum and the callosal convolution. Turning downwards round the genu of the corpus callosum, it reaches the base of the brain, and terminates in the basilar vein.

The **deep Sylvian vein** lies deeply in the fissure of Sylvius; it anastomoses freely with the superficial Sylvian vein, receives tributaries from the island of Reil and the adjacent opercula, and terminates in the basilar vein.

The **basilar vein** commences at the anterior perforated space; it is formed by the union of the anterior cerebral vein with the deep Sylvian vein and with the inferior striate vein. Passing backwards round the crus cerebri, it terminates in a vein of Galen. Its tributaries are derived from the tuber cinereum, the corpus albicans, the posterior perforated space, the uncinate gyrus, the inferior cornu of the lateral ventricle, and the crus cerebri.

**Veins of the Mid-brain.**—The veins of the mid-brain terminate for the most part in the veins of Galen.

**Cerebellar Veins.**—These veins also are divisible into two groups, the superficial and the deep. The former are quite independent of and much more numerous than the arteries. They form two sets, the superior and the inferior.

The **superior superficial cerebellar veins** (vv. cerebelli superiores) terminate in a single median or vermian efferent vessel which is sometimes double, and in several lateral efferents. The superior vermian vein runs forwards and ends in the vena magna Galeni, and the lateral superior cerebellar veins terminate in the lateral sinuses or in the superior petrosal sinuses.

The **inferior superficial cerebellar veins** (vv. cerebelli inferiores) also form a small vermian and numerous lateral efferents; the former runs backwards and joins either the straight sinus or one of the lateral sinuses, and the latter end in the inferior petrosal and occipital sinuses.

The **deep cerebellar veins** issue from the substance of the cerebellum and terminate in the superficial veins.

**Veins of the Pons Varolii.** The deep veins from the substance of the pons pass forwards to its anterior surface, where they become superficial, and, anastomosing together, form a plexus which is drained by superior and inferior efferent veins. The superior efferent veins join the basilar vein; the inferior efferent veins either unite with the cerebellar veins, or they open into the superior petrosal sinus.

**Veins of the Medulla Oblongata.**—Deep veins of the bulb issue from its substance and end in a superficial plexus. This plexus is drained by an anterior and a posterior median vein and by radicular veins.

The **anterior median vein** is continuous below with the corresponding vein of the spinal cord; it communicates above with the plexus on the surface of the pons.

The **posterior median vein** is continuous below with the posterior median vein of the cord, from which it ascends to the lower end of the fourth ventricle, where it divides into two branches which join the inferior petrosal or basilar sinuses.

The **radicular veins** issue from the lateral parts of the plexus and run with the roots of the last four cranial nerves; they end in the inferior petrosal and occipital sinuses.

## Blood Sinuses of the Cranium.

The **venous sinuses** of the cranium are spaces between the layers of the dura mater; they are lined by an endothelium which is continuous with the endothelium of the veins. They receive the veins of the brain, communicate frequently with the meningeal veins and with veins external to the cranium, and terminate directly or indirectly in the internal jugular vein. Some of the cranial blood sinuses are unpaired, others are paired.

**Unpaired Sinuses.**—These are the superior longitudinal, the inferior longitudinal, the straight, the circular, and the basilar.

The **superior longitudinal sinus** (sinus sagittalis superior) commences in the anterior fossa of the cranium, at the crista galli, where it communicates through the foramen cæcum with the veins of the nasal cavity or with the angular vein. It passes upwards, then backwards, and finally downwards in the convex margin of the falx cerebri, grooving the frontal, parietal, and upper part of the occipital bones. As it descends it passes slightly to the right side, and it ends at the level of the internal occipital protuberance by becoming the right lateral sinus. Instead

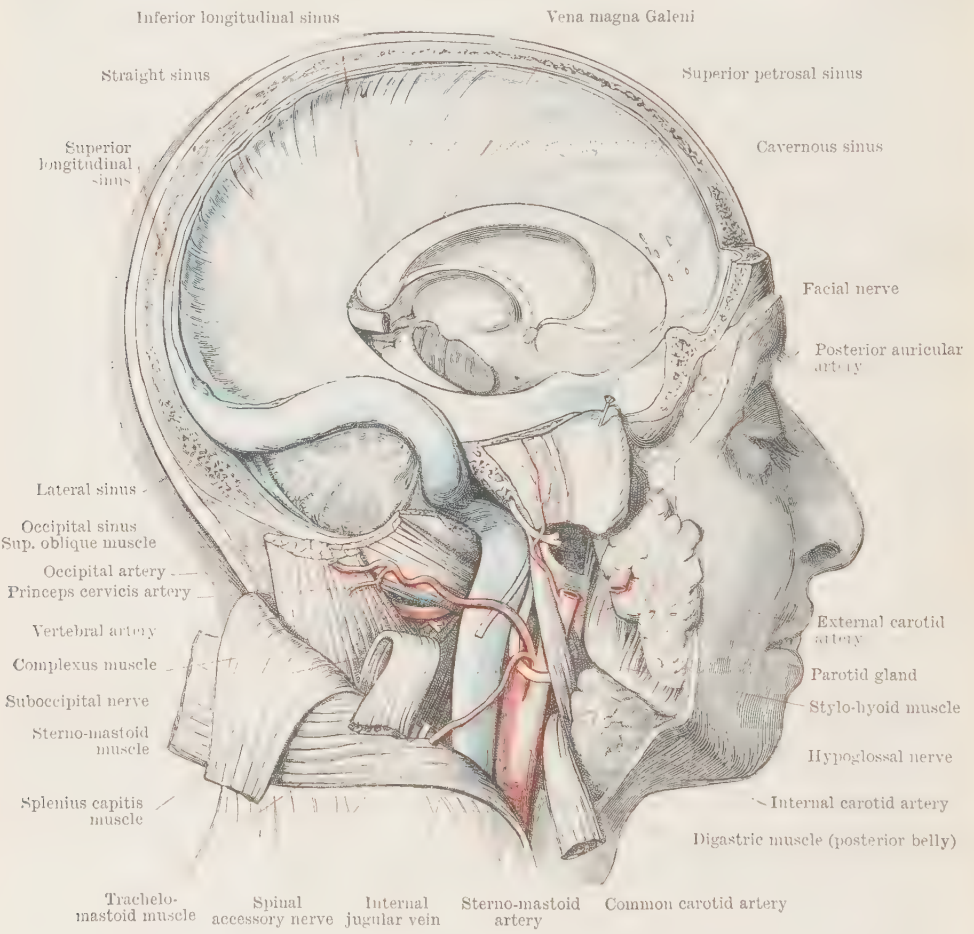

FIG. 650.—DISSECTION OF THE HEAD AND NECK, showing the cranial blood sinuses and the upper part of the internal jugular vein.

of passing to the right, it occasionally turns to the left, and ends in the left lateral sinus. In either case its termination is associated with a well-marked dilatation, the *torcular Herophili*, which marks a confluence of sinuses, and which is lodged in a depression at one side of the internal occipital protuberance. The torcular is connected, across the protuberance, by an anastomosing channel with a similar dilatation, which marks the junction of the straight sinus with the lateral sinus of the opposite side. Opening into the superior longitudinal sinus are the superior cerebral veins, and it communicates on each side by small openings with a series of spaces in the dura mater, the **lacunæ laterales**, into which the Pacchionian bodies (arachnoidal villi) project. It also communicates, by emissary veins which pass through the foramen cæcum and through each parietal foramen (emissarium parietale), with the veins on the exterior of the cranium. Its cavity, which is triangular in transverse section, is crossed by several fibrous strands called the **chordæ Willisii**.

The **inferior longitudinal sinus** (sinus sagittalis inferior) lies in the posterior two-thirds of the lower free margin of the falx cerebri. It terminates posteriorly

by joining with the vena magna Galeni to form the straight sinus. It is circular in transverse section, and it receives tributaries from the falx cerebri and from the inner surface of the middle third of each cerebral hemisphere.

The **circular sinus** (sinus circularis) is situated in the pituitary fossa, and surrounds the pituitary body. It is usually formed by anterior (sinus intercavernosus anterior) and posterior (sinus intercavernosus posterior) transverse channels which pass across the pituitary fossa from one cavernous sinus to the other.

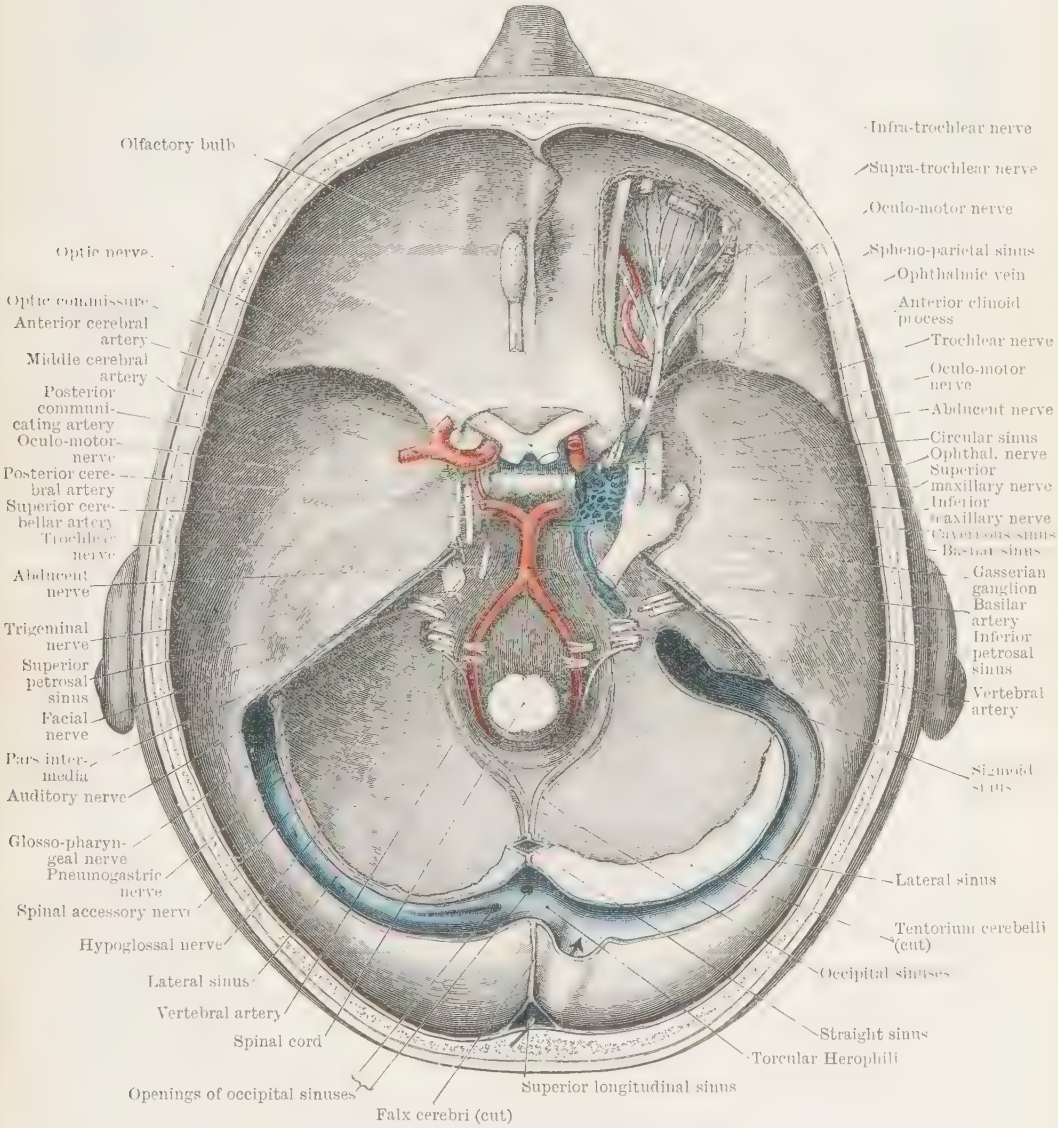

FIG. 651.—BASAL BLOOD SINUSES OF THE DURA MATER.

The **basilar sinus** (plexus basilaris).—The term basilar sinus is applied to a venous plexus situated in the dura mater on the basilar part of the occipital bone. It connects the posterior ends of the cavernous or the anterior ends of the inferior petrosal sinuses together, and communicates below with the anterior spinal veins.

The **straight sinus** (sinus rectus) is formed by the union of the inferior longitudinal sinus with the great vein of Galen. It runs downwards and backwards, along the line of attachment of the falx cerebri to the tentorium cerebelli. As a general rule it turns to the left at the internal occipital protuberance, dilates somewhat, and becomes continuous with the left lateral sinus, its dilatation being united

with the corresponding dilatation on the lower end of the superior longitudinal sinus—the torcular Herophili—by a transverse anastomosing channel. Occasionally the straight sinus terminates in the right lateral sinus, and in that case the superior longitudinal sinus ends in the left lateral sinus. It receives some of the superior cerebellar veins and a few tributaries from the falx cerebri.

**Paired Sinuses.**—There are six pairs of sinuses, viz. the lateral, the occipital, the cavernous, the superior petrosal, the inferior petrosal, and the spheno-parietal.

**Lateral Sinuses.**—Each lateral sinus (sinus transversus) commences at the internal occipital protuberance, the right usually as the continuation of the superior longitudinal, and the left as the continuation of the straight sinus. Each passes outwards in the outer border of the tentorium cerebelli and in a groove in the occipital bone. From the lateral angle of the occipital bone it passes on to the posterior inferior angle of the parietal bone, which it grooves; then it leaves the tentorium and turns downwards on the inner surface of the mastoid portion of the temporal bone; from the latter it passes to the upper surface of the jugular process of the occipital bone, and turns forwards and then downwards into the jugular foramen, where it becomes continuous with the internal jugular vein.

Its tributaries are some of the superior and inferior cerebellar veins, a posterior diploic vein, and the superior petrosal sinus. It is connected with the veins outside the cranium by emissary veins which pass through the mastoid and posterior condylar foramina.

The **occipital sinuses** (sinus occipitales) lie in the attached border of the falx cerebelli and in the dura mater along the postero-lateral boundaries of the foramen magnum; frequently they unite above and open by a single channel into the commencement of either the right or the left lateral sinus, but their upper extremities may remain separate, and then each communicates with the commencement of the lateral sinus of its own side. They open below into the terminal part of the corresponding lateral sinuses, and they communicate with the posterior spinal veins. Each occipital sinus is an anastomosing channel between the upper and lower extremities of the lateral sinus of the same side, and each receives a few inferior cerebellar veins.

The **cavernous sinuses** lie at the sides of the body of the sphenoid bone. Each sinus (sinus cavernosus) commences anteriorly at the inner end of the sphenoidal fissure, where it receives the corresponding ophthalmic vein, and it terminates at the apex of the petrous portion of the temporal bone by dividing into the superior and the inferior petrosal sinuses. Its cavity, which is irregular in size and shape, is so divided by numerous fibrous strands that it assumes the appearance of cavernous tissue, and in its outer wall are embedded the internal carotid artery with its sympathetic plexuses, the third, fourth, first, and second divisions of the fifth, and the sixth cranial nerves. Its tributaries are the spheno-parietal sinus and the inferior cerebral veins, including the superficial Sylvian vein. It communicates with the opposite cavernous sinus by means of the circular sinus; with the pterygoid plexus in the zygomatic fossa by an emissary vein which passes either through the foramen ovale or through the foramen Vesalii; with the internal jugular vein by small venous channels which accompany the internal carotid artery through the carotid canal, and by the inferior petrosal sinus; with the lateral sinus by the superior petrosal sinus, and through the ophthalmic vein with the angular vein.

The **spheno-parietal sinuses** (s. spheno-parietales) are lodged in the dura mater on the under surfaces of the small wings of the sphenoid bone close to their posterior borders. Each sinus communicates with the middle meningeal veins, receives veins from the dura mater, and terminates in the anterior part of the corresponding cavernous sinus.

**Superior Petrosal Sinuses.**—Each superior petrosal sinus (s. petrosus superior) commences at the apex of the petrous portion of the temporal bone in the posterior end of the corresponding cavernous sinus. It runs backwards and outwards in the attached margin of the tentorium cerebelli, above the fifth cranial nerve, and grooves the upper border of the petrous portion of the temporal bone, at the outer extremity of which it terminates in the lateral sinus at the point where the latter is turning downwards on the inner surface of the mastoid portion of the temporal bone. It receives inferior cerebral, superior cerebellar, tympanic, and diploic veins.

**Inferior Petrosal Sinuses.**—An inferior petrosal sinus (s. petrosus inferior) commences at the posterior end of each cavernous sinus; it runs backwards, outwards, and downwards in the posterior fossa of the cranium, in a groove along the lower margin of the petrous portion of the temporal bone and the adjacent border of the basilar portion of the occipital bone, to the anterior compartment of the jugular foramen of the same side, through which it passes. It crosses the last four cranial nerves either externally or internally, and it terminates in the internal jugular vein. Its tributaries include inferior cerebellar veins and veins from the internal ear, which pass to it through the internal auditory meatus, the aqueductus cochlea, and the aqueductus vestibuli.

## The Spinal Veins.

The spinal veins include—

(1) The extra-spinal veins.
  (*a*) The anterior spinal plexus.
  (*b*) „ posterior „
(2) The veins of the bodies of the vertebræ.
(3) The intra-spinal veins.
  (*a*) The anterior longitudinal veins.
  (*b*) „ posterior „ „
(4) The veins of the spinal cord.

The **anterior spinal plexus** lies in front of the bodies of the vertebræ. It consists of a number of relatively small anastomosing channels, which communicate with the veins of the bodies of the vertebræ, and which receive tributaries from the adjacent muscles and ligaments. Its efferent vessels terminate in the cervical region in the anterior deep cervical vein, in the dorsal region in intercostal veins, in the lumbar region in the lumbar veins, and in the sacral region in the lateral sacral veins.

The **posterior spinal plexus** consists of numerous anastomosing venous channels which lie on the laminæ and round the spines and the articular and transverse processes of the vertebræ. The plexus receives tributaries from the muscles and skin of the back, and communicates, through the ligamenta subflava, with the posterior longitudinal spinal veins in the interior of the spinal canal. Its efferent vessels pass between the transverse processes of the vertebræ, or through the sacral foramina, and terminate in the vertebral, the intercostal, the lumbar, and the lateral sacral veins respectively.

**Veins of the Bodies of the Vertebræ.**—The cancellous tissue of the bodies of the vertebræ is permeated by large venous channels which communicate anteriorly with the anterior spinal plexus. These channels terminate posteriorly in the *venæ basis vertebræ*, which open into transverse anastomosing vessels which connect the anterior longitudinal spinal veins.

**Anterior Longitudinal Spinal Veins.**—Two anterior longitudinal spinal veins collect blood from the bodies of the vertebræ, from the adjacent ligaments, and from the spinal dura mater. They are plexiform vessels which extend from the foramen magnum to the coccyx, behind the bodies of the vertebræ and along the margins of the posterior common ligament, and they are connected together, opposite each vertebral body, by transverse anastomoses which lie between the posterior common ligament and the bodies of the vertebræ; these transverse anastomoses are greatly dilated opposite the centres of the bodies where they receive the venæ basis vertebræ. Each anterior longitudinal spinal vein communicates round the margin of the canal with the corresponding posterior vein, and it gives off efferent vessels which pass through the intervertebral foramina to terminate, according to the region in which they are placed, in the vertebral, intercostal, lumbar, or lateral sacral veins.

Superiorly the anterior longitudinal spinal veins give off large offsets, above the arch of the atlas, which form the commencement of the vertebral veins; through the foramen magnum they communicate with the basilar and with the occipital sinuses.

The **posterior longitudinal spinal veins** are placed, one on each side, between the dura mater anteriorly and the laminæ and ligamenta subflava posteriorly. They are plexiform vessels which extend along the whole length of the spinal canal. They receive tributaries from the laminæ, ligaments, and spinal membranes, and from a post-spinal plexus of veins which lies between the laminæ of the vertebræ and the deep muscles of the back; they anastomose with each other by transverse channels which pass across the laminæ, with the posterior spinal plexus by vessels which pierce the ligamenta subflava, and with the

anterior longitudinal veins round the margins of the canal. Their efferent vessels unite with those of the anterior longitudinal veins, and terminate with them.

By means of the longitudinal spinal veins and the anastomoses between them, a venous ring is formed within the spinal canal opposite each vertebra. Commencing in front, opposite the body of the vertebra, where it receives the vena basis vertebra, it passes outwards to the anterior longitudinal spinal vein, turns backwards along the inner side of the pedicle and the inner surface of the lamina to the posterior longitudinal vein, and is completed by the anastomoses between the posterior longitudinal veins. This ring communicates through the ligamenta subflava with the posterior spinal plexus, and through the intervertebral foramina with the vertebral, with the dorsal tributaries of the intercostal or lumbar veins, or with the lateral sacral veins, according to the region in which it lies.

Superiorly the posterior longitudinal spinal veins communicate with the occipital sinuses, and as these also communicate with the anterior spinal veins, and the latter with the basilar sinus, a venous ring is completed round the foramen magnum.

**Veins of the Spinal Cord.**—The veins of the spinal cord issue from the substance of the cord, and terminate in a plexus in the pia mater. In this plexus there are six longitudinal channels—one *antero-median*, along the anterior fissure, two *antero-lateral*, immediately behind the anterior nerve roots, two *postero-lateral*, immediately behind the posterior nerve roots, and one *postero-median*, over the posterior septum. Radicular efferent vessels issue from the plexus, and pass along the nerve roots to communicate with the efferent vessels from the anterior and posterior longitudinal spinal veins, and to terminate in them. The veins of the spinal cord vary very much in size, but they are largest on the lower and on the posterior portions of the cord.

The postero-median and antero-median veins are continued above into the corresponding veins of the medulla oblongata.

The antero-lateral and postero-lateral veins pour their blood partly into the median veins and partly into the radicular veins; indeed, the greater part of the blood from the spinal cord is returned by the latter veins.

## THE VEINS OF THE UPPER EXTREMITY.

The veins of each upper extremity are divisible into two sets—viz. **superficial** and **deep**. Both sets open eventually into a common terminal trunk which is known as the **axillary vein**. This vein is therefore the chief efferent stem of the upper extremity. It is continued as the subclavian vein to the innominate vein, and its blood, together with that of the corresponding side of the head and neck, reaches the superior vena cava.

### The Deep Veins of the Upper Extremity.

The deep veins, with the exception of the axillary vein, are arranged in pairs which accompany the different arteries and are similarly named. So far as these veins (venæ comites) are concerned it will be sufficient to state that they are provided with valves, that they are situated one on either side of the artery with which they are associated, and that they are usually united together by numerous transverse anastomoses which cross in front of or behind the artery. The axillary vein, however, requires more detailed consideration.

### The Axillary Vein.

The **axillary vein** (v. axillaris, Fig. 629) commences as the direct continuation of the basilic vein, opposite the lower border of the teres major. It passes upwards and inwards through the axilla, along the inner side of the corresponding artery, and terminates at the outer border of the first rib by becoming the subclavian vein. It possesses a bicuspid valve which is usually situated opposite the lower border of the subscapularis muscle.

**Relations.**—Its anterior relations are similar to those of the axillary artery, but, in addition, the vein is crossed in front, under cover of the clavicular part of the pectoralis

major, by the pectoral branches of the acromio-thoracic artery, and by branches of the internal anterior thoracic nerve, and it receives in front, just above the upper border of the pectoralis minor, the termination of the cephalic vein.

Behind it are the muscles which form the posterior wall of the axilla, the axillary fat, and the first serration of the serratus magnus. The long thoracic nerve intervenes between it and the serratus magnus, and the subscapular nerves and the subscapular artery pass between it and the subscapularis.

It is separated from the axillary artery on the outer side, in the lower part of its extent by the ulnar and internal cutaneous nerves, in the middle of its course by the inner cord of the brachial plexus, and in the upper part of the axilla, behind the costo-coracoid membrane, by the internal anterior thoracic nerve. To its inner side lie the outer set of axillary glands, and in the lower part of the axilla the lesser internal cutaneous nerve.

**Tributaries.**—In addition to tributaries corresponding with the branches of the axillary artery, it receives the venæ comites of the brachial artery, at the lower border of the subscapularis, and the cephalic vein, which joins it at the upper border of the small pectoral muscle.

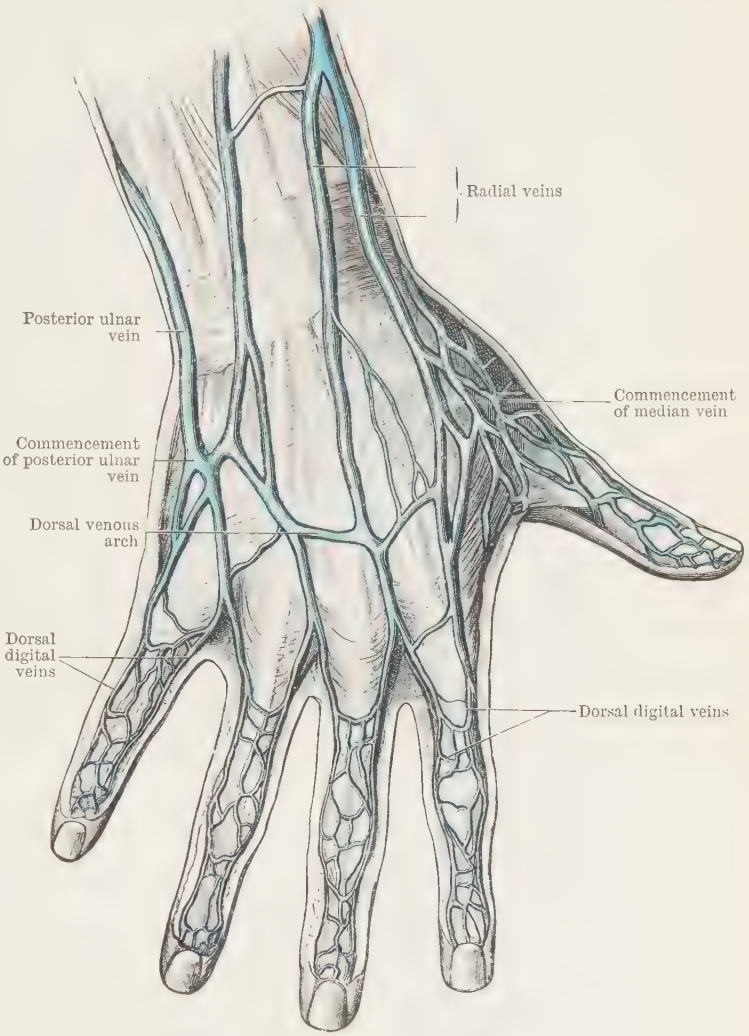

FIG. 652.—SUPERFICIAL VEINS ON THE DORSUM OF THE HAND AND DIGITS.

## THE SUPERFICIAL VEINS OF THE UPPER EXTREMITY.

The superficial veins of the upper extremity commence in the superficial fascia of the palm and dorsum of the hand and of the fingers.

The superficial veins of the palmar aspects of the fingers terminate for the most part in **dorsal digital veins**, which run along the dorso-lateral borders of the digits; some, however, pass upwards into the palm and join the superficial palmar veins, which, in comparison with the superficial dorsal veins, are relatively few and small. The superficial veins of the palm anastomose together, forming a more or less polygonal plexus from which some efferent vessels pass laterally round the borders of the palm to the dorsal plexus of the hand, whilst others ascend towards the wrist, where they end either in the median or the anterior ulnar superficial veins of the forearm.

The superficial veins on the dorsal aspect of each digit form two longitudinal vessels, the **dorsal digital veins** (vv. digitales dorsales propriæ), which ascend along the dorso-lateral borders of the digit. They receive tributaries from the palmar aspect of the digit, from the pulp of the tip, from the subungual tissues, and from the superficial tissues of the dorsum. The dorsal digital veins, which run along the adjacent borders of the second, third, and fourth interdigital clefts, unite, at the apices of the clefts, to form three **dorsal interosseous** or **interdigital veins** (vv. metacarpæ dorsales), which terminate on the dorsum of the hand in a dorsal venous arch or dorsal venous plexus; the radial or outer vein of the index-finger ends in the same arch.

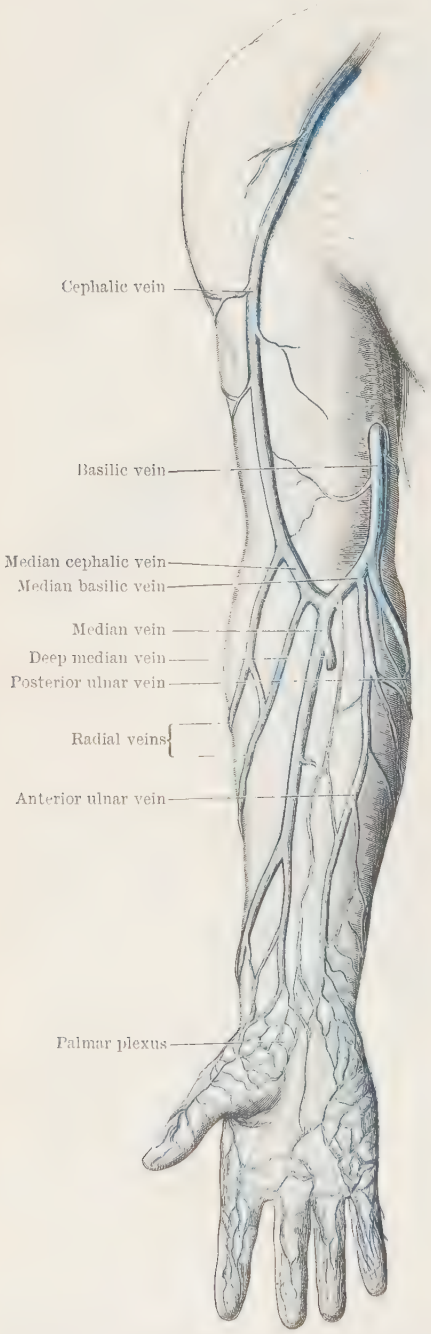

Fig. 653.—Superficial Veins on the Flexor Aspect of the Upper Extremity.

The **dorsal venous arch** of the hand receives not only the dorsal interosseous or interdigital veins, and the radial digital vein of the index-finger, but also numerous tributaries from the superficial tissues of the dorsum of the hand, which anastomose frequently together and form a plexiform network. The arch lies opposite the lower parts of the shafts of the four inner metacarpal bones, and terminates at its radial end in the superficial radial vein, and at its ulnar end in the posterior or dorsal ulnar vein; the dorsal digital veins of the thumb open into the superficial radial vein, and the innermost or ulnar digital vein of the little finger ends in the posterior superficial ulnar vein.

**Superficial Veins of the Forearm.**—There are four main superficial venous trunks in the forearm—viz. the median, the radial, and the anterior and posterior ulnar veins.

The **median vein** (v. mediana cubiti) commences, as a rule, on the dorsal aspect of the base of the thumb by the union of a number of efferents from the dorsal plexus; it turns round the radial border of the forearm, receives numerous tributaries from the radial and median portions of the palm, and ascends to the middle of the bend of the elbow, where it is joined by the *deep median vein*, a large anastomosing channel which connects it with the deep veins, and immediately afterwards terminates by dividing into median cephalic and median basilic branches.

The **median cephalic** (v. mediana cephalica), or outer branch of the median vein, runs upwards and outwards in the groove between the biceps and the supinator longus muscles. It crosses the musculo-cutaneous nerve superficially, and terminates, a short distance above the external condyle, by uniting with the radial vein to form the cephalic vein.

The **median basilic vein** (v. mediana basilica) is the inner branch of the median vein. Running more transversely than the median cephalic vein, it passes upwards and inwards along the groove between the biceps and the pronator radii teres. It is crossed superficially by the anterior terminal branch of the internal cutaneous nerve; it lies upon the bicipital fascia, which separates it from the brachial artery, and it terminates by uniting with the anterior and posterior ulnar veins to form the basilic vein.

The **radial vein** (v. radialis) commences in the dorsal venous plexus of the hand, and, after receiving some of the dorsal digital veins of the thumb, runs up the radial border of the forearm in relation with the anterior division of the musculocutaneous nerve. It receives tributaries from the subcutaneous tissue through which it passes, and terminates at the outer side of the bend of the elbow by uniting with the median cephalic branch of the median vein to form the cephalic vein. It contains several valves.

The **anterior** and **posterior ulnar veins** (vv. ulnares) vary considerably in size, but as a rule the posterior is the larger. Both are provided with valves.

The **anterior ulnar vein** commences at the base of the little finger, by the union of tributaries from the ulnar part of the dorsal venous plexus and from the ulnar side of the palm; it ascends along the front of the ulnar side of the forearm, and it terminates in the basilic branch of the median vein.

The **posterior ulnar vein** commences in the dorsal venous plexus; it receives the ulnar dorsal digital vein of the little finger, and ascends along the dorsal side of the ulnar aspect of the forearm. It terminates by joining the basilic branch of the median vein to form the basilic vein.

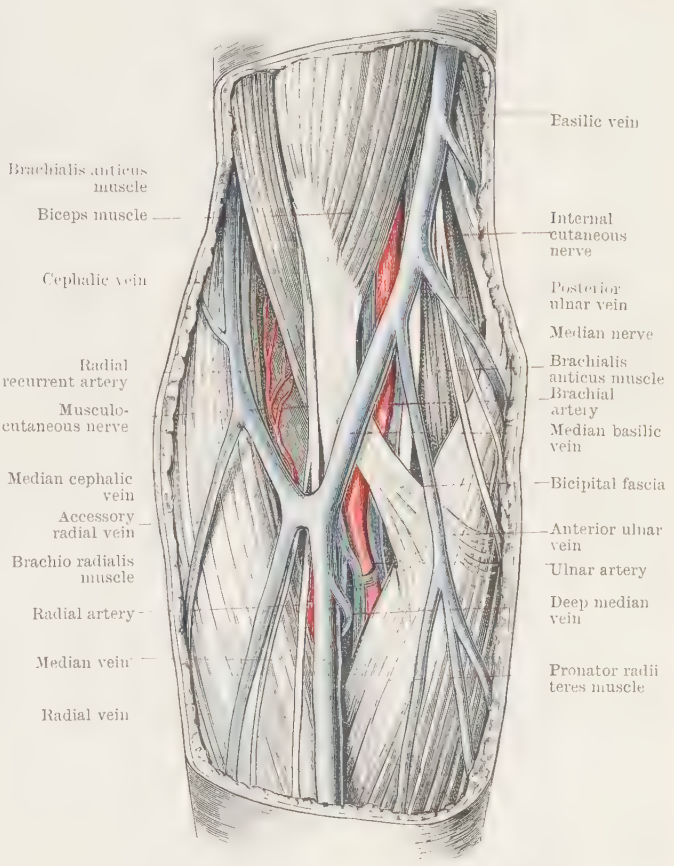

FIG. 654.—SUPERFICIAL VEINS AT THE BEND OF THE ELBOW.

**Superficial Veins of the Upper Arm.**—Only two large superficial trunks, the basilic and the cephalic, are found in the upper arm.

The **basilic vein** (v. basilica) commences at the upper and inner part of the bend of the elbow by the union of the median basilic with the posterior ulnar vein. It ascends in a groove along the inner border of the biceps to the middle of the upper arm, where it passes through an opening in the deep fascia, the hiatus semilunaris, and in the rest of its course lies deeply along the inner side of the brachial artery. It terminates at the lower border of the teres major by becoming the axillary vein, and it contains one or more bicuspid valves.

The **cephalic vein** (v. cephalica) is formed at the upper and outer part of the bend of the elbow by the union of the radial vein with the cephalic branch of the

median vein. It ascends first along the outer border of the biceps, where it is accompanied by the superior external cutaneous branch of the musculo-spiral nerve; then, after piercing the deep fascia, it is continued upwards between the adjacent borders of the deltoid and pectoralis major muscles, accompanied by the descending or humeral branch of the acromio-thoracic axis. Just below the clavicle it turns inwards, crosses the pectoralis minor, pierces the costo-coracoid membrane, and terminates in the upper or third part of the axillary vein. It is provided with a bicuspid valve at its termination. In its primitive form it terminated in the external jugular vein, to reach which it passed either over or through the clavicle. This condition occasionally persists, or is represented by a small communicating vein.

### THE INFERIOR VENA CAVA AND ITS TRIBUTARIES.

The **inferior vena cava** (Fig. 655) is a large venous trunk which receives the whole of the blood from the lower extremities, and the greater part of the blood from the walls and contents of the abdomen and pelvis. It commences opposite the right side of the body of the fifth lumbar vertebra, behind and to the right of the right common iliac artery, ascends through the abdomen in front and to the right of the vertebral column and the right crus of the diaphragm, and pierces the cupola of the diaphragm, between the middle and right sections of the central tendinous leaflet, at the level of the eighth dorsal vertebra. It then pierces the fibrous pericardium, enters the middle mediastinum, and terminates in the lower and back part of the right auricle. Its intrapericardial portion is very short, and it is covered on its anterior and lateral aspects by the parietal portion of the serous layer. Attached to the lower and front margin of its auricular orifice is the Eustachian valve, which is a remnant of an important fold of endocardium by which, in the fœtus, the blood from the inferior vena cava is directed, through the foramen ovale, into the left auricle.

**Relations.**—The inferior vena cava is in relation behind with the bodies of the lower lumbar vertebræ and the corresponding part of the anterior common ligament, the anterior portion of the right psoas muscle, the right lumbar sympathetic cord, the roots of the right lumbar arteries, the right crus of the diaphragm, the right renal artery, the right semilunar ganglion, the right inferior phrenic artery, and the inner and upper portion of the right suprarenal body.

In front of it, from below upwards, are the following structures—the right common iliac artery, the lower end of the mesentery and the superior mesenteric artery, the right spermatic artery and the third part of the duodenum, the head of the pancreas, the portal vein and the first part of the duodenum, the foramen of Winslow, and the posterior surface of the liver. More superficially are coils of small intestine, the great omentum, and the transverse colon and mesocolon.

To its left side are the aorta and the right crus of the diaphragm.

On its right side and below is the right ureter, whilst at a higher level the right kidney is only separated from it by a short interval.

**Tributaries.**—In addition to the two common iliac veins, by the union of which it is formed, and through which it receives blood from the pelvis and from the lower extremities, the inferior vena cava receives the following tributaries:—The hepatic veins, the right inferior phrenic vein, the right suprarenal vein, the right and left renal veins, the right spermatic or ovarian vein, and the right and left lumbar veins.

**Hepatic Veins** (vv. hepaticæ, Fig. 655).—These veins convey blood which has passed through the liver from the portal veins and from the hepatic artery, and they open into that portion of the inferior vena cava which lies immediately below the diaphragm, and behind the right lobe of the liver. They form two groups, an upper group of two or three large trunks, and a lower group of smaller veins.

The upper group occasionally consists of only two veins, a right and a left; more frequently there are three vessels, a right, a left, and a middle vein, and in the latter case the middle vein issues from the Spigelian lobe.

The veins of the lower group vary in number from six or seven to twenty; they return blood from the right and Spigelian lobes.

The hepatic veins commence in the interior of the lobules of the liver as

*intralobular veins*; these issue from the upper and posterior aspects of the lobules, and unite together to form *sublobular veins*; and the latter, uniting with one another as they converge towards the posterior surface of the liver, form the larger hepatic veins.

**Inferior Phrenic Veins** (vv. phrenicæ inferiores).—The venæ comites of the inferior phrenic arteries are formed by tributaries which issue from the substance

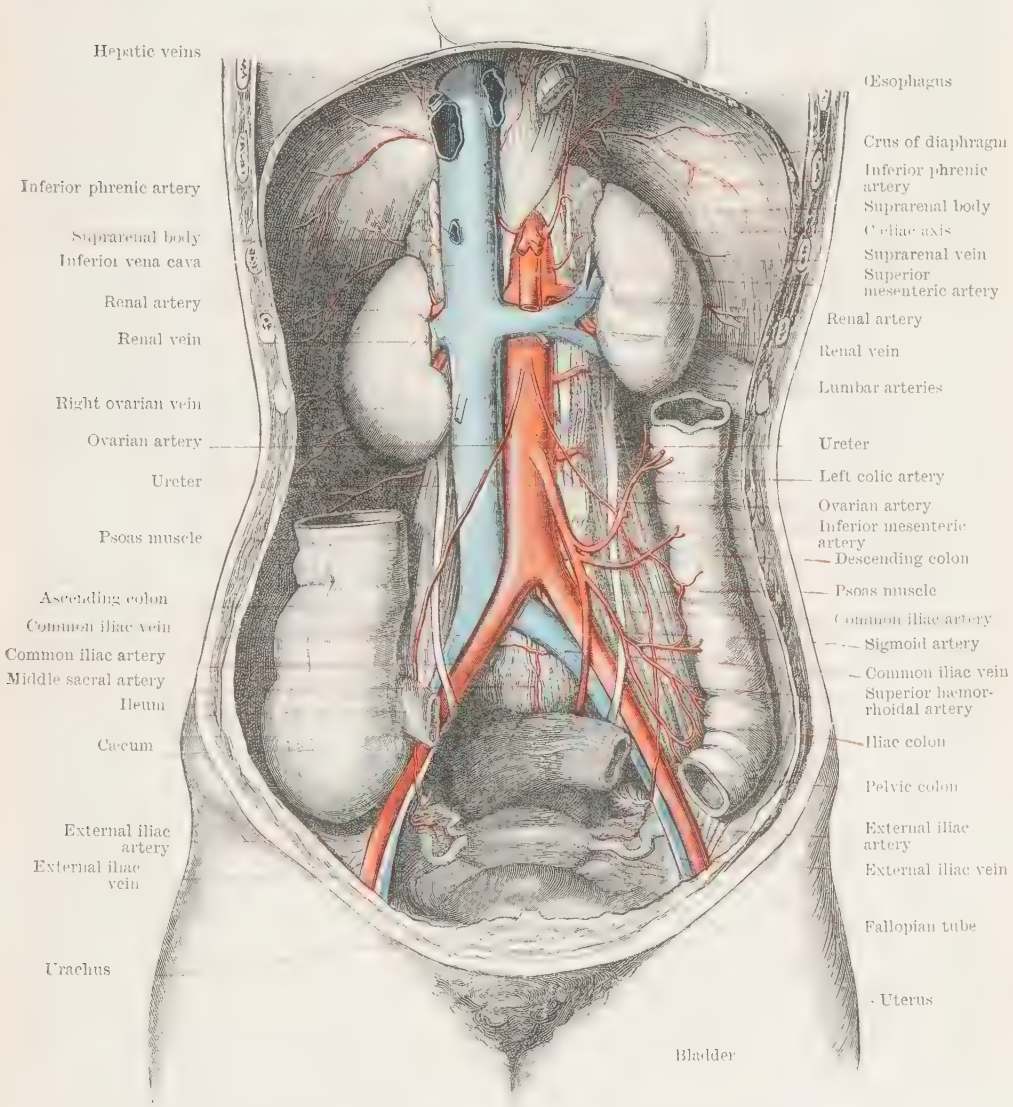

Fig. 655.—The Inferior Vena Cava and its Tributaries.

of the diaphragm. The right vein terminates in the upper part of the inferior vena cava. The left veins pass behind the œsophagus, and usually end in the left suprarenal vein.

**Suprarenal Veins.**—A single suprarenal vein (v. suprarenalis) issues from the hilum on the anterior surface of each suprarenal body; the right vein terminates in the inferior vena cava; the left usually ends in the left renal vein, but sometimes it opens directly into the inferior vena cava.

**Renal Veins** (vv. renales).—Each renal vein is formed by the union of five or six tributaries which issue from the hilum of the kidney, where they lie in front of the corresponding arteries.

The **right renal vein** is about one inch long; it passes behind the second part of the duodenum, and terminates in the right side of the inferior vena cava.

The **left renal vein** crosses in front of the left psoas, the left crus of the diaphragm, and the aorta immediately below the superior mesenteric artery. It lies behind the pancreas and the fourth part of the duodenum, and, running above the third part of the duodenum, terminates in the left side of the inferior vena cava. The left spermatic or ovarian vein, according to the sex, and almost invariably the left suprarenal vein, open into it.

**Lumbar Veins** (vv. lumbales).—There are usually four lumbar veins on each side, one with each lumbar artery; the vein with the subcostal artery is not included in this number. The lumbar veins are formed by the union of anterior and posterior trunks between the transverse processes of the vertebræ. The anterior tributaries commence in the lateral walls of the abdominal cavity, where they communicate with the superior and deep epigastric veins. The posterior tributaries issue from the muscles of the back in the lumbar region, and receive tributaries from the spinal plexuses. The main stems pass forwards on the bodies of the vertebræ; on each side they run behind and to the inner side of the psoas muscle, whilst those of the left side also pass behind the aorta. They terminate in the posterior part of the inferior vena cava. Not uncommonly the corresponding veins of opposite sides unite together to form a single trunk which enters the back of the inferior vena cava. All the lumbar veins of each side are united together by a longitudinal anastomosing vessel, the ascending lumbar vein, which passes upwards in front of the transverse processes of the lumbar vertebræ, and usually ends above in an azygos vein, whilst below it connects the lumbar veins with the ilio-lumbar and lateral sacral veins.

**Spermatic Veins** (vv. spermaticæ).—The spermatic veins on each side issue from the testicle and epididymis and form a plexus, the *pampiniform plexus*. The plexus forms part of the spermatic cord, and consists of from eight to ten veins, most of which lie in front of the vas deferens; it passes upwards in the inguinal canal, and, near the internal abdominal ring, terminates in two main trunks which ascend with the corresponding spermatic artery for some distance, receiving tributaries from the ureter, and, occasionally, on the left side from the iliac and pelvic colon; ultimately the two veins unite together and a single terminal vein is formed. The terminal spermatic vein on the right side opens into the inferior vena cava, that on the left side into the left renal vein. The left spermatic veins are longer than the right, the left testicle being lower than the right, and the termination in the left renal vein being at a higher level than the termination of the right vein in the inferior vena cava. The spermatic veins on each side lie upon the psoas muscle and the ureter. They are covered by peritoneum, and they are crossed on the right side by the termination of the ileum and the third part of the duodenum, and on the left side by the iliac colon. They are provided with valves both in their course and at their terminations, but occasionally the valve at the orifice of the left spermatic vein is absent.

The **ovarian veins** (vv. ovaricæ), on each side, issue from the hilum on the anterior border of the ovary. They pass between the layers of the broad ligament, where they anastomose freely and form the *pampiniform plexus*, which extends outwards towards the brim of the pelvis. From the plexus two veins are formed which accompany the corresponding ovarian artery; they pass in front of the external iliac artery, and then upwards behind the peritoneum and in front of the psoas muscle and ureter. The veins of the right side, like the corresponding spermatic veins, also pass behind the termination of the ileum and the third part of the duodenum; whilst the left veins, near the brim of the pelvis, pass behind the commencement of the pelvic colon.

The two veins on each side ultimately fuse together to form a single terminal vein which ends, on the right side in the inferior vena cava, and on the left side in the left renal vein. As the left ovarian veins ascend on the psoas they sometimes receive tributaries from the iliac and pelvic colon.

## The Iliac Veins.

The **common iliac veins** (Figs. 640 and 655), right and left, are formed by the union of the corresponding external and internal iliac veins. Each commences opposite the brim of the pelvis, immediately behind the upper part of the internal iliac artery of its own side, and both vessels pass upwards to the right side of the body of the fifth lumbar vertebra, at the upper part of which, just behind and to the outer side of the right common iliac artery, they unite together to form the inferior vena cava.

The **right common iliac vein** (v. iliaca communis dextra) is much shorter than the left; it passes in front of the obturator nerve and the ilio-lumbar artery, and at first behind and then somewhat to the outer side of the corresponding common iliac artery.

The **left common iliac vein** (v. iliaca communis sinistra) is much longer than the right, and is also placed more obliquely. It passes upwards and to the right, in front of the body of the fifth lumbar vertebra, and across the middle sacral artery. For some distance it runs along the inner side of the left common iliac artery, and then passes behind the right common iliac artery. It also passes behind the mesentery of the pelvic colon and the superior hæmorrhoidal artery.

**Tributaries.**—Each common iliac vein receives the corresponding external and internal iliac veins and the ilio-lumbar veins. The left common iliac vein receives in addition the middle sacral vein.

The **ilio-lumbar veins** (vv. ilio-lumbales) receive tributaries from the iliac fossa, from the lower parts of the spinal muscles, and from the spinal canal. There is a single vein on each side which accompanies the corresponding artery. It passes behind the psoas muscle and terminates in the common iliac vein.

**Middle Sacral Veins.**—The venæ comites of the middle sacral artery commence by the union of tributaries which issue from the venous plexus in front of the sacrum, through which they communicate with the lateral sacral veins and receive blood from the sacral part of the spinal canal. They unite above into a single stem (v. sacralis media), which terminates in the left common iliac vein.

The **internal iliac vein** (v. hypogastrica, Fig. 640) is a short trunk formed by the union of tributaries which correspond to all the branches of the internal iliac artery, with the exception of the hypogastric or umbilical and the ilio-lumbar branches.

It commences at the upper border of the great sciatic notch, and ascends to the brim of the pelvis, where it unites with the external iliac vein to form the common iliac vein. It lies immediately behind and slightly to the inner side of the internal iliac artery, is crossed externally by the obturator nerve, and is in relation internally, on the left side with the pelvic colon, and on the right side with the lower part of the ileum.

**Tributaries.**—The tributaries, which are numerous, are conveniently divisible into extra-pelvic and intra-pelvic groups.

The *extra-pelvic tributaries* are all **parietal**, and include the obturator, internal pudic, sciatic, and gluteal veins.

**Obturator Vein** (v. obturatoria).—This vein is formed by the union of tributaries which issue from the hip-joint and from the muscles on the upper and inner part of the thigh. It enters the pelvis through the obturator foramen, runs backwards along the lateral wall lying on the pelvic fascia immediately below the corresponding artery, and, passing between the internal iliac artery on the outside and the ureter on the inside, terminates in the internal iliac vein.

**Sciatic Veins** (vv. glutaeæ inferiores).—The venæ comites of the sciatic artery commence in the subcutaneous tissues on the back of the thigh; they ascend with the sciatic artery, and pass deeply into the buttock beneath the gluteus maximus, where they receive numerous tributaries from the surrounding muscles. Entering the pelvis through the great sciatic foramen, they unite into a single vessel, which terminates in the lower and anterior part of the internal iliac vein below the termination of the obturator vein.

**Gluteal Veins** (vv. glutaeæ superiores).—The venæ comites of the gluteal artery are formed by tributaries which issue from the muscles of the buttock. They accompany

the artery through the great sciatic foramen, and terminate in the internal iliac vein; they frequently unite together before reaching their termination.

**Internal Pudic Veins.**—The venæ comites of the internal pudic artery commence by tributaries which emerge from the corpus cavernosum of the penis (vv. profundæ penis) or clitoris (vv. profundæ clitoridis). They follow the course of the internal pudic artery, and usually join together into a single vessel (v. pudenda interna) which terminates in the internal iliac vein. As tributaries they receive the veins from the bulb, the superficial perineal and inferior hæmorrhoidal veins (vv. hæmorrhoidales inferiores), and veins from the muscles of the buttock.

The **inferior hæmorrhoidal veins**, which commence in the substance of the external sphincter of the anus and in the walls of the anal canal, anastomose with the middle and superior hæmorrhoidal veins, and consequently connect the portal and vena caval systems together.

The *intra-pelvic tributaries* of the internal iliac vein are either (*a*) **parietal** or (*b*) **visceral**; the former comprises the lateral sacral veins, the latter includes the efferent vessels from the plexuses around the several pelvic viscera.

(*a*) **Parietal: Lateral sacral veins** (vv. sacrales laterales) accompany the corresponding arteries, and terminate on each side in the inner and back part of the internal iliac vein.

(*b*) **Visceral tributaries** are derived from the rectum and from the plexuses associated with the uterus, vagina, bladder, and prostate. They include the middle hæmorrhoidal, the uterine, the vaginal, and the vesical veins.

The **middle hæmorrhoidal veins** (vv. hæmorrhoidales mediales) are very irregular; sometimes they cannot be distinguished. When present they are formed by tributaries which commence in the submucous tissue of the rectum, where they communicate with the superior and inferior hæmorrhoidal veins; they pass through the muscular coat, and fuse together to form two middle hæmorrhoidal veins, right and left, each of which runs outwards beneath the peritoneum, on the upper surface of the levator ani, to terminate in the internal iliac vein. In the male each middle hæmorrhoidal vein receives tributaries from the seminal vesicle and vas deferens of its own side.

**Uterine Plexuses and Veins.**—The **uterine plexuses** lie along the lateral borders of the uterus; they receive tributaries, which are entirely devoid of valves, from the uterus, and they communicate above with the ovarian, and below with the vaginal plexuses.

The **uterine veins** (vv. uterinæ), usually two on each side, issue from the lower parts of the uterine plexuses above their communications with the vaginal plexuses. At first the uterine veins on each side lie in the inner part of the base of the broad ligament above the lateral fornix of the vagina and the ureter; they then pass backwards, accompanying the corresponding artery, in a fold of peritoneum which lies between the back of the broad ligament and the recto-uterine fold; finally they ascend in the floor of the ovarian fossa, and terminate in the internal iliac vein.

**Vaginal Plexuses and Vaginal Veins.**—The **vaginal plexuses** lie at the sides of the vagina. They receive tributaries from the walls of the vagina, and communicate above with the uterine plexuses, below with the veins of the bulb, in front with the vesical plexus, and behind with the veins which issue from the middle and lower parts of the hæmorrhoidal plexus. A single **vaginal vein** issues from the upper part of the vaginal plexus on each side; it accompanies the corresponding arteries, and terminates in the internal iliac vein.

**Superior Vesical Plexus.**—The superior vesical plexus of veins lies on the outer surface of the muscular coat of the bladder at the fundus and the sides. It receives tributaries from the mucous and muscular walls, and its efferent vessels terminate in the prostatico-vesical plexus in the male, and in the inferior vesical plexus in the female.

**Prostatico-vesical Plexus.**—This plexus is distributed round the prostate and the neck of the bladder, and is enclosed between the proper fibrous capsule of the prostate and its sheath of recto-vesical fascia. In front it receives the dorsal vein of the penis, which usually terminates by two branches; behind and above it communicates with the superior vesical plexus, and receives tributaries from the seminal vesicles and vasa deferentia. One or more efferent vessels pass from it on each side and open into the corresponding internal iliac vein.

The **inferior vesical plexus** of the female, which represents the prostatico-vesical plexus of the male, surrounds the upper part of the urethra and the neck of the bladder. It receives the dorsal vein of the clitoris, and its efferent vessels terminate in the internal iliac vein.

**Dorsal Veins of the Penis** (vv. dorsales penis).—There are two dorsal veins of the penis—the superficial and the deep.

The **superficial dorsal vein** receives tributaries from the prepuce, and runs backwards immediately beneath the skin to the symphysis, where it divides into two branches which terminate in the superficial external pudic veins.

The **deep dorsal vein** lies on the dorsum of the penis beneath the deep fascia. It commences in the sulcus behind the glans, by the union of numerous tributaries from the glans and the anterior parts of the corpora cavernosa, and runs backwards in the mid-dorsal line, in the sulcus between the corpora cavernosa from which it receives many additional tributaries. At the root of the penis the vein passes between the two layers of the suspensory ligament, and then between the sub-pubic ligament and the deep transverse ligament of the perineum, thus reaching the space between the two layers of the triangular ligament, where it lies above the membranous part of the urethra, and is enclosed in some of the fibres of the compressor urethræ. Passing through the posterior layer of the triangular ligament, it enters the pelvis, and terminates, usually by two branches, in the prostatico-vesical plexus.

The **dorsal vein of the clitoris** in the female has a similar course to that of the deep dorsal vein of the penis in the male. It terminates in the inferior vesical plexus.

## THE VEINS OF THE LOWER EXTREMITY.

The veins of the lower extremity, like those of the upper extremity, are arranged in two groups, the **superficial** and the **deep,** and in the lower as in the upper limb the deep veins are associated with the arteries as venæ comites, whilst the superficial veins which lie in the subcutaneous tissues ultimately terminate in the deep veins. There is, therefore, a general similarity in the arrangement of the veins of the upper and the lower limbs, but there are differences in the details of the arrangement which are of some importance. Thus, in the upper extremity, there are two deep veins with each artery from the fingers to the root of the limb, where a single trunk, the axillary vein, is formed; but in the lower extremity each main artery has two venæ comites only as far as the middle of the limb, where a single trunk is formed. This vessel, the **popliteal vein,** is the commencement of the main venous stem of the lower extremity; it is continued upwards through the thigh as the **femoral vein,** and along the brim of the pelvis as the **external iliac vein,** which terminates by uniting with the internal iliac vein to form the common iliac vein.

Further, the superficial veins of the upper limb are more numerous than those of the lower limb, for in the forearm there are four main superficial veins, and in the leg two; in the arm two main superficial veins, and in the thigh only one.

In the upper limb the blood which passes through the superficial veins is poured into the efferent trunk vein at the root of the limb—that is, into the axillary vein; but in the lower limb the blood from the superficies of the outer parts of the leg and foot passes into the commencement of the main efferent vein, the popliteal vein, at the middle of the limb—that is, in the region of the knee, whilst the blood from the superficial parts of the inner aspect of the lower limb is poured into the femoral vein near the root of the limb in the upper part of Scarpa's triangle.

In addition to the above-mentioned differences in the general arrangement of the veins of the upper and the lower extremities, it must also be noted that in the upper extremity all the blood of the limb, both that from the shoulder-girdle region as well as that from the projecting portion of the limb, is returned to the main efferent venous trunk; but in the lower extremity the greater part of the blood from the region of the pelvic girdle, and a considerable portion from that of the thigh, is returned by the gluteal, obturator, sciatic, and pudic veins to the internal iliac vein, which in the adult is not the main efferent vein of the lower extremity.

### The Deep Veins of the Lower Extremity.

All the arteries of the lower limb except the popliteal and femoral trunks are accompanied by two *venæ comites.* They usually lie one on each side of the artery; they are connected with each other by transverse channels which pass in front of or behind the artery, and they are provided with numerous valves.

The **popliteal vein** (v. poplitea, Fig. 643) is formed, at the lower border of the popliteus muscle, by the union of the venæ comites of the anterior and posterior tibial arteries. At its commencement it lies to the inner side of and somewhat superficial to the popliteal artery, and to the outer side of the internal popliteal nerve. As it ascends through the popliteal space it gradually inclines towards the outer side of the artery, and in the middle of the space it is directly behind the artery, separating the artery from the internal popliteal nerve, which is still more posterior, whilst at the upper end of the space it is to the outer side of the artery,

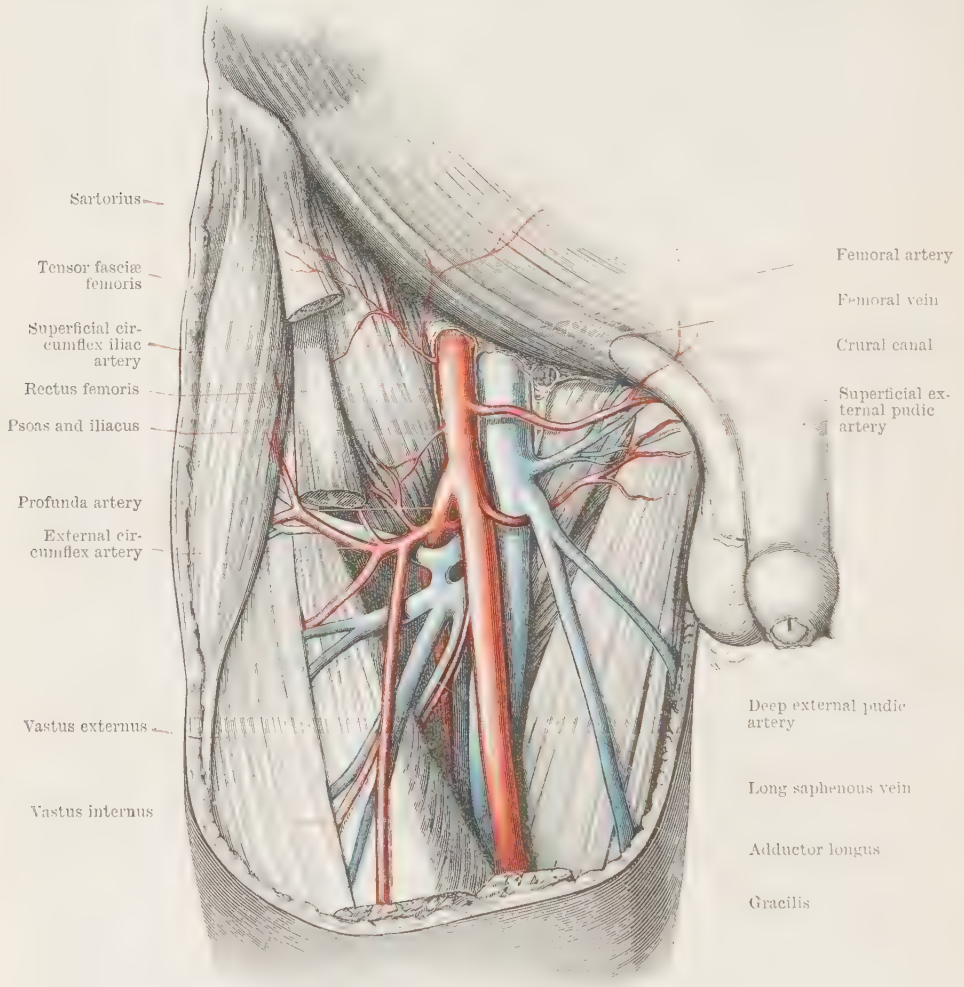

Fig. 656.—The Femoral Vessels in Scarpa's Triangle.

and still between it and the internal popliteal nerve. It then passes through the adductor magnus muscle and becomes the femoral vein.

The popliteal vein, which is provided with two or three bicuspid valves, is closely bound to the artery by a dense fascial sheath. Not uncommonly there are one or more additional satellite veins which anastomose with the popliteal vein, and in these cases the artery is more or less completely surrounded by venous trunks.

**Tributaries.**—In addition to the venæ comites of the anterior and posterior tibial arteries, it receives tributaries which correspond with the branches of the popliteal artery, and it also receives one of the superficial veins of the leg, viz. the external or short saphenous vein.

The **femoral vein** (v. femoralis) is the direct continuation of the popliteal vein.

It commences at the junction of the middle and lower thirds of the thigh, at the opening in the adductor magnus muscle. It then ascends through Hunter's canal, and through Scarpa's triangle, and terminates a little to the inner side of the middle of Poupart's ligament by becoming the external iliac vein.

In Hunter's canal it lies behind, and at first to the outer side of, the femoral artery, and upon the adductors magnus and longus which separate it from the profunda vessels. In the lower part of Scarpa's triangle it is behind and to the inner side of the artery, and immediately in front of the profunda vein which separates it from the profunda artery, but in the upper part of Scarpa's triangle it is directly on the inner side of the femoral artery. About one and a-half inches below Poupart's ligament it enters the middle compartment of the femoral sheath, through which it ascends to its termination, lying between the compartment for the femoral artery on the outer side and the crural canal on the inner side.

It usually contains two bicuspid valves—one near its termination and the other just above the entrance of its profunda tributary.

**Tributaries.**—It receives tributaries (venæ comites) which correspond with the branches of the femoral artery and the larger of the two superficial veins of the lower extremity, viz. the long saphenous vein, which enters the femoral vein where that vessel lies in the middle compartment of the femoral sheath.

Fig. 657.—The Internal or Long Saphenous Vein and its Tributaries.

The **external iliac vein** (v. iliaca externa, Figs. 637, 640, and 655) is the upward continuation of the femoral vein. It commences on the inner side of the termination of the external iliac artery, immediately behind Poupart's ligament, and ascends along the brim of the pelvis to a point at the level of the lumbo-sacral articulation and opposite the sacro-iliac joint, and immediately behind the internal iliac artery, where it ends by joining the internal iliac vein to form the common iliac vein. It lies at first on the inner side of the external iliac artery, but on a somewhat posterior plane, and then directly behind the artery, whilst just before its termination it crosses the outer side of the internal iliac artery, and separates that vessel from the inner border of the psoas muscle. In its whole course the vein lies anterior to the obturator nerve. It is usually provided with one biscupid valve, but sometimes there are two. Its tributaries correspond to the branches of the external iliac artery; thus the deep circumflex iliac (v. circumflex ilium profunda) and deep

epigastric (v. epigastrica inferior) veins open into it close to its origin, whilst in addition it frequently receives the pubic vein.

The **pubic vein** forms a communication between the obturator vein and the external iliac vein. It varies in size, and may form the main termination of the obturator vein from which it arises. Commencing in the obturator foramen, it ascends at the side of the pubic branch of the deep epigastric artery, and reaches the external iliac vein.

### The Superficial Veins of the Lower Extremity.

The superficial veins of the lower extremity terminate in two trunks, one of which, the **external** or **short saphenous vein**, passes from the foot to the popliteal space; whilst the other, the **internal** or **long saphenous vein**, extends from the foot to the groin.

The superficial veins of the sole of the foot form a fine plexus, immediately beneath the skin, from which anterior and lateral efferents pass. The anterior efferents terminate in a transverse arch which lies in the furrow at the roots of the toes, and the lateral efferents pass round the sides of the foot to the internal or external saphenous veins. The transverse arch also receives small plantar digital veins from the toes, and it gives off interdigital efferent branches to the dorsal venous arch.

The superficial veins on the dorsal aspect of each toe unite together to form two **dorsal digital veins** (v. digitales pedis dorsales) which run along the borders of the dorsal surface. The dorsal digital veins of the adjacent borders of the interdigital clefts unite, at the apices of the clefts, to form four dorsal interdigital veins which terminate in the dorsal venous arch. The dorsal digital vein from the inner side of the great toe ends in the long saphenous vein, and that from the outer side of the little toe terminates in the short saphenous vein.

The **dorsal venous arch** (arcus venosus dorsalis pedis) lies in the subcutaneous tissue, between the skin and the branches of the musculo-cutaneous nerve, opposite the lower parts of the shafts of the metatarsal bones. It ends internally by uniting with the inner dorsal digital vein of the great toe to form the long saphenous vein, and externally by joining the outer dorsal digital vein of the little toe to form the short saphenous vein. The dorsal venous arch receives the dorsal interdigital veins; interdigital efferents from the plantar transverse arch, and numerous tributaries from the dorsum of the foot, which anastomose freely together, forming a wide-meshed dorsal venous plexus, open into it behind.

The **internal** or **long saphenous vein** (v. saphena magna) is formed by the union of the inner extremity of the dorsal venous arch with the inner dorsal digital vein of the great toe. It passes upwards in front of the internal malleolus, crosses the inner surface of the lower part of the shaft of the tibia, and ascends immediately behind the internal border of that bone to the knee, where it lies just behind the internal condyle of the femur; continuing upwards, with an inclination forwards and outwards, it gains the upper part of Scarpa's triangle, where it perforates the cribriform fascia and the femoral sheath to reach its termination in the femoral vein. In the foot and leg it is accompanied by the long saphenous nerve, and for a short distance below the knee by the superficial branch of the anastomotic artery. In the thigh, branches of the internal cutaneous nerve lie in close relation with it. It contains from eight to twenty bicuspid valves.

**Tributaries.**—It communicates freely through the deep fascia with the deep intermuscular veins. In the foot it receives tributaries from the inner part of the sole and from the dorsal venous plexus. As it ascends in the leg it is joined by tributaries from the dorsum of the foot, the inner side and back of the heel, the front of the leg and the back of the calf, and it anastomoses freely with the short saphenous vein. In the thigh it receives numerous tributaries, some of which usually converge to form two **superficial femoral veins**. Of these, one, the *external*, ascends from the outer side of the knee and terminates in the internal saphenous vein about the lower part of Scarpa's triangle; the other, the *internal*, receives a communication from the external saphenous vein, and ascends from the back of the thigh along its inner side to terminate in the long saphenous

vein almost opposite the termination of the external superficial femoral vein. The last tributaries to enter the long saphenous vein are the **superficial circumflex iliac, epigastric,** and **pudic veins.** They accompany the corresponding arteries, and terminate in the long saphenous vein immediately before the latter vessels perforate the cribriform fascia.

The superficial circumflex iliac vein receives blood from the lower and outer part of the abdominal wall and the upper and outer part of the thigh. The superficial epigastric vein drains the lower and inner part of the abdominal wall, and the superficial pudic vein receives blood from the dorsum of the penis and the scrotum in the male, and from the labium majus in the female.

The **external** or **short saphenous vein** (v. saphena parva) is formed by the union of the outer extremity of the dorsal venous arch with the outer dorsal digital vein of the little toe. At first it passes backwards along the outer side of the foot and below the external malleolus, lying on the external annular ligament in company with the external saphenous nerve; then it ascends behind the external malleolus, and along the outer border of the tendo Achillis, still in company with the external saphenous nerve, to the middle of the calf, above which it is continued in the superficial fascia, accompanied by the superficial sural artery, to the lower part of the popliteal space, where it pierces the deep fascia, and terminates in the popliteal vein. It communicates round the inner side of the leg with the internal saphenous vein, and through the deep fascia with the deep veins, and it contains from six to twelve bicuspid valves.

Fig. 658.—The External or Short Saphenous Vein and its Tributaries.

**Tributaries.**—It receives tributaries from the outer side of the foot, from the outer side and back of the heel, from the back of the leg, and occasionally a descending tributary from the back of the thigh. Just before it pierces the popliteal fascia it gives off a small branch which ascends round the inner side of the thigh and unites with the internal superficial femoral vein. In this way a communication is established between the external and internal saphenous veins; this communication is frequently enlarged, and not uncommonly constitutes the main continuation of the external saphenous vein.

## THE PORTAL SYSTEM.

The portal system includes the veins which convey blood from almost the whole of the abdominal and pelvic parts of the alimentary canal, and from the spleen and pancreas, to the liver. The tributaries of origin of these veins agree closely with the terminal branches of the corresponding arteries. They are single vessels, which for some distance accompany the corresponding arteries, and are similarly named. The larger or terminal veins, however, leave their associated arteries; the **inferior mesenteric vein** joins the **splenic vein**, and the latter unites with the **superior mesenteric vein** to form the **portal vein,** which passes to the liver. These veins, together with their tributaries, constitute the portal system. All the vessels of this system are devoid of valves.

The **portal vein** (vena portæ) is a wide venous channel, about three inches long, which conveys blood from the stomach, from the whole of the intestine, except the terminal portion of the rectum, and from the spleen and pancreas to the liver. Unlike other veins, it ends like an artery by breaking up into branches, which ultimately terminate in capillaries in the substance of the liver; from these portal capillaries the hepatic veins (p. 892), which also receive the blood conveyed to the liver by the hepatic artery, arise; and as these open into the inferior vena cava, the portal blood ultimately reaches the general systemic circulation.

The portal vein commences by the union of the superior mesenteric and the

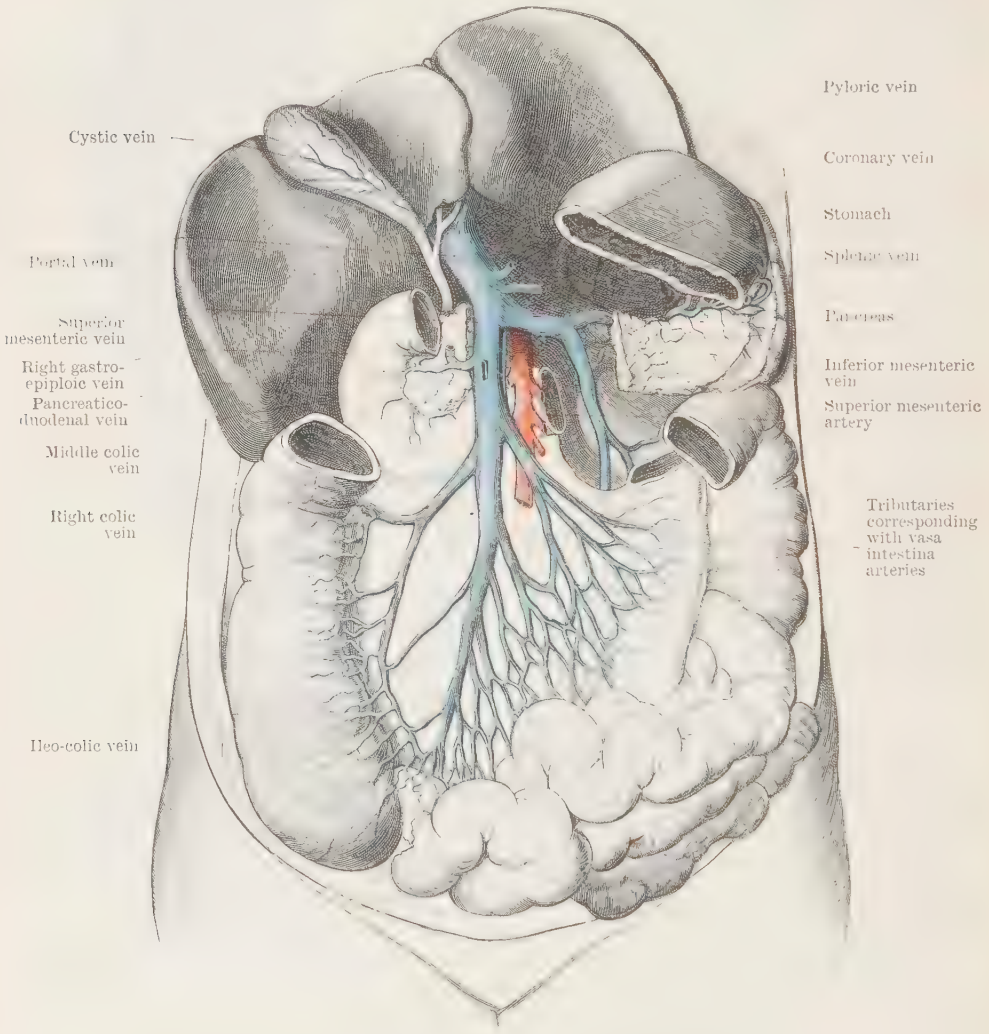

Fig. 659.—The Portal Vein and its Tributaries.

splenic veins behind and to the left of the neck of the pancreas, and either in front of the left border of the inferior vena cava, at the level of the body of the first lumbar vertebra, or in front of the upturned extremity of the lower portion of the head of the pancreas. It ascends in front of the inferior vena cava, and behind the neck of the pancreas and the first part of the duodenum, to the lower border of the foramen of Winslow, where it passes forwards, in the right pancreatico-gastric fold of peritoneum, and enters the lower border of the gastro-hepatic omentum; continuing its upward course, it lies behind the common bile-duct and hepatic artery, and in front of the foramen of Winslow; it ultimately reaches the right end of the transverse fissure of the liver, where it ends by dividing into a

short and wide right and a longer and narrower left branch. Just before its termination it enlarges, forming the sinus of the portal vein.

The **right branch** generally receives the **cystic vein** and then enters the right lobe of the liver, in which it breaks up into numerous branches which terminate in the portal capillaries round the periphery and in the substance of the liver lobules.

The **left branch** runs from right to left along the transverse fissure, giving off branches to the Spigelian and quadrate lobes; it crosses the longitudinal fissure, and ends in a similar manner to the right branch, but in the substance of the left lobe of the liver.

As it crosses the longitudinal fissure, the left branch of the portal vein is joined in front by the **round ligament** of the liver, a fibrous cord which is the remains of the left umbilical vein of the fœtus; and, somewhat to the right of the attachment of the round ligament anteriorly, a fibrous cord springs from it posteriorly and connects it with the upper part of the inferior vena cava; this cord is the remains of the **ductus venosus**, a blood-vessel of the fœtus, through which blood coming from the placenta, by the umbilical vein, passed into the inferior vena cava without going through the liver.

The portal vein is accompanied by numerous lymphatic vessels, and it is surrounded in the gastro-hepatic omentum by filaments of the hepatic plexus of nerves.

**Tributaries.**—Soon after its formation the portal vein receives the coronary and pyloric veins, and the cystic vein opens into its right branch.

The **coronary vein** (v. coronaria ventriculi) commences in the gastro-hepatic omentum by the union of tributaries from both surfaces of the stomach. It runs to the left between the layers of the gastro-hepatic omentum, and along the lesser curvature of the stomach, with the corresponding artery, to the œsophagus, where it receives œsophageal tributaries. It then turns backwards in the left pancreatico-gastric fold, and reaches the posterior wall of the abdomen, where it again changes its direction to run from left to right, behind the lesser sac of the peritoneum, to the right pancreatico-gastric fold, at the root of which it opens into the portal vein.

The **pyloric vein** (v. pylorica) is a small vessel which is formed by the union of tributaries from the upper parts of both surfaces of the stomach. It runs from left to right along the right portion of the lesser curvature, between the layers of the gastro-hepatic omentum, and terminates in the portal vein, after that vessel has entered the gastro-hepatic omentum.

The **cystic vein** (v. cystica) is formed by the union of tributaries which accompany the branches of the cystic artery on the upper and lower surfaces of the gall-bladder; it ascends along the cystic duct and, as a rule, terminates in the right branch of the portal vein.

## The Mesenteric and Splenic Veins.

The **superior mesenteric vein** (v. mesenterica superior) commences in the right iliac fossa in connexion with the lower part of the ileum. It ascends along the right side of the superior mesenteric artery in the root of the mesentery, forming a curve with the convexity to the left.

As it ascends it passes in front of the right ureter, the lower part of the inferior vena cava, the third part of the duodenum, and the lower part of the head of the pancreas; and, after passing behind the root of the transverse mesocolon, it terminates behind the neck of the pancreas by uniting with the splenic vein to form the portal vein.

Its **tributaries** correspond with the branches of the superior mesenteric artery. It is formed by the union of the ileo-cæcal and appendicular veins. In front and towards the left side the tributaries (vv. intestinales) from between the folds of the mesentery enter it; the right colic and ileo-colic veins enter its right side; the middle colic vein joins it in front at the lower border of the head of the pancreas, and close to its termination it receives the right gastro-epiploic and the pancreatico-duodenal veins.

The **right gastro-epiploic vein** (v. gastro-epiploica dextra) runs from left to right along the lower border of the stomach, and between the two anterior layers of the great omentum. It receives tributaries from both surfaces of the stomach, and near the pylorus turns backwards in the right pancreatico-gastric fold of peritoneum, passes behind the neck of the pancreas, and ends in the superior mesenteric vein.

The **pancreatico-duodenal** vein receives tributaries (vv. pancreatico-duodenalis) from the head of the pancreas and the adjacent parts of the duodenum; it ascends along the superior pancreatico-duodenal artery, and terminates in the upper part of the superior mesenteric vein.

The **splenic vein** (v. lienalis) is formed by the union of five or six tributaries which issue from the hilum on the anterior surface of the spleen. It passes backwards and inwards in the lieno-renal ligament to the kidney, then turning to the right it runs behind the upper border of the pancreas and below the splenic artery; it crosses the front of the abdominal aorta, immediately below the origin of the cœliac axis, and terminates behind the neck of the pancreas, by joining the superior mesenteric vein to form the portal vein.

**Tributaries.**—It receives the vasa brevia or gastric veins, the left gastro-epiploic vein, the pancreatic veins, and the inferior mesenteric vein. Occasionally the coronary vein terminates in it.

The **vasa brevia** or **gastric veins** (vv. gastricæ breves) are a series of small venous channels which gather blood from the region of the left portion of the great curvature of the stomach; they pass backwards towards the spleen in the gastro-splenic omentum, and terminate either in the trunk of the splenic vein or in one of its main tributaries.

The **left gastro-epiploic vein** runs from right to left along the lower border of the stomach between the layers of the great omentum. At the left extremity of the stomach it enters the gastro-splenic omentum, through which it passes towards the hilum of the spleen, and it terminates in the commencement of the splenic vein. It receives tributaries from both surfaces of the stomach.

The **pancreatic veins** issue from the substance of the pancreas, and terminate directly in the splenic vein.

The **inferior mesenteric vein** (v. mesenterica inferior) commences, as the superior hæmorrhoidal vein, in the venous plexus which lies between the muscular and mucous coats of the rectum. The **superior hæmorrhoidal vein** (v. hæmorrhoidalis superior) drains the greater part of the blood from the hæmorrhoidal plexus, through which it communicates with the middle and inferior hæmorrhoidal veins. It ascends in company with the superior hæmorrhoidal artery, and between the layers of the meso-rectum, to the brim of the pelvis, where it passes in front of the left common iliac artery and becomes the inferior mesenteric vein.

The inferior mesenteric vein runs upwards on the left of the aorta, behind the peritoneum, and in front of the left psoas muscle and the left spermatic artery. Near its termination it crosses in front of the left renal vein, and, passing behind the body of the pancreas, ends in the splenic vein. Occasionally it terminates in the angle of union of the superior mesenteric and splenic veins.

**Tributaries.**—In addition to the superior hæmorrhoidal vein, of which it is the direct continuation, the inferior mesenteric vein receives **sigmoid tributaries** (vv. sigmoidæ) from the iliac and pelvic colon, and the **left colic vein** from the descending colon and splenic flexure.

## THE LYMPH VASCULAR SYSTEM.

The vessels of the lymph vascular system (vasa lymphatica) contain a colourless fluid, rich in white corpuscles, called lymph. In many respects they resemble blood-vessels, especially the veins; but unlike veins they communicate with intercellular spaces and with serous sacs, and their continuity is interrupted by interposed nodular aggregations of lymph tissue which are known as **lymph glands** (lymphoglandulæ).

Lymph is collected in intercellular spaces from which lymph capillaries arise; the latter terminate in lymphatic vessels, which unite together, forming larger vessels; and ultimately two terminal trunks—viz. the **thoracic duct** and the **right lymphatic duct**—open into the venous system, at the commencement respectively of the left and right innominate veins.

There are no outgoing vessels, but it is customary to speak of afferent (vasa afferentia) and efferent (vasa efferentia) lymphatics with reference to vessels which enter or leave the interposed lymph-glands.

Lymph vessels, and the spaces in which they commence, merely collect and convey lymph. The lymphatic glands act, in part at least, as filters, and possibly also some of the white corpuscles are formed in them.

The greater part, if not the whole, of the lymph of the body passes through one or more of the lymph glands before it reaches the blood vascular system.

**Lymphatic spaces.**—Lymph spaces are simply intervals or clefts in connective tissue. The larger spaces are lined by a layer of flattened endothelial cells, with sinuous outlines, similar to the cells of the lymphatic capillaries; but the smaller spaces have no endothelial lining, and they are limited only by the cells of the tissue in which they lie. The precise nature of the communications between lymphatic spaces and lymph capillaries has not been definitely ascertained; but

undoubtedly lymph passes from the spaces into the capillaries, and probably it does so because the spaces and vessels are directly continuous.

As alternative explanations, it may be suggested either that the passage is due to the existence of stomata in the walls which separate spaces from the capillaries, or that it may be due to transudation through intervening tissues.

**Lymph capillaries.**—Lymph capillaries are not only much larger and more irregular than blood capillaries, but they are also larger than the lymphatic vessels into which they open. They are lined by a single layer of endothelial cells which possess very sinuous outlines; apparently they are in direct structural continuity with lymph spaces, and they anastomose freely together, forming plexiform labyrinths.

**Lymphatic vessels.**—The smallest lymphatic vessels are much narrower in calibre than the lymph capillaries with which they are continuous. Their walls consist of an internal lining of endothelial cells of fusiform shape and regular outline, and an outer layer of fine connective tissue. They are provided with numerous valves, and when distended have a beaded appearance.

The larger lymph vessels possess three coats—(1) An internal coat (tunica interna), formed by a layer of endothelial cells, of fusiform shape, and of regular, but sinuous, outline. (2) A middle coat (tunica media) of unstriped muscle fibres, arranged for the most part circularly, but some of them run obliquely or longitudinally. The interspaces between the muscle fibres are filled with a fine connective tissue. (3) An outer coat (tunica externa) of mixed white fibrous and elastic tissue, which is not sharply separated from the middle coat on the inner side or from the surrounding tissues on the outer side. It may also contain a few unstriped muscle fibres. In the largest vessels the two outer coats consist principally of muscle; they are, therefore, very friable.

All the large vessels are provided with numerous bicuspid valves, which are formed by folds of the inner coat; and as the lumina of the vessels are enlarged just beyond the attachments of the valves, the vessels assume a characteristic beaded appearance when they are distended.

Lymphatic vessels anastomose freely together, and the majority form communicating channels between different groups of lymphatic glands, leaving the more distal glands as *efferent vessels* and entering the more proximal glands as *afferent vessels*. Some of the lymphatic vessels, however, are afferent only; they simply carry lymph from the periphery to the nearest glands; whilst others, which carry lymph from the last set of glands to the terminal trunks, are efferent only.

The lymphatic vessels, unlike the veins which they usually accompany, do not increase greatly in calibre as they converge towards their terminations; they often branch, and they frequently anastomose together. In certain places, particularly the central nervous system and the spleen, lymph capillaries or even lymphatic vessels completely ensheath the smaller blood-vessels, forming perivascular lymphatic spaces.

A precise knowledge of the afferent and efferent lymph vessels, and of the several groups of glands which are interposed between them, is of the greatest practical importance; both infective micro-organisms from injured and inflammatory areas and detached cells from malignant tumour growths not unfrequently travel by afferent lymphatics to the nearest glands where they may be arrested, in which case micro-organisms may excite secondary infective inflammation, whilst cells of malignant growths may form secondary growths (metastatic growths) of similar nature in the glands.

It is therefore essential that the pathologist should be well acquainted with the anatomy of the pathways which convey lymph, with the glands associated with any given area, and also with the communications between adjacent glands.

**Lymphatic glands.**—Lymphatic glands are globular, ovoid, flattened, or irregular bodies, and each gland presents a localised depressed area which is known as the hilum. They vary considerably in size, some being no larger than a pin's-head, whilst others are as large as a bean. In colour they are usually grayish pink, but the tint varies with the position, vascularity, and state of activity of the gland. The glands of the lung are generally blackened by the deposition of carbonaceous

material in their substance, and those of the liver and spleen have frequently a brownish hue. The glands of the mesentery are creamy or white whilst the chyle is rapidly passing through them, but when the absorption of food-material from the intestine ceases they become a rosy pink.

**Structure of Lymphatic Glands.**—Lymphatic glands consist of (1) a skeleton or framework, (2) lymph sinuses, and (3) lymph follicles and cords.

(1) The **skeleton** or framework consists of a **capsule** and of primary, secondary, and tertiary **trabeculæ**.

The *capsule* is formed of white fibrous tissue interspersed with elastic fibres, and in some cases with unstriped muscular fibres.

The *primary trabeculæ* spring from the deep surface of the capsule and radiate towards the hilum, where they anastomose together and become again continuous with the capsule; they divide the interior of the gland into lobes. Where they spring from the capsule they are flattened, but as they approach the centre of the gland they become rounded; their structure is the same as that of the capsule, and from their surfaces the secondary trabeculæ are given off. The *secondary trabeculæ*, springing from the surfaces of the primary trabeculæ, cross the lymph sinuses and enter the lymph cords and follicles, where they terminate by dividing into tertiary trabeculæ. As they cross the lymph sinuses they anastomose freely together, forming a fine mesh-work through which the lymph passes in its course from the afferent to the efferent vessels. The secondary trabeculæ consist of fine strands of fibrous tissue devoid of nuclei, and their surfaces are covered with endothelial cells. The *tertiary trabeculæ* are finer and more delicate than the secondary trabeculæ, from the terminations of which they spring, but they have a similar structure. They anastomose together, forming a fine network in the lymph cords and follicles, and the spaces of the network are filled with lymph corpuscles.

(2) The **lymph sinuses** lie beneath the capsule and around the primary trabeculæ which form their boundaries on one side, whilst on the other they are limited by the lymph cords and follicles. They are traversed by the secondary trabeculæ, and their channels are thus converted into a kind of sponge-work through which the lymph stream flows. In the peripheral or cortical parts (substantia corticalis) of the glands they form more or less cylindrical channels, but towards the central or medullary parts (substantia medullaris) and near the hilum they become moniliform. Afferent vessels (vasa afferentia) enter the sinuses which lie immediately beneath the capsule at various points, whilst the efferent vessels (vasa efferentia) emerge close together at the hilum.

(3) The **lymph follicles and cords** are interposed between the lymph sinuses. They consist of dense masses of lymphoid cells embedded in a stroma formed by the tertiary trabeculæ. The follicles and cords are quite similar in structure, but the follicles are large masses which intervene between the sinuses in the cortex of the gland, and the cords are rounded and irregular strands which lie between the moniliform sinuses of the medullary portion of the gland.

It is generally believed that the lymph corpuscles in the follicles and cords are white blood corpuscles undergoing proliferation. If this belief is well founded, lymph glands must be looked upon as one of the sources from which white corpuscles are derived.

The **lymph glands** are embedded in the connective tissues, some lying superficially in the subcutaneous tissues, but the majority more deeply and usually at the sides of the great blood-vessels. As a rule they are arranged in groups of from two to fifteen, but a few of those which lie in the subcutaneous tissues are solitary.

They form centres to which afferent lymphatic vessels converge, and from which efferent vessels pass onwards to the larger lymph channels.

The student should therefore acquaint himself with the various groups of glands, with their afferents and efferents, and with the exact position and relations of the large lymphatic trunks; he will then be in a position to understand the course which minute organisms or particles, which have gained access to the lymph spaces, may take as they are carried in the lymph stream, and he will realise that such structures may either be entangled in the glands through which the lymph passes, or, having escaped all obstructions, that they will finally enter the veins at the root of the neck. At the same time, if he bears in mind the existence of the numerous anastomoses between the lymphatic vessels, he will have no difficulty in appreciating that variations from any regular course may not infrequently occur, and his clinical experience at a later period will show that such variations are by no means uncommon.

## THE TERMINAL LYMPH VESSELS.

The terminal lymph vessels are the **thoracic duct** and the **right lymphatic duct.**

**Thoracic Duct.**—The thoracic duct (ductus thoracicus) is the larger and

the longer of the two terminal lymph vessels. It commences in the umbilical region of the abdomen as an elongated ovoid dilation—the **receptaculum chyli** (cisterna chyli)—which measures 6 to 8 mm. ($\frac{1}{6}$ to $\frac{1}{8}$ in.) in its broadest diameter, and from 5 to 7·5 cm. (2 to 3 in.) in length. The receptaculum chyli lies between

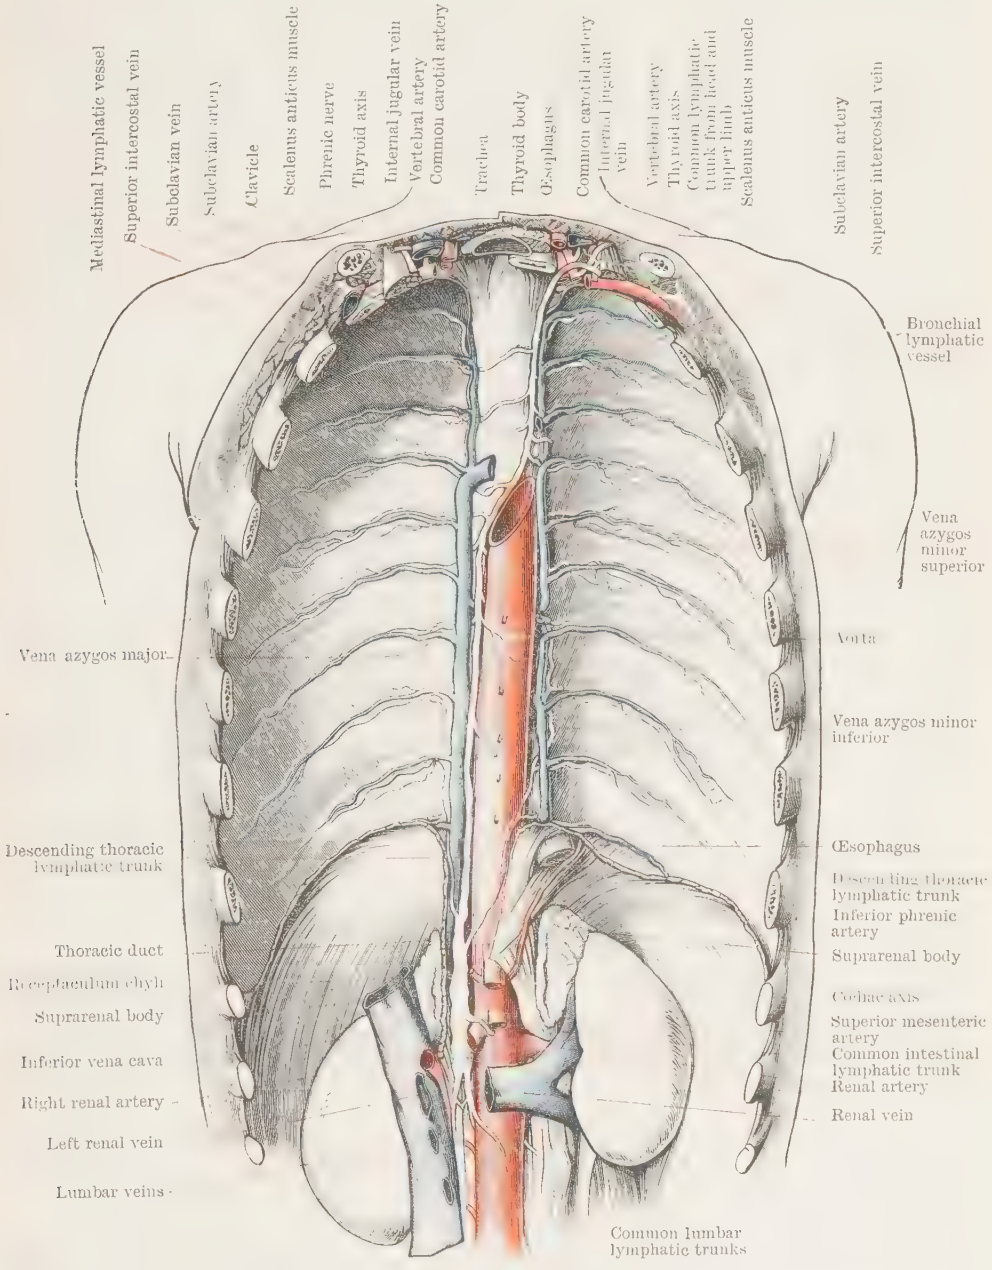

FIG. 660.—THE THORACIC DUCT AND ITS TRIBUTARIES.

the aorta and the lower part of the vena azygos major, under cover of the right crus of the diaphragm, and opposite the first and second lumbar vertebræ. Passing upwards from the receptaculum, the thoracic duct traverses the aortic opening of the diaphragm and enters the posterior mediastinum, through which it ascends, lying in front of the vertebral column and to the right of the middle line, to the level of the fifth dorsal vertebra; it then crosses somewhat abruptly from the right to the left of the median plane, and ascends through the superior mediastinum to

the root of the neck, where it turns outwards, between the vertebral and common carotid arteries, to terminate at the inner border of the scalenus anticus by joining the commencement of the left innominate vein.

**Length and diameter.**—The total length of the duct averages about 18 inches (45 cm.). It is dilated both at its origin and termination. As a rule it is narrowest opposite the fifth dorsal vertebra, but its calibre is very variable, and sometimes the thoracic portion is broken up into a series of anastomosing channels. The widest portion of the tube is usually the receptaculum, but occasionally this dilatation is entirely absent. The duct is provided with several valves, formed by semilunar folds of the inner coat, arranged in pairs, and the most perfect of these is situated at the orifice of communication with the innominate vein.

**Relations.**—In the abdomen the receptaculum chyli lies in front of the upper two lumbar vertebræ and the corresponding lumbar arteries, between the aorta on the left and the vena azygos major and the right crus of the diaphragm on the right. In the posterior mediastinum the thoracic duct is separated from the vertebral column and the anterior common ligament, by the right aortic intercostal arteries and the transverse parts of the small azygos veins; it is covered in front in the lower part of its extent by the right pleural sac, and in the upper part by the œsophagus; to its right is the vena azygos major, and to its left the descending aorta. In the superior mediastinum it passes forwards from the vertebral column, and it is separated from the left longus colli muscle by a mass of fatty tissue; the œsophagus lies in front of it in this region, but the left margin of the duct projects beyond the œsophagus, and is in relation in front, and from below upwards, with the termination of the arch of the aorta, the left subclavian artery and the pleura. As the duct enters the root of the neck it passes behind the left common carotid artery, whilst to its right and somewhat in front is the œsophagus, and the left pleura is still in association with its left border.

At the root of the neck it arches outwards above the apex of the pleural sac and the first part of the left subclavian artery. It passes in front of the vertebral artery and vein, the roots of the inferior thyroid, transverse cervical, and suprascapular arteries, the inner border of the scalenus anticus and the phrenic nerve, and behind the left carotid sheath and its contents.

**Tributaries.**—The receptaculum chyli commonly receives six tributaries. (1) The **common intestinal** or **pre-aortic lymphatic trunk** (truncus intestinalis), which is formed by the efferent of the cœliac and upper pre-aortic glands, and conveys lymph from the lower and anterior part of the liver, the stomach, the small intestine, the spleen, and the pancreas. (2) Two **common lumbar** or **lateral aortic lymphatic trunks** (trunci lumbales), one on each side; they are formed by the efferents of the lateral aortic glands, and are sometimes joined by efferents of the retro-aortic glands; they carry lymph from the lower extremities, from the deep portions of the abdominal and pelvic walls, the large intestine and the pelvic viscera, and from the kidneys and suprarenal capsules. (3) A **retro-aortic trunk** from the retro-aortic glands (see p. 922); and (4) Two **descending lymphatic trunks**, one on each side, each of which is formed by the efferent vessels from the corresponding lower intercostal glands; these descend to the receptaculum through the aortic opening of the diaphragm. Occasionally they unite to form a single trunk.

In its course through the posterior mediastinum the thoracic duct receives efferents from the upper and back part of the liver, and from the posterior mediastinal and œsophageal glands.

In the superior mediastinum the vessels which open into it are derived from the upper left intercostal glands; it also receives lymph from the heart and lungs by efferents from the left peritracheo-bronchial glands and the intertracheo-bronchial glands, though as a rule the lymphatics of these glands unite with the internal mammary lymphatic to form a common trunk which may open either into the thoracic duct or into the innominate vein.

At the root of the neck, just before its termination, it receives the efferents from the glands of the left upper extremity, which frequently unite to form a common trunk (truncus subclavius), and the left common jugular lymphatic (truncus jugularis), which conveys the lymph from the left side of the head and neck, but either or both of these vessels may end separately in the innominate vein.

**Right Lymphatic Duct.**—The right lymphatic duct is not always present (ductus lymphaticus dexter, Fig. 664). It is a short trunk, from half to three-quarters of an inch (12 to 17 mm.) in length, which lies at the right side of the root of the neck along the inner border of the scalenus anticus, and it is formed by the confluence of the right common jugular lymphatic vessel and the efferent vessels from the glands of the right upper extremity; it also receives efferents from the intercostal glands of the upper intercostal spaces on the right side; the internal mammary lymphatics and the right efferents from the peritracheo-bronchial glands on the right side. It thus receives lymph from the right side of the head and neck, the right upper limb and the right side of the trunk, including the upper part of the thoracic wall, the right lung and pleura, the right half of the heart and pericardium, the right side of the diaphragm, and the upper surface of the liver. As a rule the right lymphatic duct is not present, and the right jugular lymphatic carrying the lymph from the head and neck, the right subclavian lymphatic bearing lymph from the right upper extremity, and the trunk formed by the fusion of the right internal mammary lymphatic and the right efferents from the peritracheo-bronchial glands, end separately in the upper part of the right innominate vein, but any two of the three main trunks of the right side may unite together.

## THE LYMPHATIC VESSELS AND GLANDS OF THE HEAD AND NECK.

The **lymphatic vessels of the head and neck** form two groups—(1) the intracranial and (2) the extracranial.

(1) The **intracranial lymphatics** are (*a*) the cerebral and (*b*) the meningeal.

(*a*) The **cerebral lymphatic vessels** commence in the substance of the brain as perivascular spaces round the branches of the cerebral arteries; they accompany the cerebral branches of the internal carotid and the vertebral arteries, and, leaving the skull with the main arterial trunks and the internal jugular vein, terminate in the upper deep cervical glands.

(*b*) The **meningeal lymphatic vessels** commence in the substance of the dura mater; they accompany the meningeal blood-vessels, and they terminate in the internal maxillary glands and in the upper deep cervical glands.

(2) The **extra-cranial lymphatics** are either (*a*) superficial or (*b*) deep, and the two sets anastomose freely together.

(*a*) The **superficial lymphatic vessels** commence in the subcutaneous tissues and superficial muscles of the face and scalp.

(*b*) The **deep lymphatic vessels** originate in the walls of the nose and mouth, in the tongue, in the walls of the pharynx, the œsophagus, the larynx and trachea, in the contents of the orbital and other extracranial fossæ, and in the muscles, bones, and ligaments of the neck.

All the extracranial lymphatic vessels, both superficial and deep, are afferents to some of the glands of the head or neck, and their general distribution and terminations are mentioned in connexion with the glands with which they are associated.

The **lymphatic glands of the head** include the following:—

The **occipital glands** (lymphoglandulæ occipitales), two or three in number lie beneath the deep fascia of the neck upon the upper part of the trapezius muscle, or, if the trapezius is small, upon the upper part of the complexus muscle. They receive afferent vessels from the occipital region of the scalp and from the superficial parts of the upper and back portion of the neck, and their efferents terminate in the superficial and deep cervical glands. Some of the lymph vessels of the occipital region pass directly to the deep cervical glands.

The **mastoid glands** (lymphoglandulæ auriculares posteriores) lie on the upper part of the sterno-mastoid muscle and on the mastoid portion of the temporal bone, and they are bound down by a sheathing of deep cervical fascia. They receive afferent vessels from the posterior part of the parietal region of the scalp, and from the inner surface of the pinna; their efferents join the superficial and deep cervical glands.

The **zygomatic** or **internal maxillary glands** (lymphoglandulæ faciales profundæ)

are very variable both in number and size; they lie, in part in association with the internal maxillary artery, extending from the posterior part of the buccinator muscle, across the external pterygoid muscle, to the anterior part of the wall of the pharynx. Their afferent vessels are derived from the orbit, the temporal fossa, the zygomatic fossa, the palate, the nose, and the cerebral meninges. Their efferent vessels open into the upper deep cervical glands.

The **parotid lymphatic glands** (lymphoglandulæ auriculares anteriores), which are embedded in the substance of the parotid gland, some superficially immediately beneath the fascia on the external surface and others deeply. The *superficial* receive afferents from the frontal and the temporal regions of the scalp, from the eyebrow, the upper and lower eyelids, the upper part of the cheek, the root of the nose, and the outer surface of the pinna. Their efferents pass to the superficial and the upper deep cervical glands. The *deep parotid lymphatic glands* (lympho-glandulæ parotideæ) lie along the course of the upper part of the external carotid artery. They receive afferents from the external meatus, the tympanum, the soft palate, the posterior part of the nose, and the deeper portions of the cheek. Their efferents open into the upper deep cervical glands, and they also communicate with the glands round the external jugular vein.

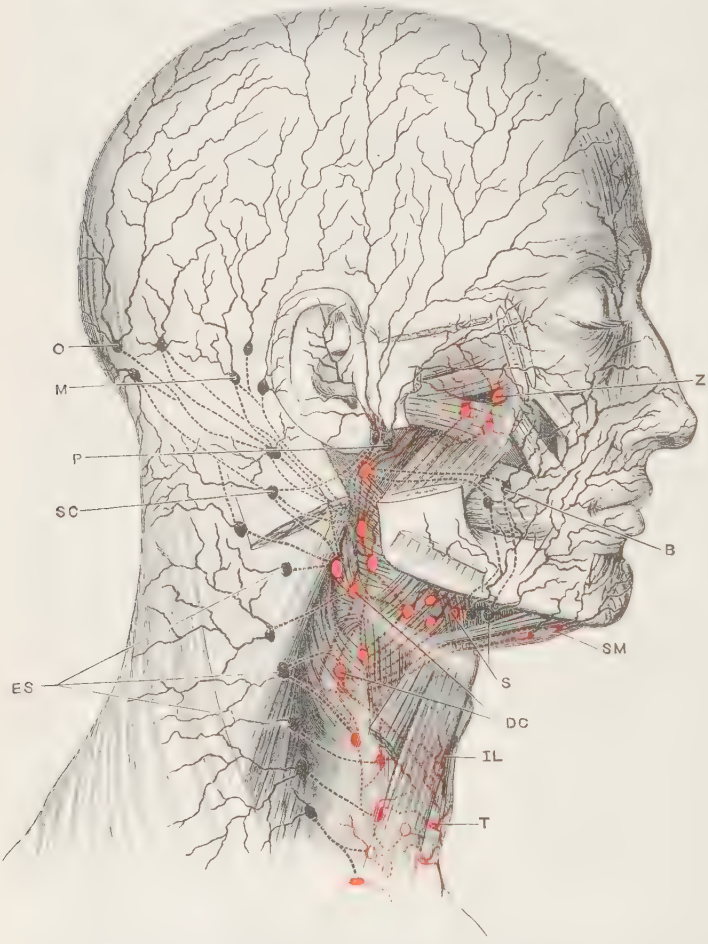

FIG. 661.—LYMPHATIC VESSELS AND GLANDS OF THE HEAD AND NECK.

The afferent vessels are shown in continuous lines; the efferent and inter-glandular vessels are represented by dotted lines.

The **Facial Glands.**—Several glands or groups of glands have been found by different observers in the tissues of the face. Those most regularly present are the **mandibular glands**, which lie close to the facial artery as it crosses the mandible immediately in front of the masseter muscle. A number of **buccal glands**, irregular in number and size, are met with on the outer surface of the fascia covering the buccinator muscle, some near its anterior part and others near the point where the buccinator is pierced by Stensen's duct. A *lateral nasal gland* is sometimes present in the angle between the ala of the nose and the cheek, and an *infraorbital* and a *malar* gland are described. These glands receive lymph from the tissues in their im-

mediate neighbourhood, and their efferents pass to the submaxillary or parotid glands.

The **lingual glands** (lymphoglandulæ inguales) lie between the genio-hyo-glossi muscles and, on the outer surfaces of the hyo-glossi and genio-hyo-glossi muscles, under cover of the mylo-hyoid muscles; they are simply small lymphatic nodules interposed in the course of the lymphatics which are passing from the tongue and the floor of the mouth to the deep cervical glands.

The **lymphatic glands of the neck** include—

The **superficial cervical lymphatic glands** (lymphoglandulæ cervicales superficiales). These lie on or are embedded in the deep fascia along the course of the external jugular vein, superficial to the sterno-mastoid. They receive afferent vessels from the superficial tissues of the neck, the mastoid, the superficial parotid, and the submaxillary lymphatic glands. Their efferent vessels terminate in the upper deep cervical glands and the supra-clavicular glands.

The **submaxillary lymphatic glands** (lymphoglandulæ submaxillares) vary in number from three to six. They lie under cover of the deep fascia of the neck in the angle between the lower border of the mandible and the submaxillary gland, and the largest of the series is usually situated near the point where the facial artery turns round the lower border of the mandible. Occasionally some smaller gland nodules are found on the deep surface of the submaxillary gland, but these are comparatively rare. The afferent vessels of the submaxillary lymphatic glands carry lymph from the side of the nose, the upper lip, the outer part of the lower lip, the anterior third of the border of the tongue, the gums, the submaxillary and sublingual glands, and the adjacent parts of the floor of the mouth. The efferents descend over the superficial surface of the submaxillary gland, and terminate in the upper deep cervical glands, more particularly in those in the immediate neighbourhood of the termination of the common carotid artery.

The **supra-hyoid** or **submental glands** lie immediately beneath the chin superficial to the mylo-hyoid muscles and between the two anterior bellies of the digastric muscles. They are apt to become enlarged in diseased conditions of the middle part of the lower lip, the adjacent part of the gums, the anterior part of the floor of the mouth, the tip of the tongue, and the skin beneath the chin, for their afferent vessels drain those parts. The efferents from this group of glands pass partly to the submaxillary lymphatic glands, and partly to a deep cervical gland situated on the superficial surface of the internal jugular vein at the level of the cricoid cartilage.

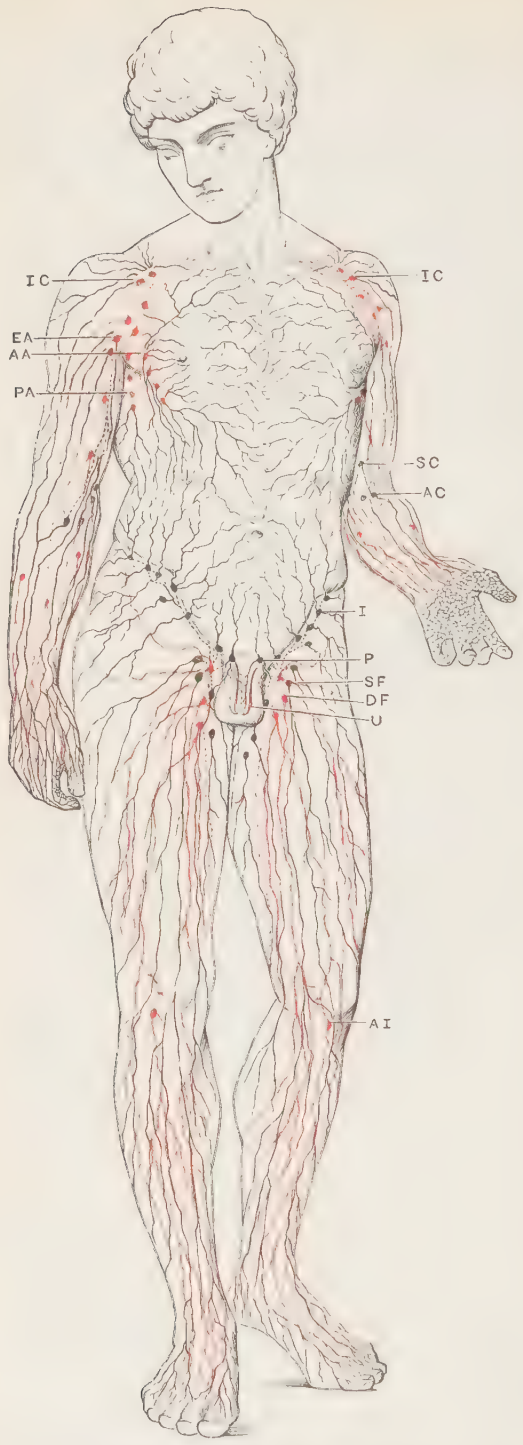
The **post-pharyngeal glands** lie behind the pharynx and in front of the upper two cervical vertebrae. Their afferents are derived from the nasal cavities and the air sinuses communicating with them, the naso-pharynx, the Eustachian tube and tympanic cavity, and the adjacent muscles, ligaments, and bones. Thus they receive the lymph outflow from a large area much subject to inflammatory conditions, and on this account they not uncommonly become infected and form the foci of post-pharyngeal abscesses.

Their efferents terminate in the upper deep cervical glands.

The **anterior jugular glands** are of small size; they are very variable and of little importance. When they are present they lie along the course of the anterior jugular vein.

The **pre-laryngeal glands** are also very variable. When present they lie in the crico-thyroid space between the anterior borders of the crico-thyroid muscles. Their afferents are derived from the lower and middle parts of the larynx, the upper part of the trachea, and the thyroid body. Their efferents as a rule terminate in the lower deep cervical glands, but they also anastomose with the afferents of the pre-tracheal glands, and occasionally they ascend, and, uniting with the lymphatics from the region of the upper part of the larynx, they terminate in the upper deep cervical glands in the region of the posterior belly of the digastric muscle.

The **pre-tracheal glands** are generally present, but are small. They lie upon the surface of the trachea, receiving afferents from the trachea, the lower part of the thyroid body, and occasionally from the pre-laryngeal glands. Their efferents join the lower deep cervical glands.



The **deep cervical glands** lie under cover of the sterno-mastoid and in the posterior triangle of the neck. The former are designated sub-sterno-mastoid and the latter supra-clavicular. They form in reality a continuous sheet of glandular nodules connected together by vessels, but it is usual to separate them, on account of their positions, into those which are sub-sterno-mastoid and those which lie in the posterior triangle and are therefore supra-clavicular.

The **sub-sterno-mastoid glands** are separable into external and internal chains.

The *external chain* of sub-sterno-mastoid glands lies behind the internal jugular vein under cover of the posterior border of the sterno-mastoid muscle and on the roots of the cervical plexus of nerves. The glands of this chain receive afferents from the occipital, mastoid, and external jugular glands, from the pinna, the posterior part of the scalp and the adjacent muscles, and the bones and skin of the neck. The group is continuous below with the supra-clavicular glands, and its efferents terminate either in those glands or in the glands of the internal sub-sterno-mastoid chain. When they become enlarged the external sub-sterno-mastoid glands can be felt and even seen projecting from under cover of the posterior border of the sterno-mastoid.

The *internal chain* of sub-sterno-mastoid glands extends along the internal jugular vein from the base of the cranium to the clavicle, and it is not uncommonly spoken of as consisting of two groups of glands which are called the upper and lower deep cervical glands, the former lying above and the latter below the level of the thyroid cartilage. There is, however, no distinct separation between the two groups, and the division is made use of merely for convenience in indicating the higher or lower terminations of the afferent vessels.

FIG. 662.—SUPERFICIAL LYMPHATIC VESSELS OF THE TRUNK, AND THE LYMPHATIC GLANDS AND VESSELS—SUPERFICIAL AND DEEP—OF THE LIMBS (diagrammatic). All superficial lymphatics are printed black; the deep lymphatics throughout are coloured red. Afferent vessels are represented by continuous lines; efferent and interglandular vessels by dotted lines.

U. Urethral lymphatics.

The upper group (lymphoglandulæ cervicales profundæ superiores) extends from the base of the skull to the bifurcation of the common carotid artery at the level of the upper border of the thyroid cartilage. Its constituent glands vary considerably in size, and one of the largest, which lies under cover of the posterior belly of the digastric muscle, receives the majority of the lymphatics from the tongue, and is therefore of great clinical importance. The glands of this group are connected with many important regions, and are therefore liable to become enlarged as a result of diseased conditions in many of the upper parts of the head and neck. Their afferents are derived from the interior of the cranium, the nose, the pharynx, the palate, the tonsils, the upper part of the larynx, the whole of the tongue, except its tip and the anterior third of each lateral border, and the thyroid body. They also receive as afferents the efferent vessels from the buccal, the internal maxillary, the retro-pharyngeal, the sub-parotid, and the deep parotid glands, and from some of the glands of the external sub-sterno-mastoid chain. They occasionally receive the efferents from the pre-laryngeal glands carrying lymph from the lower part of the larynx.

The lower glands of the internal sub-sterno-mastoid chain or the lower deep cervical glands (lymphoglandulæ cervicales profundæ inferiores) lie along the lower part of the internal jugular vein. They receive the efferents from the external chain of sub-sterno-mastoid glands, from the pre-laryngeal glands, and from a group of small glands which lie in the groove between the trachea and œsophagus, along the course of the recurrent laryngeal nerve. These glands receive lymph from the trachea, œsophagus, and the lower part of the thyroid body.

The efferents of both the upper and lower deep cervical glands unite together at the lower part of the neck to form a common jugular lymphatic trunk which terminates on the right side either by uniting with the subclavian lymphatic from the upper limb to form the right lymphatic duct, or separately in the commencement of the innominate vein. On the left side the jugular lymphatic trunk generally ends in the thoracic duct, but it may end either in the internal jugular, the subclavian, or innominate veins.

The **supra-clavicular glands** lie in the anterior part of the posterior triangle of the neck amidst the descending branches of the cervical plexus and on the roots of the brachial plexus. The uppermost part of this group is continuous with the external sub-sterno-mastoid glands, and the lowermost is situated in the region of the termination of the external jugular vein. The afferent vessels are derived from the neck and the posterior part of the scalp; from the upper extremity, many of the efferents of the external axillary glands terminating in the supra-clavicular glands, whilst occasionally the lymphatics which accompany the cephalic vein cross the clavicle, instead of dipping into the subclavian glands, and terminate in the supra-clavicular glands. In addition, some of the lymphatics on the pectoral region, amongst which may be included some occasional vessels from the mammary gland, also end in the supra-clavicular glands.

It is well known that the supra-clavicular glands sometimes become enlarged subsequent to the appearance of malignant conditions in the abdomen and the mediastinum, and more particularly subsequent to affections of the œsophageal portion of the stomach. The course along which the infective material travels in these cases is not yet known, for as yet no afferent vessels have been traced to the supra-clavicular glands from the mediastinum.

The efferents of the supra-clavicular glands usually terminate in the jugular lymphatic trunk.

## LYMPHATIC GLANDS AND VESSELS OF THE UPPER EXTREMITY.

The **lymphatic glands of the upper extremity** are divisible into (1) superficial and (2) deep sets.

(1) The **superficial glands** lie in the subcutaneous tissue, and form two groups, a lower and an upper. The *lower* or *ante-cubital group* is frequently absent; when present it includes two or three glands which lie in front of the elbow; they receive afferent vessels from the front of the forearm and from the median part of

the palm, and occasionally become enlarged subsequent to infective inflammations of those areas. They give off efferent vessels which pass upwards and inwards along the antero-internal aspect of the arm. At varying levels these efferents pierce the deep fascia and terminate in the external axillary glands. The *upper* or *supra-trochlear group* lies a short distance above the internal condyle; as a rule it includes two glands only, but the number may be increased to four; they lie close to the commencement of the basilic vein, and their afferent vessels are derived from the inner two or three digits, the inner side of the forearm, and the inner side of the palm. Their efferents pass upwards along the basilic vein, which they accompany through the opening in the deep fascia; they then join the deep lymphatics, which are ascending along the brachial artery, and accompany them to the external axillary glands.

(2) The **deep glands** lie along the vessels in the axilla and, just below the clavicle, in the groove between the pectoralis major and the deltoid muscles. They are accordingly divisible into (*a*) the axillary and (*b*) the infra-clavicular or subclavian glands.

One or two small glands are occasionally found with the arteries of the forearm and a few with the brachial artery; they receive deep afferent lymphatics from the adjacent muscles, ligaments, and the bones, and they give off efferent vessels which terminate in the external axillary glands.

(*a*) The **axillary glands** are arranged in four groups—external, anterior, posterior, and central.

(i.) The **external group** (lymphoglandulæ axillares) consists of from six or more glands which form a chain along the antero-internal aspect of the axillary vessels, extending from the lower border of the pectoralis major to the outer border of the first rib. They receive afferent vessels, both superficial and deep, from the whole of the upper extremity; many of these pass directly to the glands from the tissues, the remainder include the efferents of the superficial and deep glands of the forearm and arm, and some of the efferents of the anterior and posterior axillary glands. The efferents of the external axillary glands pass along the subclavian vein, and the majority either terminate in the subclavian glands or unite with their efferents to form a common subclavian trunk, which terminate on the right side in the right lymphatic duct or in the innominate vein, and on the left side in the thoracic duct; but some of the efferents end in the supra-clavicular glands, and others in the central glands.

(ii.) The **anterior axillary** or **pectoral glands** (lymphoglandulæ pectorales), four or five in number, lie at the anterior part of the axilla, in the angle between the pectoral muscles and the serratus magnus. They receive afferent vessels from the superficial parts of the anterior and lateral walls of the body above the umbilicus, and from the outer two-thirds of the mammary gland. Some of their efferents pass to the external axillary glands, some to the subclavian glands, and others end in the glands of the central group.

(iii.) The **posterior** or **subscapular set** of axillary glands (lymphoglandulæ subscapulares), four or five in number, lie along the sides of the subscapular artery on the posterior wall of the axilla. Their afferents are the superficial lymphatics of the lateral and posterior parts of the body-wall above the umbilicus, and the superficial lymphatics of the lower and back part of the neck. Their efferents generally join the external and central axillary glands, but some may end in the subclavian glands.

(iv.) The **central group** lies at the base of the axilla resting on the axillary fascia between the other groups. It consists of from three to five glands which receive afferents from the external, posterior, and anterior groups of glands, and its efferents pass to the subclavian glands.

(*b*) The **infra-clavicular** or **subclavian glands** lie in relation with the upper part of the axillary vein, and appear to be the upward extension of the external and anterior axillary glands. They receive efferents from all four groups of axillary glands, a deep lymphatic from the mamma which pierces the pectoralis major, and also the lymphatics which accompany the cephalic vein and carry lymph from the outer side of the hand, forearm, and arm. In the course of

these latter vessels a few small glands are sometimes interpolated in the groove between the deltoid and pectoralis major muscles.

The **lymphatic vessels of the upper extremity** are, like the glands, arranged in two sets, (1) the superficial and (2) the deep.

The **superficial lymphatic vessels** commence in cutaneous plexuses which are finest and most dense on the palmar aspects of the fingers and hand. The efferents from the palmar digital plexuses, in each digit, converge to four trunks, which lie two on each side in the subcutaneous tissue on the lateral margins of the dorsal aspects of the digits. They accompany the dorsal digital veins, and, at the roots of the digits, they pass to the dorsum of the hand, where they anastomose together. The plexus in the palm of the hand is extremely fine, and efferents pass from it not only upwards, but also downwards and laterally. The upper efferents, three or four in number, accompany the median vein, and terminate either in the superficial glands at the bend of the elbow or in the supra-trochlear glands. The lower efferents pass to the interdigital spaces, and turn backwards to the dorsum to join the digital trunks. The lateral efferents turn round the borders of the hand, those on the inner side join the efferents from the little finger, and those on the outer side the efferents from the thumb. Occasionally some of the efferents which pass towards the outer side fuse to form a fairly large

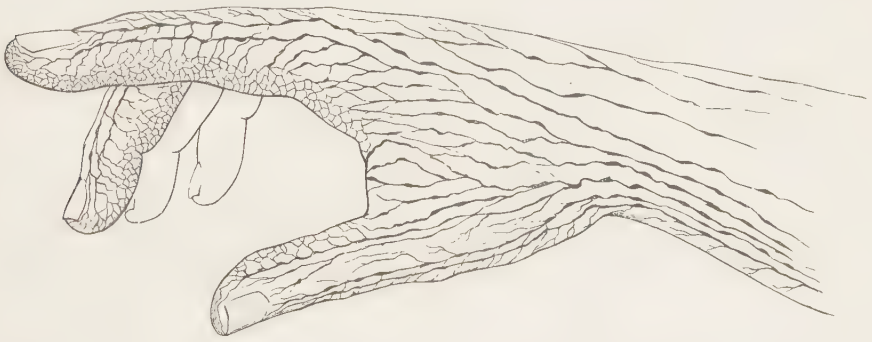

Fig. 663.—Superficial Lymphatics of the Digits and of the Dorsal Aspect of the Hand.

trunk, the so-called *central lymphatic*, which turns round the outer side of the second metacarpal bone and unites with the lymphatic vessels of the thumb and index-finger.

The superficial lymphatic vessels of the forearm, including those which ascend from the dorsum and the palm of the hand, are grouped, for the main part, along the radial, median, and ulnar veins, the lateral vessels being joined at intervals by tributaries from the dorsum of the limb.

The lymphatic trunks which accompany the ulnar veins terminate in the supra-trochlear glands, and those which accompany the median vein in the glands at the bend of the elbow, the ante-cubital glands, or, if these are not present, in the supra-trochlear glands.

The efferent vessels of the ante-cubital and supra-trochlear glands have already been described (p. 914).

A few of the lymphatics of the outer side of the forearm and some of those of the upper arm accompany the cephalic vein and carry lymph to the infra-clavicular glands, or to some small glands which lie in the groove between the deltoid and pectoralis major muscles whose efferents join the infra-clavicular glands.

All the remaining superficial vessels of the upper arm and forearm pass towards the axilla. They pierce the deep fascia, and terminate in the external set of axillary glands.

The **deep lymphatics of the upper extremity** commence in the bones, periosteum, ligaments, muscles, and intermuscular connective tissue; they accompany the main vessels, and some of them terminate in the deep glands of the forearm and arm, but the majority ascend to the external set of axillary glands.

## THE LYMPHATIC GLANDS AND VESSELS OF THE LOWER EXTREMITY.

**Lymphatic Glands of the Lower Extremity.**—Like those of the upper extremity, these glands are arranged in two sets, (1) superficial and (2) deep.

(1) **Superficial Glands.**—The superficial glands all lie in the region of the groin, and form three groups—the superior, the inferior, and the internal, which are all closely associated together by numerous inter-communicating channels.

(*a*) The **superior** or **inguinal group** includes from four to seven flattened ovoid glands which lie parallel with and just below Poupart's ligament. They receive afferent vessels from the back and outer part of the thigh and the buttock, and the superficial lymphatics from the body-wall below the level of the umbilicus, except those from the lower and anterior part which pass to the internal group of glands. Their efferents pass through the deep fascia, and terminate in either the deep femoral or the lower external iliac glands.

(*b*) The **inferior** or **superficial femoral group** is formed by from three to six oval glands which are disposed vertically along the upper part of the internal or long saphenous vein. They receive all the superficial lymphatics of the foot and leg, except a few which accompany the external saphenous vein to the popliteal glands; all the superficial lymphatics of the thigh, except those from the upper and outer part, which terminate in the superior set of glands, and a few from the upper and inner part which terminate in the inner group of glands. They also occasionally receive lymphatics from the perineum and scrotum. The efferent vessels of the femoral group pass through the saphenous opening, and terminate either in the deep femoral glands or in the lower external iliac glands.

(*c*) The **internal** or **pubic group** includes two, three, or four rounded glands which lie internal to the saphenous opening and close to the spine of the pubis. They receive afferent vessels from the lower and middle portion of the abdominal wall, from the upper and inner part of the thigh, from the skin of the external genitals, including some of the lymphatics from the lower third of the vagina in the female, and from the perineum, including some of the lymphatics of the lowest part of the anal passage and anus, in both sexes. The vessels from the lower third of the vagina and the corresponding part of the rectum communicate not only with the inguinal glands but also with the sacral glands. The efferent vessels of the pubic glands communicate with the efferents of the superior and inferior groups, and, after passing through the saphenous opening, they terminate either in the deep femoral or the lower external iliac glands. Although the general arrangement of the afferent vessels of the superficial inguinal glands is that above indicated, it must be understood that it is not constant, and that lymphatics which frequently terminate in one group may in some cases end in an adjacent group, a fact which must be kept in mind in the investigation of diseased conditions.

(2) **Deep Glands.**—The deep lymphatic glands of the lower extremity are found on the upper part of the interosseous membrane of the leg, in the popliteal space, and in Scarpa's triangle.

The **anterior tibial gland** (lymphoglandula tibialis anterior) is situated near the anterior tibial artery on the upper part of the front of the interosseous membrane. It receives afferent vessels from the deep parts of the sole and the dorsum of the foot, and from the deep parts of the front of the leg. It gives off two efferent vessels which pass backwards along the anterior tibial artery and terminate in the popliteal glands.

The **popliteal glands** (lymphoglandulæ popliteæ) are four or five in number; they lie in the popliteal space, generally round the popliteal artery, but occasionally there is one immediately beneath the deep fascia near the entrance of the external saphenous vein. They receive afferent vessels from the sole of the foot and the back of the leg, from the anterior tibial gland and the knee-joint; they also receive the superficial lymphatics which accompany the external saphenous vein. The majority of the efferent vessels join the deep femoral glands, but some become superficial and end in the inferior superficial femoral glands, and it is stated that others accompany the sciatic nerve and end in the lateral pelvic glands.

The **deep femoral glands**, three or four in number, lie on the inner side of the

femoral vein, and the largest of the group, known as the *gland of Cloquet* or Rosenmüller, is embedded in the crural canal. Their afferent vessels are the efferents of the popliteal glands, some of the efferents from the superficial glands of the groin, the lymphatics from the glans penis and some of the lymph vessels from the penile portion of the urethra, and the deep lymphatic vessels from the front and outer side of the thigh and knee. Their efferents pass to the external iliac glands.

**Lymphatic Vessels of the Lower Extremity.**—There are two sets of these vessels, (1) the superficial and (2) the deep.

(1) **Superficial Vessels.**—The superficial lymphatics lie in the subcutaneous tissues. They commence in plexuses which are best marked on the plantar aspects of the toes and foot. The lymphatic vessels which emerge from the plantar plexus in each toe terminate in four digital vessels which are arranged in pairs along the dorso-lateral border of the digit, and these end posteriorly in a plexus on the dorsum of the foot.

Some of the vessels which drain the plexus in the sole of the foot turn round the outer and inner borders of the foot and join the dorsal plexus, whilst others pass up the leg with the efferent vessels from the dorsal plexus.

The efferent vessels from the dorsal lymphatic plexus of the foot form two groups, an inner and an outer. The inner vessels are the more numerous, and they are joined by additional vessels from the inner part of the sole and heel. Some of them pass upwards in front of and others behind the internal malleolus; in the leg they accompany the internal saphenous vein, and they terminate in the lower or femoral set of superficial glands. The outer group of vessels is reinforced by tributaries from the outer side of the sole and heel; most of the vessels of this group pass upwards in front of the external malleolus, but some go behind that prominence of bone; they gradually turn inwards as they ascend, and, passing across the front of the leg, they join the internal group, being first reinforced by numerous additional vessels from the front and outer side of the leg, and they terminate, with the vessels of the inner group, in the superficial femoral glands.

A few vessels of the outer group, and one or two large vessels which rise from the back of the heel and the lower part of the leg, ascend along the external saphenous vein, pierce the popliteal fascia, and terminate in the popliteal glands.

The superficial lymphatic vessels from the front, the lower and outer, lower and inner, and the back parts of the thigh and knee, terminate in the superficial femoral glands. The vessels from the upper and outer parts of the thigh and from the buttock end in the superficial inguinal glands, and those from the upper portions of the inner and back parts of the thigh in the superficial pubic glands.

(2) **Deep Vessels.**—The deep lymphatics of the lower extremity commence in the bones, periosteum, ligaments, muscles, and deep connective tissue. They follow the main arteries, and they terminate in the anterior tibial, popliteal, and deep femoral glands.

The vessels which terminate in the anterior tibial gland have already been mentioned (p. 916).

The majority of the deep vessels from the sole accompany the plantar arteries; they ascend in the leg along the posterior tibial vessels, and are joined by the deep lymphatics of the back of the leg which accompany the peroneal and posterior tibial arteries. At the lower border of the popliteus the deep vessels of the back of the leg meet the efferent vessels from the anterior tibial gland and ascend with them to the popliteal glands.

The deep lymphatics of the front of the thigh and the efferents of the popliteal glands end in the deep femoral glands; those of the upper part of the back of the thigh and buttock accompany the sciatic and gluteal vessels, and terminate in the lateral pelvic glands; the deep vessels which originate amidst the upper portions of the adductor muscles and their surroundings accompany the obturator vessels, and terminate in the obturator or in the lateral pelvic glands.

## THE LYMPHATIC GLANDS AND VESSELS OF THE ABDOMEN AND PELVIS.

The **superficial lymphatics** of the abdominal wall have already been sufficiently referred to as afferent vessels of the axillary glands and of the superficial glands of the groin (pp. 914 and 916).

**Deep Lymphatic Glands and Vessels.**—The lymphatic glands of the abdomen and pelvis are arranged in two main groups, (1) the visceral glands and (2) the parietal glands. The visceral glands lie in close relation with the walls of the viscera or in the folds of peritoneum, by which the viscera are either connected together or attached to the walls of the abdomen or pelvis; they receive the majority of the lymphatic vessels from the viscera with which they are associated. The parietal glands lie between the peritoneum and the walls of the abdomen and pelvis; they receive deep vessels from the abdominal and pelvic parietes, and from the deep parts of the thigh and buttock. They also receive efferent lymphatics from the glands of the lower extremities, as well as some of the efferent vessels from the visceral glands, and a few vessels which pass directly to them from the walls of the viscera.

(1) The **visceral glands** include the following :—

**Gastric Glands.**—The gastric glands are separable into the coronary, the sub-pyloric, and the retro-pyloric groups.

The coronary glands (lymphoglandulæ gastricæ superiores) are situated in relation with the upper part of the small curvature of the stomach between the layers of the gastro-hepatic omentum, and in the left pancreatico-gastric fold immediately behind and to the right of the cardiac orifice. They receive afferents from the small curvature, except at the pyloric end, and from a little more than the right halves of the anterior and posterior walls of the vertical portion of the stomach. They also receive afferents from the left and posterior part of the upper surface of the liver. Their efferents terminate in the cœliac group of pre-aortic glands.

The **sub-pyloric glands** lie in the gastro-colic omentum near the pyloric end of the stomach. Their afferents are derived from the lower part of the great curvature and from the immediately adjacent parts of the anterior and posterior surfaces of the stomach. Their efferents end in the retro-pyloric glands.

The **retro-pyloric glands** are very variable. They are situated directly behind the pyloric end of the stomach and the first part of the duodenum, in close association with the gastro-duodenal artery and in the right pancreatico-gastric fold. They receive as afferents the efferents of the sub-pyloric glands, and also afferent vessels from the right part of the small curvature and from the posterior surface of the pyloric portion of the stomach. Their efferents pass to the cœliac group of pre-aortic glands.

In certain cases of disease of the gastric glands, more particularly of the coronary group, metastatic deposits occur in the supra-clavicular glands, but no direct connexion between the two groups of glands has hitherto been discovered.

The lymphatics from the anterior and posterior walls of the left half of the vertical portion of the stomach pass to the splenic glands.

The **splenic glands** lie near the hilum of the spleen in relation with the tail of the pancreas, and in the lieno-renal ligament; they receive the lymph vessels from the left half of the vertical portion of the stomach, from the capsule and the substance of the spleen, and from the pancreas. Their efferent vessels, accompanied by some of the lymphatics from the left part of the great curvature of the stomach, pass inwards in the lieno-renal ligament and terminate in the cœliac glands.

The **hepatic glands** lie in the hilum of the liver and in the small omentum beneath it. Many lie along the left side of the vertical portion of the portal vein, and others along the common, the hepatic, and the cystic bile ducts. The highest of the latter, which lies close to the neck of the gall bladder, is known as the cystic gland; it constitutes, however, but one of the hepatic glands. The cystic gland receives afferents from the lateral and under surface of the right lobe to the right of the gall bladder, and the remaining hepatic glands receive afferents from the

anterior surface, from the Spigelian and the quadrate lobes, and from the lower and anterior portion of the deep substance of the liver. The efferents of the hepatic glands pass to the cœliac group of pre-aortic glands.

The **pancreatic glands** (lymphoglandulæ pancreaticæ), which are sometimes included in the splenic group, lie along the upper border of the pancreas behind the small sac of the peritoneum; they receive the lymphatics which issue from the pancreas, and efferents from the splenic and from the diaphragmatic glands. Their efferent vessels terminate in the cœliac glands.

The **superior mesenteric glands** (lymphoglandulæ mesentericæ) are numerous (100 to 200); they are scattered between the layers of the mesentery and in the transverse mesocolon, and they are most numerous in that portion of the mesentery which is connected with the jejunum. They vary in size, but the largest are rarely larger than an almond; the smaller glands lie near the intestine, and the larger near the attached border of the mesentery. They receive afferent vessels from the walls of the jejunum and ileum, and from the ascending colon, the cæcum, and the transverse colon. Their efferents terminate in the pre-aortic glands.

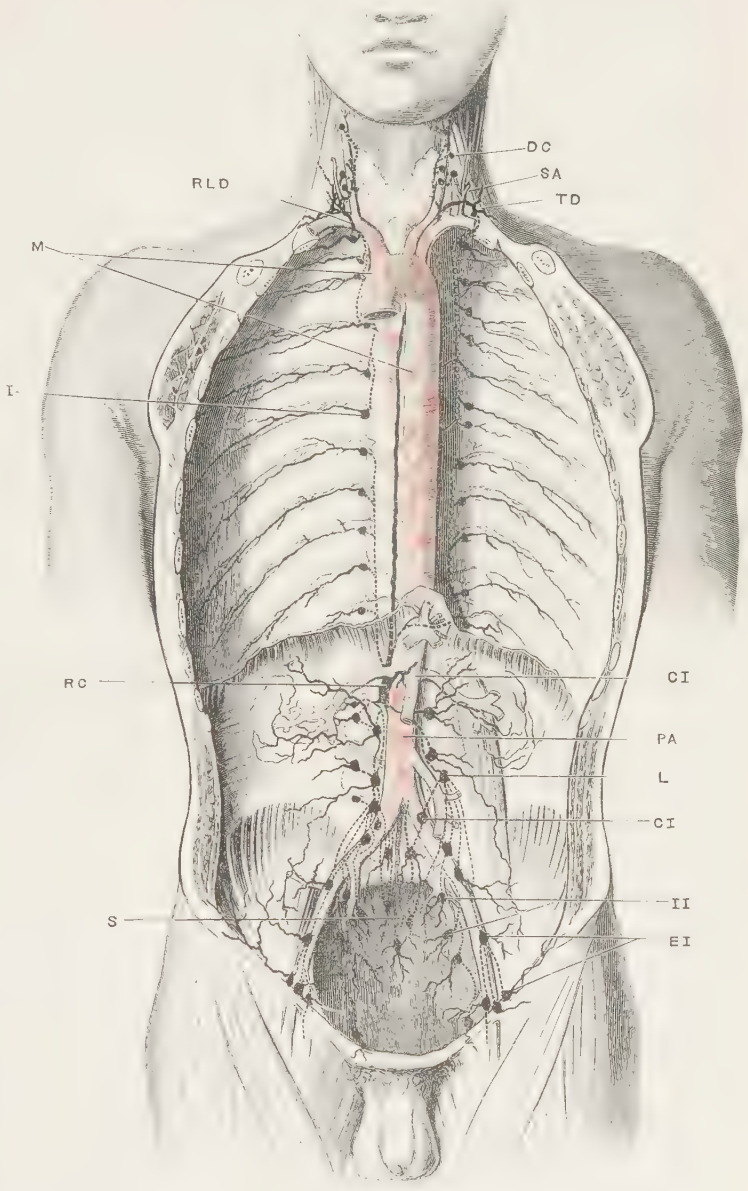

Fig. 664.—Deep Lymphatic Glands and Vessels of the Thorax and Abdomen (diagrammatic).

Lateral lymphatics are coloured black, and mesial red. Afferent vessels are represented by continuous lines, and efferent and interglandular vessels by dotted lines.

| | | | |
|---|---|---|---|
| C. | Common iliac glands. | M. | Mediastinal glands and vessels. |
| C.I. | Common intestinal trunk. | P.A. | Pre-aortic glands and vessels. |
| D.C. | Deep cervical glands. | R.C. | Receptaculum chylii. |
| E.I. | External iliac glands. | R.L.D. | Right lymphatic duct. |
| I. | Intercostal glands and vessels. | S. | Sacral glands. |
| I.I. | Internal iliac glands. | S.A. | Scalenus anticus muscle. |
| L. | Lateral aortic glands. | T.D. | Thoracic duct. |

The **ileo-cæcal glands**, four or five in number, are a subsidiary group of the mesenteric glands, and are situated in the lowest part of the mesentery near the angle between the ileum and the ascending colon. They receive afferent vessels from the lowest part of the ileum, from the cæcum, and from the vermiform appendix, and their efferent vessels pass, with those of the other mesenteric glands, into the pre-aortic glands. One of them, the *appendicular gland*, is occasionally separated from the rest, and is placed in the base of the mesentery of the vermiform appendix. This gland is of special interest, not only because it receives the lymphatics of the appendix, but also because in the female some of the lymphatics of the right ovary terminate in it.

The **colic glands** are also, for the main part, a subsidiary group of superior mesenteric glands; they lie in relation with the ascending portion of the colon and in the transverse mesocolic fold of the peritoneum. They receive the lymphatic vessels which issue from the portion of the gut in their immediate neighbourhood, and their efferent vessels terminate in the juxta- and pre-aortic glands and in glands round the root of the superior mesenteric artery.

The **inferior mesenteric glands** are situated in the course of the inferior mesenteric artery and its branches; they receive lymph from the ileo-pelvic and descending colon and transmit it to the juxta- and pre-aortic glands.

The **rectal glands** are a few small glands which lie in the meso-rectum and the areolar tissue between the rectum and the sacrum; they are small, and they receive lymphatic vessels from the upper part of the rectum. Their efferent vessels terminate in the juxta-aortic and sacral glands.

The **cœliac glands** (lymphoglandulæ cœliacæ) surround the cœliac axis, and lie in front of the abdominal aorta above the origin of the superior mesenteric artery, and are simply a group of the upper pre-aortic glands. They vary in number, and are of large size; they receive the efferent vessels from the gastric, splenic, pancreatic, and hepatic glands, and their efferent trunks unite with the efferents from the pre-aortic glands, and form with them a single trunk, the common intestinal lymphatic trunk, which terminates in the receptaculum chyli.

(2) The **parietal glands of the abdomen and pelvis** are as follows:—

The **external iliac glands** are arranged in three groups, an outer, a middle, and an inner, placed respectively to the outer side, in front of, and to the inner side of the external iliac artery. The *inner group* is situated in the cavity of the pelvis between the external iliac vein and the obturator nerve, but inasmuch as it is directly associated with the efferent vessels from the deep crural glands it must be ascribed to the external iliac group. Each group forms a chain consisting of three or more glands, and the lowest gland of each chain, which is situated immediately above Poupart's ligament, is known as a *retro-crural gland*. The internal chain of external iliac glands receives afferents from the deep and superficial inguinal glands, from the deeper portions of the abdominal wall from the region of the umbilicus downwards, from the adductor group of muscles along the obturator nerve and artery, from the neck of the bladder, from the prostate, from the membranous and bulbous parts of the urethra, and also afferents from the glans penis or the glans clitoris which have passed along the crural canal. Its efferents pass to either the common or internal iliac glands.

The *middle chain* is connected by anastomosing vessels both with the internal and external chains, and it also receives afferent vessels from the neck of the uterus and the upper part of the vagina in the female, from the prostate in the male, and from the bladder in both sexes. Its efferents pass to the common iliac glands.

The afferents of the external chain convey lymph from the superficial and deep inguinal glands from the deeper parts of the lateral and anterior portions of the abdominal wall, and a certain amount of lymph from the glans penis or clitoris which passes along vessels which traverse the inguinal canal.

If the student bears in mind what has already been said with regard to the inguinal and external iliac glands, it will be obvious to him that whilst the lymphatics of the scrotum and the skin of the penis terminate entirely, or almost entirely, in the superficial inguinal glands, those of the glans pass to the deep crural and the retro-crural glands, and it is worth noting that some of those which end in

the retro-crural glands pass to their terminations along the crural and others along the inguinal canal. It is also a matter of clinical importance to remember that the lymphatics from the urethra also end partly in the deep inguinal glands, partly in the external iliac glands, and partly in the internal iliac glands: those which terminate in the latter glands including some which carry lymph from the prostatic, membranous, and bulbar parts of the canal.

The efferents of the external iliac glands terminate in the common iliac glands.

The **obturator gland** is situated in the pelvis at the upper end of the obturator canal below and behind the obturator nerve. It is not constant, but when it is present it receives lymph from the deeper parts of the inner portion of the thigh, and its efferent vessels end in the inner chain of external iliac glands.

**The deep glands of the anterior wall of the abdomen.**—These glands are irregular both in number and occurrence, and they are small in size. When they are present they lie along the deep circumflex iliac and the deep epigastric arteries, and are known as the circumflex iliac and epigastric glands. In addition, however, there are, at least in the child, one or two small glands lying in relation with the posterior surface of the sheath of the rectus abdominis above the umbilicus, the supra-umbilical glands, and there is frequently a single infra-umbilical gland situated to one or the other side of the middle line below the umbilicus. The *circumflex iliac* and *epigastric glands* receive afferents from the adjacent parts of the abdominal walls, and their efferents end in the external iliac glands. The *supra-* and *infra-umbilical glands* are connected with the rich lymphatic plexuses of the umbilical region. It is probable that the supra-umbilical glands are also associated with the lymphatics of the anterior part of the upper surface of the liver; and the infra-umbilical gland with the lymphatics of the upper and anterior part of the bladder. At all events it seems certain that the lymphatics of the bladder are connected with those of the umbilical plexuses, and it is almost certain that in some cases at least they are either directly or indirectly associated with the infra-umbilical gland.

The **internal iliac glands** are not in all cases to be clearly defined from the inner set of external iliac glands, but if it be accepted that all glands on the side wall of the pelvis above and in front of the obturator nerve be looked upon as external iliac glands,—and this is a reasonable view inasmuch as they are in direct association with the deep crural glands,—then all other glands which lie in relation with the side wall of the pelvis may be considered as internal iliac glands. As a general rule it may be said that the larger glands of the internal iliac group are situated in the regions of the origins of the branches of the internal iliac artery, extending in an irregular row from the root of the obliterated hypogastric artery in front to the origin of the gluteal artery behind. They receive afferents from the upper part of the anal passage, and from the lower part of the rectum; from the middle part of the vagina and the lower part of the uterus; some lymphatics from the lower and posterior part of the bladder; from the prostate, the prostatic and membranous parts of the urethra; and from the deeper parts of the back of the thigh and the buttock which are supplied by the sciatic and gluteal arteries. The efferent vessels pass to the posterior group of the common iliac glands.

The **lateral sacral glands** may be considered as associates of the internal iliac group of glands. They lie along the front of the sacrum to the inner sides of the anterior sacral foramina. They receive afferents from the adjacent bones and ligaments and from the neck of the uterus, the lower part of the vagina, and in the male from the prostate; their efferents end either in the internal or in the common iliac glands.

The **common iliac glands** lie along the common iliac artery, some to its outer side, some posterior to it, and some to its inner side. The latter are naturally close to their fellows of the opposite side, and the two groups of opposite sides are sometimes spoken of collectively as the *glands of the promontory*. The number of glands in each set varies from two to four. The external and posterior glands receive as afferents the efferents from the external and internal iliac glands, and possibly a few lymphatics from the adjacent muscles and bones. The internal group receives afferents from the base of the bladder in both sexes, from the upper

and posterior part of the prostate in the male, and from the neck of the uterus and the lower part of the vagina in the female. The efferents of the common iliac glands terminate in the lateral aortic glands.

The **lumbar glands** are of small size, and they are very irregular in occurrence and in number. When they are present they lie close to the transverse processes of the lumbar vertebræ behind the psoas muscle, and correspond, therefore, in position with the posterior intercostal glands of the thorax. They receive afferent vessels which accompany the lumbar arteries from the deeper parts of the abdominal walls. Their efferent vessels end either in the lateral aortic glands, or they unite with the efferents of those glands to form the lateral aortic efferents, or common lumbar trunks.

The **aortic glands** are situated in front of, at the sides of, and behind the abdominal part of the aorta, and are therefore known as the pre-aortic, the lateral aortic, and the retro-aortic glands. The lateral aortic glands have usually been known as the mesial lumbar glands, but during the last few years it has been becoming more customary to speak of them as lateral aortic on account of their close association with that great blood-vessel.

The *pre-aortic glands* lie along the anterior aspect of the abdominal aorta, either forming a continuous chain or arranged in three groups which are situated respectively in the regions of the origins of the inferior and superior mesenteric arteries and round the root of the cœliac axis, and the latter group constitutes so distinct an entity that it is most commonly spoken of as the cœliac group. The afferent vessels of the pre-aortic glands are derived from the superior mesenteric, the inferior mesenteric, and the colic glands. The cœliac group also receives afferents from the hepatic, the sub-pyloric, the retro-pyloric, and the coronary, and the pancreatic and splenic glands. Numerous communications pass between the pre- and the lateral aortic glands, but speaking broadly it may be said that the pre-aortic glands receive the greater part of the lymph from the abdominal portion of the alimentary canal and from the associated glands. The afferent vessels from the lower glands of the group either terminate in the cœliac glands or join with their efferents to a large common intestinal lymphatic trunk which is one of the six tributaries of the receptaculum chyli.

The lateral aortic glands lie at the sides of the abdominal aorta, those of the right side being situated both in front of and behind the inferior vena cava. They receive afferents from the lumbar glands, or if the latter are absent, vessels which pass directly from the abdominal parietes along the lumbar arteries. They also receive the lymphatics of the kidneys, the testicles or ovaries, the suprarenal bodies, and from the upper part of the uterus. In addition they receive the efferents of the common iliac glands. They are connected by anastomoses with the pre- and retro-aortic glands, and their efferents unite on each side into a common lumbar or lateral aortic trunk which joins the receptaculum chyli.

The *retro-aortic glands* lie behind the aorta, in front of the third and fourth lumbar vertebræ. They receive a few lymphatics from the adjacent muscles, bones, and ligaments, and numerous efferents from the lateral and pre-aortic glands. Their efferents unite to form a vessel of fair size which ends in the receptaculum chyli.

It follows from what has been already said that the lymph from the pelvis and the lower extremities, and that from the pelvic viscera, passes to the receptaculum through the common iliac and the lateral aortic glands, but on account of the vessels which unite the lateral aortic with the pre- and retro-aortic glands it is obviously possible that infective material passing either from the lower extremities or from the pelvic viscera which is not intercepted by the lateral glands may pass through them and set up new foci of disease either in the pre- or retro-aortic glands, and although the lateral aortic glands are the natural terminations of the lymphatic vessels from the kidneys, testicles, ovaries, and suprarenal bodies, nevertheless infective material from any of those organs may pass through the lateral into the pre- or retro-aortic glands.

The deep lymphatic vessels of the abdomen and pelvis have been mentioned so frequently in association with the gland groups in which they terminate that no

further account of the vessels themselves is required; all necessary information regarding them will be found in the accounts of the glands of which they are the afferents. It is, however, important to bear in mind that there is a very rich lymphatic network in the region of the umbilicus. The superficial lymphatics of this region terminate in the inguinal or pubic glands, but the deeper communicate with the lumbar and external iliac glands, and are associated by anastomoses with the lymphatics of the upper part of the bladder and the upper and anterior part of the surface of the liver. They are also connected with the supra- and infra-umbilical glands, to which reference has already been made (p. 921).

## THE LYMPHATIC GLANDS AND LYMPHATIC VESSELS OF THE THORAX.

Most of the **superficial lymphatic vessels** of the thoracic wall are tributaries of the axillary glands, and they have already been described, but those of the mamma are so important from a clinical point of view that a more detailed description of their general arrangement is necessary.

The **lymphatics of the mamma** are naturally subdivided into cutaneous and glandular. The *cutaneous lymphatics* arise in the skin over the gland, and are separable into peripheral and central groups. The peripheral cutaneous vessels, like the remainder of the cutaneous vessels of the thoracic wall, pass to the axillary glands without joining the subareolar plexus which lies immediately subjacent to the nipple and the surrounding areola. The central cutaneous lymphatics converge to an areolar and a mammillary plexus from which efferent vessels pass to terminate in a deeper or subareolar plexus which receives also the majority of the glandular lymphatics.

The *glandular lymphatics* commence in the perilobular connective tissue. The majority follow the ducts of the gland and end in the subareolar plexus. The efferent vessels of the subareolar plexus terminate in the anterior axillary glands. In addition, however, to this main stream of lymph, there are three other channels by which lymph can pass from the perilobular lymphatics of the gland. One of these channels runs from the outer part of the gland directly to the anterior axillary glands without traversing the subareolar plexus. Another accompanies the pectoral branch of the acromio-thoracic artery, emerges from the posterior surface of the gland, pierces the pectoralis major, and ascends to the subclavian glands. The third set of accessory lymphatics passes from the inner part of the gland along the branches of the internal mammary artery which are distributed to the mamma. These vessels pierce the great pectoral and end in the internal mammary glands.

**Deep Lymphatics of the Thorax.**—The glands associated with the deep lymph vessels of the thorax may be divided into the parietal, and the visceral or mediastinal.

1. **Parietal glands** include the following:—

The **intercostal glands** (lymphoglandulæ intercostales), which lie in the posterior parts of the intercostal spaces near the heads of the ribs, or a little farther out, between the intercostal muscles. They receive the lymphatic vessels from the deep parts of the posterior portions of the thoracic walls, including the parietal pleura, and their efferent vessels are divided into ascending and descending trunks. The efferent vessels from the intercostal glands of the upper five or six spaces on the left side pour their lymph into the thoracic duct, terminating separately in the larger vessel or uniting first to form a common trunk. The efferents from the upper intercostal glands on the right side may end either in the thoracic duct or they may join the right broncho-mediastinal trunk. The efferent vessels from the intercostal glands of the lower four or five spaces unite to form a common trunk on each side, which descends through the aortic opening of the diaphragm and terminates in the receptaculum chyli. Some of them also communicate with the thoracic duct. In addition to the posterior intercostal glands, smaller lateral intercostal glands are sometimes interposed in the courses of the deep vessels of the thoracic wall. They have,

however, but little practical importance. When they are present they lie near the origins of the lateral branches of the intercostal arteries.

The **internal mammary** or **sternal glands** (lymphoglandulæ sternales), which lie along the side of the internal mammary artery, one or two, as a rule, being placed opposite the anterior end of each intercostal space. Their afferents are derived from the deeper parts of the anterior portion of the thoracic wall, from the deep part of the front of the abdominal wall by vessels which ascend along the superior epigastric artery, from the inner portion of the mammary gland, and from the anterior part of the diaphragm and the anterior diaphragmatic glands. Some of their efferents pass to the anterior mediastinal glands, but the majority ascend to the root of the neck, where they terminate either directly in the corresponding innominate vein, or, according to the side on which they lie, they end in the thoracic duct, or the right lymphatic duct if it is present.

The **diaphragmatic glands** are arranged in three groups—the anterior, middle, and posterior.

The anterior group lies behind the ensiform process and the anterior ends of the seventh costal cartilages. It receives lymph from the anterior part of the diaphragm, and from the anterior part of the upper surface of the liver. Its efferents pass to the internal mammary glands.

The middle group consists of two lateral portions which lie at the sides of the pericardium near the phrenic nerves. On the right side these glands are closely associated with the upper part of the inferior vena cava, and some of them lie on the anterior wall of that vessel internal to the fibrous sac of the pericardium. The afferents of the middle diaphragmatic glands are derived from the middle part of the diaphragm and from the upper surface of the liver. Their efferents join the posterior mediastinal glands.

The posterior group has very little importance, and practically constitutes a lower section of the posterior mediastinal glands. It lies between the pillars of the diaphragm and the posterior wall of the thorax, and receives lymph from the immediately adjacent parts. Its efferents end in the higher posterior mediastinal glands.

2. **Visceral Thoracic Glands.**—Of these there are:—

The **anterior mediastinal glands** (lymphoglandulæ mediastinales anteriores) are embedded in the loose tissue of the anterior mediastinal region. They receive afferents from the middle part of the upper portion of the liver which ascend through the falciform ligament, from the anterior part of the diaphragm, and from the lower sternal glands. Their efferents pass upwards to the superior mediastinum, where some of them enter the superior mediastinal glands, whilst others, continuing upwards, terminate on the right side in the right lymphatic duct, and on the left side in the thoracic duct.

The **superior mediastinal glands** (lymphoglandulæ mediastinales superiores) are grouped round the innominate veins, along the upper part of the aortic arch, and in front of the thoracic portion of the trachea. They receive afferents from the heart, the pericardium, the thymus, and the anterior mediastinal glands. Their efferents terminate at the root of the neck in the right lymphatic and thoracic ducts.

The **middle mediastinal glands** are situated round the primary bronchi and the lower end of the trachea, and they are separable into the following groups:—

The *bronchial glands*, which lie principally on the anterior aspects of the primary bronchi and along their upper borders. They receive lymph from the lungs which has previously passed through a series of inter-bronchial or pulmonary glands, which lie in the angles of division of the bronchi in the hilum and in the substance of the lungs. Their efferents unite with the efferents of the superior mediastinal and internal mammary glands to form a common broncho-mediastinal trunk on each side. This vessel when it is present ends on the left in the thoracic duct or the innominate vein, and on the right in the right lymphatic duct or in one of the large veins at the root of the neck.

The *inter-tracheo-bronchial glands*, which lie between the primary bronchi and beneath the end of the trachea. They receive afferents from the heart and from

the lower part of the trachea, and communicating vessels connect them with the bronchial glands. Their efferents either join the broncho-mediastinal trunk if it is present, or the thoracic or right lymphatic duct, or they end directly in one of the great veins at the root of the neck.

The **posterior mediastinal glands** (lymphoglandulæ mediastinales posteriores) lie along the aorta and the œsophagus in the posterior mediastinum. They receive afferents from the posterior part of the pericardium, the posterior part of the diaphragm, and from the œsophagus. Their efferent vessels pass mainly to the thoracic duct, but some of the upper ones on the right side end in the right lymphatic duct, and a few join the bronchial glands.

The **deep lymphatic vessels of the thorax** have been included in the description of the tributaries of the deep glands. As in the abdomen and pelvis, the main deep lymphatic vessels accompany the blood-vessels of the region.

## DEVELOPMENT OF THE BLOOD VASCULAR SYSTEM.

### The Pericardium, the Primitive Aortæ, and the Heart.

A general account of the development of the primitive vascular system and of the establishment of the fœtal circulation has been given in a previous chapter (see p. 60 *et seq.*), and it is there pointed out that the earliest blood-vessels of the developing ovum appear in the vascular area of the yolk sac, *i.e.* outside the body of the embryo altogether. Almost simultaneously, however, two longitudinal vessels appear in the embryo itself. They are formed in the splanchnic mesoderm of the pericardial area, and are easily distinguishable before that area is carried downwards to form the ventral wall of the foregut during the evolution of the headfold.

The two longitudinal vessels are the rudiments of the primitive heart and of the principal blood-vessels. The changes which take place in them, and which result in the formation of the fully developed heart and vessels, will be more easily understood after the development of the pericardial sac, together with the alterations it undergoes both as regards position and relations, have been carefully studied.

**Development of the Pericardium and the Primitive Aortæ.**—The pericardial area is recognisable as soon as the mesoderm has extended over the embryonic area of the developing ovum. It is somewhat semilunar in shape, it lies at the extreme anterior end of the embryonic region, and it limits the bucco-pharyngeal area or membrane in front and at the sides (Figs. 17 and 18). The mesoderm of the pericardial area is continuous laterally with the general mesoderm of the embryonic area, but in those mammals in which a pro-amnion is formed it is separated in front from the extra-embryonic mesoderm by the pro-amniotic area, whilst in other mammals also it remains quite separate from the extra-embryonic mesoderm in front though it is more closely related to it.

With the formation of the cœlom the mesoderm of the pericardial area is separated into an upper or somatic and a lower or splanchnic layer, and it is in the latter that the two small tubes which constitute the first blood-vessels of the body of the embryo appear. The two tubes, or primitive aortæ, which run longitudinally and parallel to one another, apparently end at first blindly both in front and behind, but as development proceeds they extend backwards, one on each side of the bucco-pharyngeal membrane, and beneath the mesodermal somites, to the caudal region, behind which they pass on to the walls of the yolk sac to join the blood-vessels of the vascular area; before ending they give off branches to the allantois. In the human embryo the yolk sac is relatively small and unimportant, and accordingly the branches which go to the allantois, or rather to the chorion along the body stalk, appear to form the more direct posterior continuations of the primitive vessels. The anterior end of each primitive trunk passes forwards to the anterior margin of the pericardial area, and is continued on to the yolk sac, where it also joins the vessels of the vascular area.

During the formation and evolution of the headfold the pericardial area increases in size, its cavity enlarges, and both it and the bucco-pharyngeal area are reversed in position (Figs. 27 and 49). Both these areas are carried forwards somewhat with the headfold, in which it is to be remembered the primitive foregut is included, but when the headfold is completely formed the pericardial area lies ventral to the foregut, and its primitive upper somatic surface is now its lower or anterior surface; the original lower or splanchnic surface is superior or dorsal, whilst what was, at first, the anterior border of the pericardial

area is converted into the posterior end of the reversed area, and it forms the anterior limit of the umbilical orifice. In brief, the relative positions of its several parts are reversed, and at this period the pericardial cavity which, like the area, is semilunar in shape, extends from side to side beneath the foregut, and its cornua are continuous at the sides of the foregut with the general body cavity of the embryo. Subsequently this continuity is obliterated, and the pericardial cavity is separated from the pleuro-peritoneal part of the general body cavity or cœlom.

The mesoderm at the posterior end of the reversed pericardial region, where the somatic and splanchnic layers are continuous, *i.e.* just in front of the umbilicus, increases in thickness and forms a semilunar mass, the **septum transversum**, in which the liver and the ventral part of the diaphragm are formed. The latter extends mesially from the anterior wall of the body to the foregut, immediately in front of the gastric dilatation, whilst laterally it forms two falciform projections which encroach from without upon the portions of the cœlom which lie at the sides of the foregut. Ultimately the lateral portions of the diaphragm pass inwards, and, fusing with the mesentery of the foregut, they separate the pleuro-peritoneal portion of the cœlom into three parts—two anterior, one on each side of the foregut, *the pleural sacs*, and a posterior, *the peritoneal cavity*.

When the pericardial region is completely reversed the two vessels developed in its splanchnic layer lie side by side in what is now its dorsal wall. Posteriorly they are continued through the septum transversum to the wall of the yolk sac. Anteriorly they are continued, as the first cephalic aortic arches, through the mandibular arches which have developed at the sides of the bucco-pharyngeal membrane, to the dorsal wall of the gut, where they pass backwards beneath the paraxial mesoderm to the posterior end of the body, whence they are continued, in the human subject, along the body stalk to the placental portion of the chorion, giving off branches to the walls of the alimentary canal and yolk sac.

FIG. 665.—DIAGRAM OF THE PRIMITIVE VASCULAR SYSTEM BEFORE THE FORMATION OF THE HEART.

These two primitive embryonic vessels are the **primitive aortæ**. After the formation of the cephalic and caudal folds, each primitive aorta may be looked upon as consisting of three parts united by two arches :—an anterior ventral part, the **anterior ventral aorta**, situated partly in the septum transversum and partly in the dorsal wall of the pericardium and the root of the neck ; a dorsal part, the **primitive dorsal aorta**, which extends beneath the paraxial mesoderm from the dorsal end of the mandibular arch to the tail fold ; a posterior ventral part, the **posterior ventral aorta**, which passes to the yolk sac ; the anterior part of the posterior ventral aorta soon atrophies, and the remainder of the vessel is then prolonged from the posterior part of the ventral wall of the body to the placenta by a new branch. The two arches which unite the three main portions of each primitive aorta together are an anterior, the **first cephalic aortic arch**, which lies in the mandibular arch and passes from the anterior ventral aorta to the anterior end of the primitive dorsal aorta, and a posterior, the **primary caudal aortic arch**, which passes in the tail fold and at the side of the hind gut, from the primitive dorsal aorta to the posterior portion of the primitive ventral aorta.

As development proceeds a series of transformations occurs in the various sections of the primitive aortæ. These transformations are, with few exceptions, alike on the two sides, but the transformations which occur in one section are entirely different from those met with in the other sections ; therefore each part must, to a certain extent, be considered separately.

Each anterior ventral aorta is divisible into three parts. The posterior part lies in the septum transversum. Posteriorly it forms the terminal portion of the **vitelline vein**, and carries the blood from the wall of the yolk sac. For a long time each vitelline vein remains separate from its fellow of the opposite side, but afterwards the two veins unite to form a common stem, which terminates at first in the posterior part of the heart, and subsequently in the liver. The anterior section of the posterior part of the anterior ventral aorta

rapidly enlarges and unites with its fellow of the opposite side to form the **sinus venosus** or posterior chamber of the primitive heart; after a time this grows forwards out of the septum into the pericardium, and is absorbed into the auricular portion of the heart.

The middle part of the anterior ventral aorta lies in the dorsal wall of the pericardium and projects forwards into its cavity. It lies close to its fellow of the opposite side, and as the two vessels rapidly enlarge their inner walls approach each other, and, fusing together, form a single median vessel which constitutes the primitive heart (the sinus venosus being excepted) including the **bulbus arteriosus**, the latter being afterwards developed into the roots of the pulmonary and aortic vessels.

The anterior portion of the anterior ventral aorta is embedded in the tissues at the upper or anterior part of the pericardium, that is, at the root of the neck. At first it is connected with the primitive dorsal aorta by a single cephalic aortic arch, but afterwards three, and eventually four, additional arches connect it with the anterior part of the primitive dorsal aorta. As the neck lengthens this part of the anterior ventral aorta is elongated. For the greater part of its extent it remains separate from its fellow of the opposite side, and it takes part in the formation

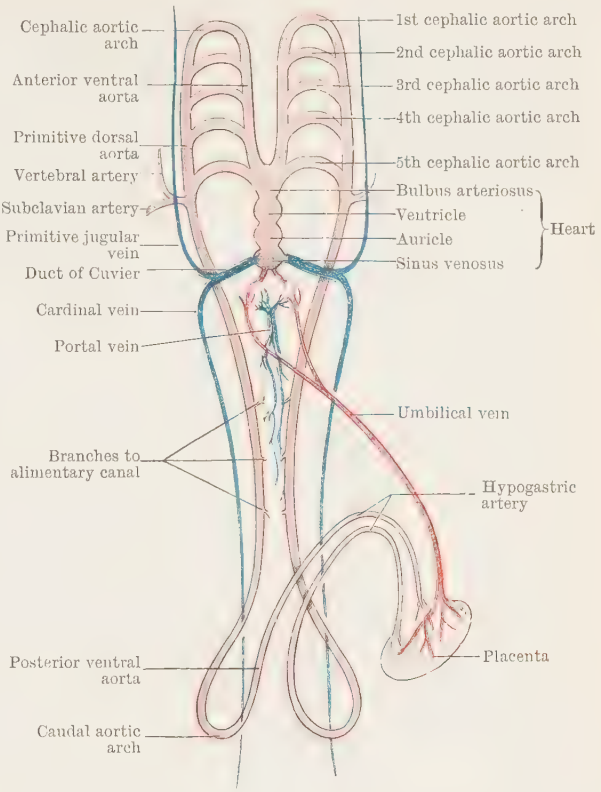

FIG. 666.—DIAGRAM OF THE PRIMITIVE BLOOD-VESSELS AFTER THE FORMATION OF THE HEART.

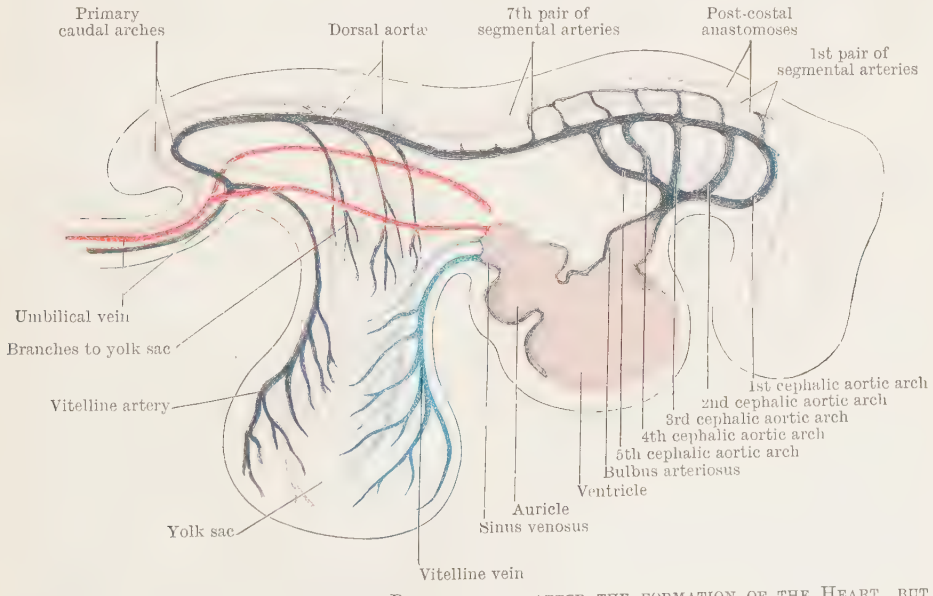

FIG. 667.—DIAGRAM OF THE PRIMITIVE BLOOD-VESSELS AFTER THE FORMATION OF THE HEART, BUT BEFORE ITS SUBDIVISION BY SEPTA INTO AURICLES AND VENTRICLES.

of the great vessels of the head and neck. Posteriorly, however, it unites with its fellow of the opposite side to form the apex of the bulbus arteriosus. After the completion of

the cephalic aortic arches the portions of the anterior ventral aorta which lie between their lower extremities are known as the **ventral roots** of the cephalic aortic arches.

The primitive dorsal aorta may be conveniently divided into two parts. The anterior part extends from the dorsal end of the first cephalic aortic arch to the root of the fore-limb. It remains separate from its fellow of the opposite side, and forms the **dorsal roots** of the cephalic aortic arches of its own side. It takes part in the formation of the great vessels of the head and neck and, on the left side, of part of the aorta of the adult.

The remaining portion extends from the root of the fore-limb to the pelvic region; it passes inwards, and unites with its fellow of the opposite side beneath the vertebral column to form the greater part of the permanent systemic aorta.

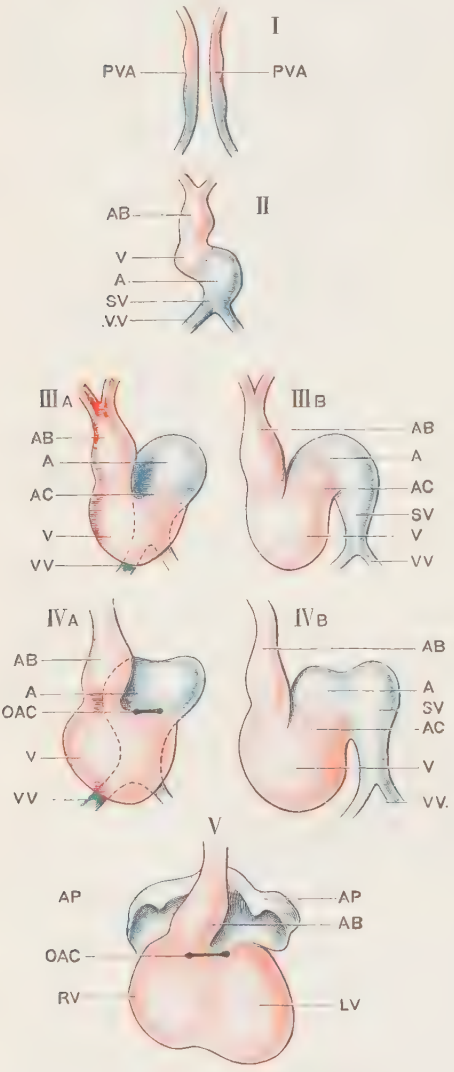

FIG. 668.—DEVELOPMENT OF THE HEART.

Diagram showing the changes of form and external appearances at different stages. Modified from His's models. III.B and IV.B are side views; the other figures represent the heart as seen from the front.

A, Auricle; A.B, Aortic bulb; A.C, Auricular canal; A.P, Auricular appendix; L.V, Left ventricle; O.A.C, Opening of auricular canal; P.V.A, Primitive ventral aorta; R.V, Right ventricle; S.V, Sinus venosus; V, Ventricle; V.V, Vitelline veins.

The primary caudal arch connects the primitive dorsal with the posterior ventral aorta. As it passes ventrally it lies on the inner side of the Wolffian duct. After a time it is replaced by a **secondary caudal arch** which lies at the outer side of the Wolffian duct, and this subsequently becomes the common and internal iliac arteries and the root of the hypogastric artery, the external iliac being merely an offset from it to the hind-limb.

The greater part of the primitive posterior ventral aorta disappears early, and its secondary continuation to the placenta becomes the remainder of the hypogastric artery, which passes from the internal iliac artery, by the side of the bladder and along the ventral wall of the abdomen, to the umbilicus, whence it is continued along the umbilical cord to the placenta.

Having considered thus briefly the main parts of the primitive aortic vessels, and having noted, shortly, the fate of each portion in the subsequent phases of development, we may now turn to a more detailed consideration of the metamorphoses which occur in those parts of primitive vessels, viz. the anterior ventral aortæ, the cephalic aortic arches, and the anterior parts of the primitive dorsal aortæ, where most striking and most complicated transformations result in the formation of the heart, the aorta in part, the pulmonary artery and its primary branches, the chief arterial trunks of the head and neck, and the first part of the main artery of the right upper extremity.

## DEVELOPMENT OF THE HEART, OF THE FIRST PART OF THE AORTA, AND OF THE PULMONARY ARTERY.

Of the three parts into which each anterior ventral aorta is divisible the middle is situated in the splanchnic mesoderm of the dorsal wall of the pericardium. As development proceeds the middle parts of both anterior ventral aortæ enlarge and project into the cavity of the pericardium, whilst at the same time they grow inwards, their inner walls come in contact, fuse together, and disappear, and so a simple single median tube is formed. This is the **primitive heart**, which is completed in front

and behind the pericardium by the fusion of the adjacent ends of the anterior and posterior parts of the anterior ventral aortæ.

The simple tubular heart, at first straight and of fairly uniform calibre, soon alters in form and in the relative position of its different parts. It becomes irregularly enlarged, and a series of four dilatations, with intervening constrictions, can be distinguished. The dilatations, from behind forwards, are as follows:—(1) the **sinus venosus** or **saccus reuniens**, (2) the **auricle** or **atrium**, (3) the **ventricle**, and (4) the **aortic bulb** or **bulbus arteriosus**. The short constriction between the auricle and ventricle is known as the **auricular canal**, and the less pronounced constriction which intervenes between the ventricle and the aortic bulb is termed the **fretum Halleri**. In addition to this alteration in form, the tubular heart elongates, much more so than the pericardium in which it lies, whilst at the same time the anterior extremity of the aortic bulb and the sinus venosus are withdrawn, from the root of the neck and the septum transversum respectively, into the pericardium. Of necessity, therefore, the single heart is bent upon itself, and it projects more and more into the pericardium, pushing forwards the visceral layer of the serous lining of this cavity, and carrying with it a mesentery of splanchnic mesoderm which is known as the mesocardium.

The bending of the heart results in the formation of a U-shaped loop, the posterior or venous limb of the loop lying to the left and below, with the body in the erect posture, the anterior or arterial limb being to the right and above, whilst the intervening stem of the loop runs from the left and below upwards, forwards, and to the right. The apex of the aortic bulb is bent a little to the left and reaches the middle line.

Subsequently the auricle ascends behind the ventricle, and the ventricular opening of the auricular canal, the short communicating passage between the auricle and ventricle, is seen as a transverse slit at the upper part of the left or posterior end of the ventricle. As the ventricular chamber enlarges its upper end passes towards the middle line, and the ventricle is no longer so obliquely directed from left to right but lies more in the mesial plane. As the result of these changes of position, and the coincident modifications in size of the different parts, the aortic bulb is eventually placed immediately in front of the auricle, and the opening of the auricular canal is nearer the middle of the upper part of the posterior wall of the ventricular chamber. During its further growth the ventricle enlarges principally at its anterior or ventral part; the dorsal part is not materially altered in position, and consequently the openings of the auricular canal and the aortic bulb remain relatively close together. The auricle increases in size by lateral expansion and by forward extension of its lateral angles; the forward extensions embrace the sides of the aortic bulb, and constitute the rudimentary auricular appendages. In the meantime the mesocardium disappears and the heart lies free in the pericardium except at its extremities.

## Division of the Heart into its different Chambers, and Division of the Aortic Bulb.

Whilst the changes in form, position, and size of the different sections of the primitive heart, which have just been described, are taking place, the division of the heart cavity into its four permanent chambers, and of the aortic bulb into its aortic and pulmonary portions commences. These divisions are brought about by the growth of **septa** in the ventricle, auricle, and aortic bulb, and by the thickening and fusion of the middle portions of the upper and lower walls of the auricular canal.

The thickenings of the walls of the auricular canal are called **endocardial cushions**; they meet and fuse together mesially to form the **septum intermedium** by which the central portion of the canal is obliterated, whilst the lateral portions are left patent as small triangular channels which still connect the auricular and ventricular chambers.

The separation of the ventricular part of the heart into right and left chambers is indicated, externally, at a very early period, by a groove, well marked in front and below, but less distinct behind where it runs upwards to the auricular canal; whilst internally, in a corresponding position, a **ventricular septum** (s. inferius) grows upwards from the inferior part of the ventricular wall. The posterior part of the upper border of this septum unites with the lower end of the fused endocardial cushions of the auricular canal; the anterior part of its upper border terminates a short distance below the orifice of the aortic bulb, where it unites with the septum of the aortic bulb which, at a later period, descends to meet it.

The division of the aortic bulb commences at its distal end between the orifices of the fourth and fifth cephalic aortic arches. It is due to the ingrowth of two endocardial

thickenings which meet and fuse together from their distal to their proximal ends, forming a septum which divides the interior of the aortic bulb into two parts, and then projects downwards into the ventricular chamber till it meets and fuses with the anterior part of the upper border of the ventricular septum. The upper or distal part of the **septum of the aortic bulb** commences from the dorsal wall of the cavity between the fourth and fifth cephalic arches, and it is placed transversely, but its lower end lies more antero-posteriorly, therefore it twists spirally as it descends, and as a result the right part of the ventricle is thrown into continuity with the fifth cephalic aortic arches, whilst the left part of the ventricle retains continuity with the remaining cephalic aortic arches.

After the septum of the aortic bulb is completed, grooves appear along its margins on the surface of the bulb; the grooves deepen until they divide the septum and consequently the bulb into two parts; the part in connexion with the right ventricle and the fifth aortic arch becomes the **pulmonary artery**, and the part in connexion with the left ventricle and the remaining arches becomes the **ascending aorta.**

The separation of the primitive auricle into right and left portions is indicated externally by the appearance of a groove on the upper and posterior wall; opposite this

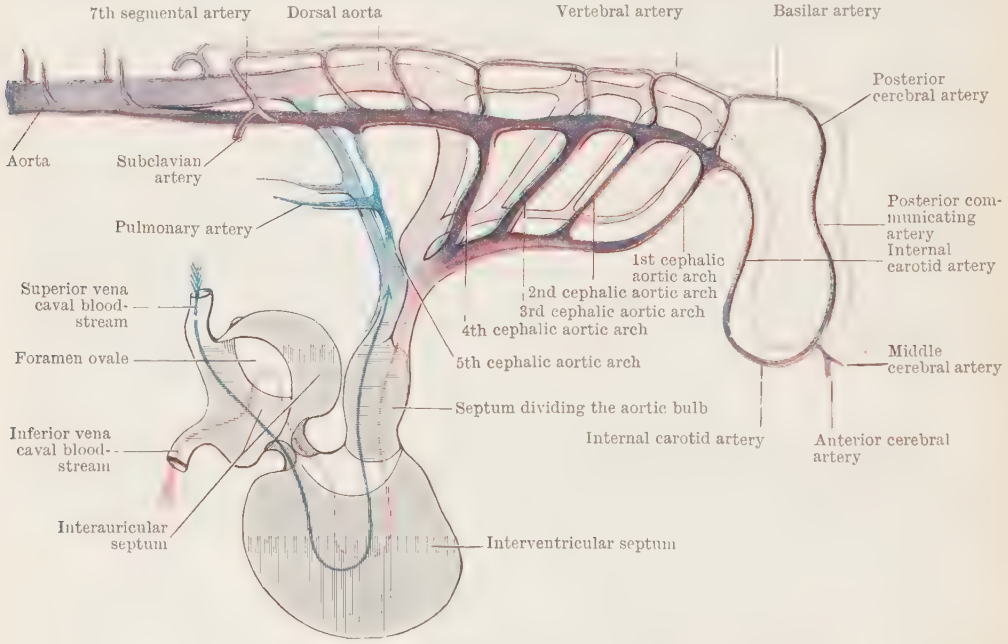

FIG. 669.—DEVELOPMENT OF THE HEART AND THE MAIN ARTERIES.
Diagram of the heart, showing the formation of its septa, and of the cephalic portion of the arterial system.

groove an **auricular septum** grows downwards in the interior of the auricle. Its lower border gradually approaches the endocardial cushion in the auricular canal, and for a time a small opening is left between the upper ends of the fused endocardial cushions and the lower edge of the septum. This is the **ostium primum**; it is closed by the fusion of the septum with the endocardial cushions, but before its closure is completed an aperture appears in the upper part of the septum; this latter aperture, the **ostium secundum**, becomes the **foramen ovale**. A second auricular septum, the *septum secundum*, grows downwards to the right of the first septum; its lower margin passes the foramen in the septum primum which is called the foramen ovale, but stops some distance from the posterior wall of the auricle, and this margin constitutes the **limbus Vieussenii**. The limbus Vieussenii forms the upper and anterior boundary of a depression in the auricular septum which is called the fossa ovalis. The floor of the fossa is formed by the *primary septum*, and the foramen ovale which lies at the upper part of the fossa is closed after birth by the fusion of the primary and secondary septa.

The **sinus venosus**, which in the early stages receives the vitelline veins from the yolk sac, the allantoic or umbilical veins from the placenta, and the ducts of Cuvier which return the blood from the Wolffian bodies and the body of the embryo, is also divided into two parts by the formation of a ledge-like projection from its posterior wall and the lower end of the septum secundum of the auricle crosses the ledge between the

two parts and becomes continuous with the Eustachian valve along the anterior margin of the inferior vena cava. The sinus venosus lies at first below and behind the auricle, with which it communicates freely. It is gradually divided into a large right and a small left cornu, and its orifice of communication with the auricle is constricted, and ultimately it is transformed into a cleft which opens from the right end of the sinus into the back of

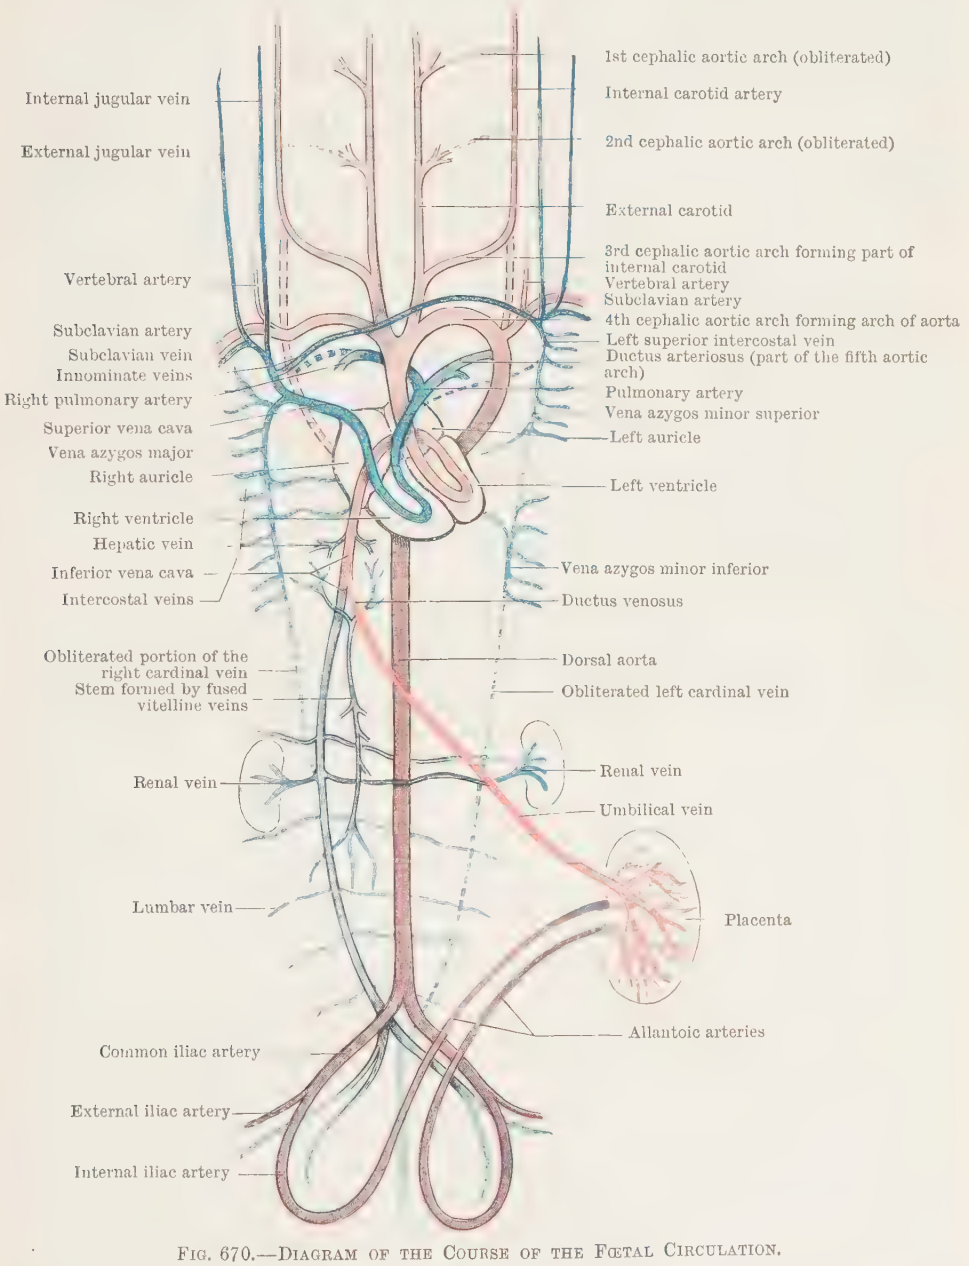

FIG. 670.—DIAGRAM OF THE COURSE OF THE FŒTAL CIRCULATION.

the right part of the auricular chamber; the cleft is guarded by two lateral valve-like folds of endocardium, the **right** and **left venous valves**, which become continuous above with a transitory downward projection from the roof of the auricle, known as the **septum spurium**. The orifice of communication is divided into two parts as the right part of the cavity is absorbed into the auricle. The left part of the orifice becomes the opening of the coronary sinus and the right is opened out as the right part of the sinus is absorbed into the auricular cavity.

In the early stages the veins of the two sides opened into the corresponding sections

of the sinus venosus, but numerous transformations, which are described in the account of the development of the veins, occur, and finally all the veins, except the left duct of Cuvier, open into the right end of the sinus, and ultimately into the auricle as the right part of the sinus is absorbed into it; the left part of the sinus becomes a mere appendage of the right, and is transformed into the **coronary sinus** which receives the blood from the walls of the adult heart.

Thus, when the development of the heart is completed, all the large veins which reach the heart, with the exception of the pulmonary veins, open into the right auricle, and into that part of the chamber formed by the absorption of the right end of the sinus venosus. Indications of the primitive separation of the auricle from the sinus venosus are still recognisable in the adult, as the **sulcus terminalis** on the exterior, the corresponding **crista terminalis** in the interior, and the **Eustachian** and **Thebesian valves**; the Eustachian valve is a remnant of part of the valvular fold which was situated at the right margin of the slit-like aperture of communication between the sinus venosus and the auricle, whilst the valve of Thebesius represents a fold of endocardium.

The **valves** which guard the auriculo-ventricular orifices are downgrowths from the lower end of the auricular canal. The valves of the pulmonary and aortic apertures are preceded by four endocardial thickenings at the lower end of the aortic bulb—anterior, posterior, and two lateral. As the septum of the bulb descends it fuses with the middle parts of the lateral thickenings; thus, when the septum of the bulb has descended below the lower orifice of the bulb, dividing it into aortic and pulmonary apertures, three endocardial thickenings are found in each aperture, one anterior and two posterior in the pulmonary aperture, and the reverse in the aortic orifice. From these thickenings the semilunar valves of the aortic and pulmonary apertures are developed, and they retain their original positions until after the sixth month of fœtal life; ultimately, however, they are twisted round, so that in the adult the pulmonary valves are placed two in front and one behind, and the aortic one in front and two behind.

### The Aortic Arches—Formation of the Chief Arteries.

The aortic arches at the head end of the embryo connect the aortic bulb and the ventral aortæ in front of the bulb with the corresponding parts of the primitive dorsal aortæ. The arches, ten in number, are arranged in pairs. There are, therefore, five arches on each side, and they are distinguished from before backwards by their numerical designation.[1]

The first is formed during the development of the head fold by the bending of the primitive aorta; it lies at the side of the bucco-pharyngeal area, and subsequently in the substance of the mandibular arch. The remaining aortic arches are formed quite differently, and grow dorsally through the substance of the remaining visceral arches, as these are formed in regular succession in the side wall of the pharyngeal portion of the foregut. The second springs directly from the anterior ventral aorta, and passes through the hyoid arch to the dorsal aorta, but the third, fourth, and fifth spring by a common trunk from the apex of the aortic bulb. Subsequently, however, and as the neck grows forwards, the anterior ventral aorta is elongated, and the third and fourth arches arise separately from it. At this later period, therefore, four vessels, two on each side, spring from the aortic bulb, viz. the two fifth arches and the two anterior ventral aortæ from which the anterior four pairs of arches arise. When the septum of the aortic bulb is developed, the bulb is divided into two parts, one (the pulmonary artery) connecting the fifth arches with the right ventricle, and the other (the ascending aorta) connecting the ventral aortic stems, and through them the first, second, third, and fourth pairs of arches, with the left ventricle. Each cephalic aortic arch is connected with the arch immediately behind it by a dorsal root, and in the cases of the first three arches by a ventral root also; but the ventral root of the fourth arch connects it with the aortic bulb. The dorsal and ventral roots of the arches are simply portions of the primitive ventral and dorsal aortæ, which are so named merely for descriptive purposes. From the dorsal roots a series of **segmental branches** are given off, which pass dorsally, between the rudiments of the transverse processes of the cervical vertebræ, to supply the spinal cord and its membranes and the muscles and fasciæ of the back.

The five pairs of arches do not all persist in their entirety, but remains of each are

[1] In some of the lower forms six aortic arches have been recognised, and it is possible that what we know as the fifth in the human subject corresponds with the sixth, the fifth not being formed, or possessing only a very transitory and rudimentary existence.

found even in the adult. The first and second pairs disappear almost entirely; from the ventral ends of the first arches, however, the superficial temporal, the internal maxillary, the lingual and the facial arteries are formed; whilst from the ventral ends of the second arches the ascending pharyngeal, posterior auricular, and occipital arteries are derived.

On each side the ventral roots of the first and second arches persist as the stem of the corresponding external carotid artery. The internal carotid is formed by the third arch together with the dorsal roots of the second and first arches, and is continued forwards to the cerebrum by an outgrowth from the anterior end of the dorsal root of the first arch. The ventral root of the third arch becomes the common carotid artery. The dorsal root of the third arch disappears. On the right side the ventral root of the fourth arch forms the innominate artery, and the arch itself is converted into part of the subclavian artery, whilst the dorsal root disappears. On the left side the ventral root of the fourth arch forms the small portion of aorta which lies between the innominate and left common carotid arteries. The left fourth arch itself and its dorsal root form the arch of the aorta from the origin of the left carotid artery to the attachment of the ductus arteriosus.

The ventral portion of the fifth arch on each side remains as the first part of the corresponding pulmonary artery. The dorsal part disappears early on the right side, but on the left side it persists and remains patent up to birth as the ductus arteriosus. After birth it is obliterated and transformed into a fibrous cord.

The fate of the **primary caudal arches**, their secondary successors, and that of the posterior ventral portions of the primitive aortæ, has already been fully considered (p. 928).

### The Primitive Dorsal Aortæ—Formation of the Descending Aorta.

Coincidently with the development of the cephalic aortic arches the anterior portions of the dorsal sections of the primitive aortæ are converted into the dorsal roots of the aortic arches. As already pointed out, certain parts of these disappear entirely, whilst other parts are utilised in the formation of the permanent vessels.

Behind the fifth arches the two primitive dorsal aortæ remain separate as far back as the root of the fore-limb. To this extent the right vessel disappears, whilst the left remains and forms a portion of the descending aorta. From the roots of the fore-limbs backwards to the caudal arches the dorsal aortæ fuse together, beneath the vertebral column, to form the remainder of the descending aorta.

### The Branches of the Primitive Dorsal Aortæ.

Each primitive dorsal aorta gives off from its dorsal surface a series of **somatic segmental arteries**, from its sides an irregular series of **intermediate** (visceral) **branches**, and from its ventral surface a group of **segmental splanchnic branches** to the walls of the alimentary canal, see (Figs. 677 and 678).

The somatic segmental arteries divide into ventral and dorsal branches which accompany the posterior and anterior primary branches of the spinal nerves respectively, and the ventral branches give off lateral offsets. The various branches of the somatic segmental vessels anastomose freely together.

The splanchnic segmental arteries also anastomose freely together. Ultimately, from the somatic vessels and their branches and anastomoses are developed the vertebral, the basilar, and the spinal arteries: part of the right subclavian artery, the whole of the left subclavian artery, and their continuations in the fore-limbs: the intercostal and lumbar arteries, and the internal mammary and deep epigastric arteries; whilst from the splanchnic segmental arteries the majority of the blood-vessels which supply the alimentary canal are developed. The intermediate visceral arteries supply the organs derived from the intermediate cell mass, viz. the suprarenal capsules, the kidney, and the ovaries or testicles; but for a full account of the transformations which the various vessels and anastomoses undergo, reference must be made to the account of the morphology of the arteries.

### The Arteries of the Limbs.

Little is known of the precise details of the development of the arteries of the limbs, but there is not much doubt that they are formed almost entirely by prolongations of or from somatic segmental arteries or their branches.

The chief arterial stem of each upper extremity is represented by the subclavian, the axillary, the brachial, and the anterior interosseous arteries; these vessels form a continuous trunk which is developed, on the left side entirely and on the right side mainly,

from the corresponding seventh somatic segmental branch of the primitive aorta, from its ventral branch, and from the lateral offset of the latter. It is indeed the lateral offset of the ventral branch, growing outwards into the developing limb, which forms the prolongation of the stem.

The root of the right stem vessel, constituted by the right subclavian artery from its origin almost as far as the point at which the right vertebral artery arises, is formed by the fourth right aortic arch; on the left side the fourth arch takes no part in the formation of the subclavian artery.

In the lower limbs the primary main arterial stem, on each side, is represented by the sciatic, the popliteal, and the peroneal arteries. The sciatic artery arises from the caudal arch, and it, together with its prolongation through the popliteal space and leg, is probably formed from a somatic segmental vessel, but to which parts of this it corresponds is not clear. The external iliac artery, prolonged into the limb as the femoral artery, is developed at a later period than the sciatic artery. It arises from the caudal aortic arch above the origin of the sciatic artery, and, like the latter trunk, is probably a modified somatic segmental vessel. The femoral artery soon after its formation unites with the primary main stem, at the upper part of the popliteal space; the sciatic artery then atrophies and loses its connexion with the popliteal artery, and ultimately a permanent chief stem vessel is formed, which includes the external iliac, the femoral, the popliteal, and the peroneal arteries, and obviously it represents the two somatic segmental vessels by which it is formed. Both in the upper and in the lower limb, branches which attain a large size are given off from the main stem artery a short distance beyond the joint between the upper and middle sections of the limb, *i.e.* below the elbow in the upper limb and below the knee in the lower limb, and on account of the relatively great enlargement of these branches the continuity of the original stem is obscured. Thus it is that, in the adult, the brachial artery, the direct continuation of the stem which is divided into subclavian, axillary, and brachial sections, appears to terminate by dividing into the radial and ulnar arteries, whilst originally it was continued through what, in the adult, is the upper part of the ulnar artery to the anterior interosseous artery; the posterior interosseous, the radial, and the ulnar arteries being merely branches from the main stem.

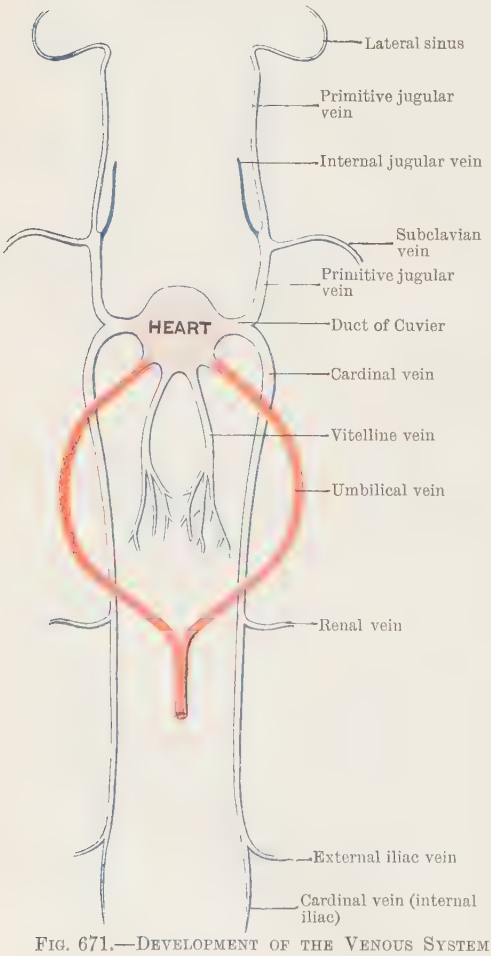

FIG. 671.—DEVELOPMENT OF THE VENOUS SYSTEM (Diagrammatic).

Stage I.—The ducts of Cuvier, the vitelline veins, and the umbilical veins open directly into the heart.

Similarly, in the lower extremity the popliteal artery, which is the continuation of the original stem artery, appears to terminate in the adult by dividing into the anterior and posterior tibial arteries, both of which in reality are branches from the sides of the main stem which was continued to the foot as the peroneal artery.

## DEVELOPMENT OF THE VEINS.

Simultaneously with the formation of the arteries by which the blood is distributed to the embryo and to the rest of the ovum, and in a similar manner, a series of vessels is developed by means of which the blood is returned to the heart. These vessels are the veins, of which there are two main groups. One group returns blood from the abdominal viscera and the annexa (the yolk-sac and allantois); the other group includes the vessels which return blood from the Wolffian bodies, the body wall, the head and neck, and the limbs of the embryo. The first group consists of the **vitelline**, **allantoic**, and **portal**

**veins**; the second group includes the **primitive jugular** and the **cardinal veins** and the **ducts of Cuvier.**

The trunks of the vitelline veins are formed by the posterior parts of the anterior primitive ventral aortæ, and necessarily they open into the posterior part of the heart (sinus venosus). They collect blood from the yolk-sac, and ascend along the vitello-intestinal duct to be continued upwards along the sides of the duodenum. Three transverse anastomoses soon form between them, of which the lower and the upper are in front of and the middle is behind the duodenum; thus two vascular circles are formed round that portion of the gut. Whilst the loops are being formed the liver grows rapidly, and it interrupts the direct connexion of the vitelline veins with the heart. When the upper vascular loop is established the two vitelline veins, which appear to be prolonged from its sides, enter the liver and break up into capillaries, from which two new vessels arise which carry the blood to the sinus venosus. The veins which carry the blood to the liver are now known as the **venæ advehentes**; they become the right and left divisions of the **portal vein.** The vessels which carry the blood to the sinus venosus are the **venæ revehentes**, and they become the **hepatic veins.**

From the inferior part of the lower venous circle the vitelline veins fuse into a common stem which receives the veins from the abdominal portion of the gut, and this, together with the left half of the lower loop, becomes the superior mesenteric vein, which passes in front of the third part of the duodenum and there receives the splenic vein. The middle anastomosis and the right half of the upper loop become the portal vein. The upper anastomosis and the left vena advehens become the left branch of the portal vein. The right vena advehens forming the right branch, and the left half of the upper and the right half of the lower loop disappear.

The allantoic or umbilical veins commence in the placenta and fuse into a single stem which traverses the umbilical cord to reach the embryo, and divides at the umbilicus into right and left divisions. The two veins then pass through the septum transversum, one to the right and the other to the left, and open into the sinus venosus. After a very short period the communications with the sinus are obliterated, and both veins end in the venous capillaries of the liver, the blood they convey now passing to the sinus venosus by the hepatic veins. This condition also is only transitory, for the right vein soon undergoes complete atrophy and disappears, whilst the left opens into the upper loop of the vitelline veins. In the meantime, however, another channel, the **ductus venosus**, has been developed, which passes directly from the upper loop of the vitelline veins, or rather from the left vena advehens to the right hepatic vein, and by this channel the greater part of the placental blood passes to the heart without traversing the liver substance. Some of the placental blood, however, goes to the liver by the left vena advehens. Finally the left vena revehens loses its connexion with the sinus venosus and opens into the right vena revehens. The left umbilical vein and the ductus venosus remain pervious until birth, when the placental circulation ceases. The two vessels then rapidly atrophy, and are subsequently represented by fibrous cords, of which that formed from the left umbilical vein is known as the **round ligament of the liver.**

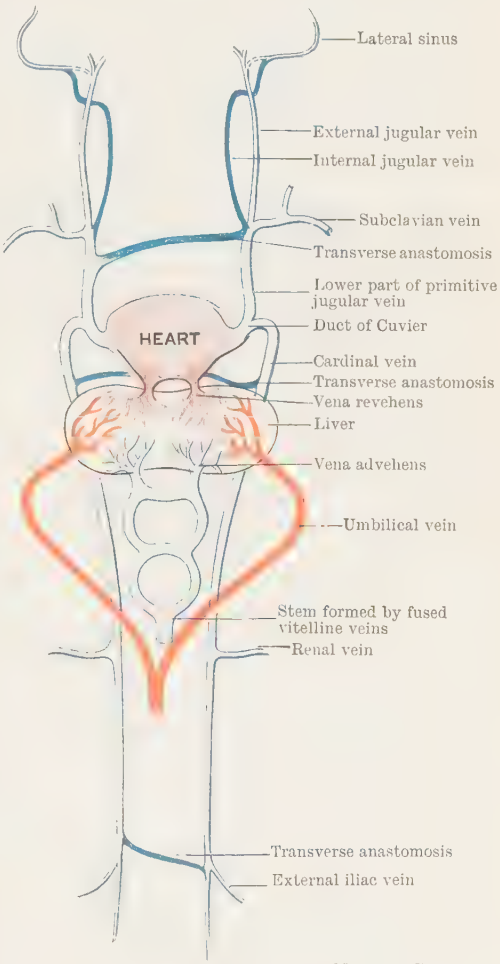

FIG. 672.—DEVELOPMENT OF THE VENOUS SYSTEM (Diagrammatic).

Stage II.—The vitelline and umbilical veins terminate in the liver, and transverse anastomoses have formed between the vitelline, cardinal, and primitive jugular veins of opposite sides.

The primitive jugular and cardinal veins, and the ducts of Cuvier, which constitute the main veins of the Wolffian body, and of the body wall, head, neck, and limbs of the embryo, are represented in the adult by the external jugular veins, the whole of the right and part of the left innominate veins, the superior vena cava, the azygos veins, the left superior intercostal vein, part of the inferior vena cava, the right common iliac vein, a small part of the left common iliac vein, and both right and left internal iliac veins.

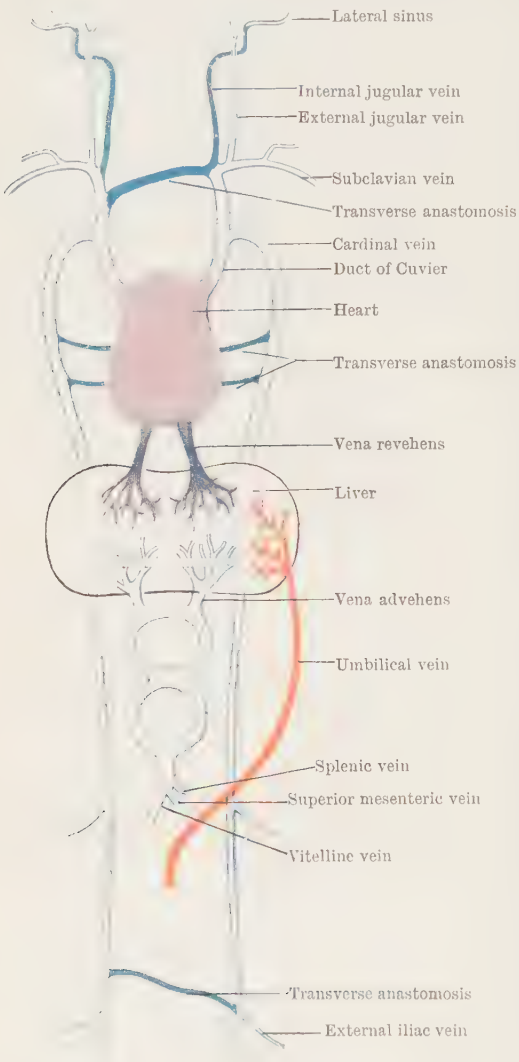

FIG. 673.—DEVELOPMENT OF THE VENOUS SYSTEM (Diagrammatic).

Stage III.—The right umbilical vein has disappeared, and the superior mesenteric and splenic veins have joined the fused vitelline veins.

The primitive jugular vein of each side returns blood from the head and neck, and corresponding upper extremity, and it terminates below by fusing with the cardinal vein to form a common trunk, the duct of Cuvier, which opens into the sinus venosus. Each cardinal vein returns blood from the body wall, the Wolffian body, and the lower extremity of its own side.

Numerous transverse anastomoses are developed between the primitive jugular and cardinal veins of opposite sides, and of these four are specially important, one between the primitive jugular veins and three between the cardinal veins; the former becomes the left innominate vein; of the latter, the upper two become the transverse parts of the upper and lower smaller azygos veins, and the third forms the left common iliac vein. As these transverse channels develop further changes occur in the primitive jugular and cardinal trunks. At first the upper extremity of the primitive jugular vein is in direct continuity with the venous sinuses of the cranium through an aperture, the post-condyloid foramen, in front of the external ear; but this continuity is destroyed, and the aperture in the skull closes as soon as a new vessel, which becomes the internal jugular vein, has grown upwards from a point on the inner side of the primitive jugular trunk and has established a communication with the lateral sinus through the jugular foramen. This vessel rises behind the sterno-clavicular joint, just opposite to, or slightly below, the entrance of the subclavian vein into the outer side of the primitive jugular vein.

With the exception of its upper extremity, the whole of the primitive jugular vein remains on both sides in the adult. On the right side, above the transverse anastomosis between the two primitive jugular veins which becomes the left innominate vein, it forms the external jugular vein, and that portion of the right subclavian vein which intervenes between the external jugular and internal jugular veins, and also the right innominate vein; below the anastomosis it forms the upper part of the superior vena cava, the lower part of the latter vessel from the entrance of the vena azygos major downwards representing the right duct of Cuvier, which, though it is placed transversely in the early stages, becomes more vertical as the heart descends in the thoracic cavity. On the left side above the transverse anastomosis it forms the external jugular vein, the innermost part of the subclavian vein, and a small part of the left innominate vein; the main part of the latter vessel being formed, as before stated, from the transverse anastomosis. The

portion of the left primitive jugular vein which lies below the anastomosis is represented in the adult by the upper part of the left superior intercostal vein.[1]

The portions of the cardinal veins lying below the transverse anastomosis which becomes the left common iliac vein remain; that on the right forms the right internal and common iliac veins, but the left forms only the left internal iliac vein and a small part of the left common iliac vein, for the transverse anastomosis commences on the left side almost opposite the point of entrance of the external iliac vein, whilst it terminates on the right side at a higher level.

From the left common iliac vein to the renal vein the cardinal vein of the left side disappears; that on the right side becomes the lower part of the inferior vena cava, to which the blood passes from the left side of the abdominal wall by means of small transverse anastomosing channels which existed between the cardinal veins, and which persist as the terminal portions of the left lumbar veins.

Above the renal veins part of the right cardinal vein persists as the vena azygos major, and the left forms the upper and lower minor azygos veins and the lower part of the left superior intercostal vein. The azygos minor veins open into the azygos major by the two transverse anastomosing channels which form between the upper parts of the cardinal veins.

The upper part of the **inferior vena cava** is developed as an outgrowth from the common trunk formed by the fusion of the ductus venosus with the right hepatic vein. It grows downwards, behind the liver and along the right side of the vertebral column, to the interval between the kidneys, where it divides into two branches, of which the right anastomoses with the right cardinal vein

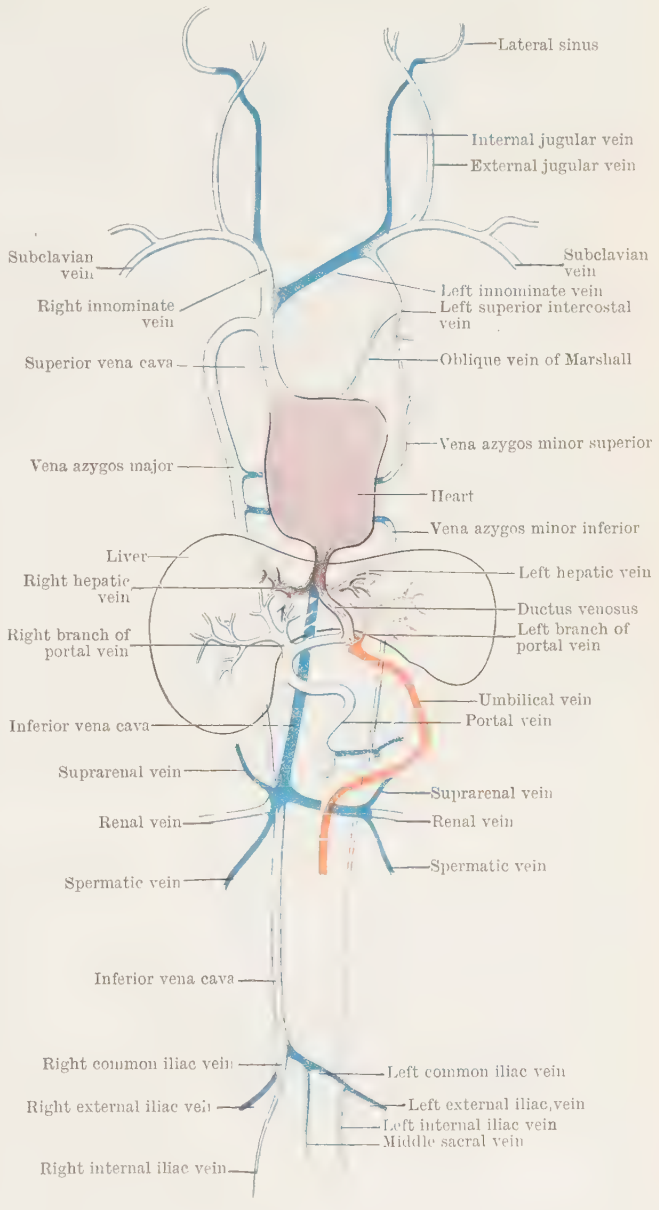

FIG. 674.—DEVELOPMENT OF THE VENOUS SYSTEM (Diagrammatic).
Stage IV.—The left umbilical has joined the upper part of the left vitelline vein; the ductus venosus and the upper part of the inferior vena cava have appeared, and portions of the primitive jugular and cardinal veins have atrophied.

[1] The account which has been given of the primitive jugular veins is that which has been generally accepted for many years, but in 1895 Salza's observations on the guinea-pig led him to dispute the correctness of the description, and Mall's recent investigations on human embryos confirm Salza's work. From the results of the investigations of these observers it appears that the external jugular vein is a secondary vein, and the internal jugular is part of the primitive jugular which originally extended forwards to the anterior end of the superior longitudinal sinus. Its connection with the sinus is soon lost, and the only intracranial remainder of the primitive vein is the cavernous sinus.

at the level of the renal vein; it receives the suprarenal vein, and it terminates in a tapering extremity which is said to become the spermatic vein of the right side. The left branch passes across the front of the aorta below the superior mesenteric artery, and unites with the left cardinal vein at the point of the entrance of the renal vein. It gives off an upper branch which becomes the left suprarenal vein, and a lower which becomes the left spermatic vein. As before pointed out, the left cardinal vein disappears between the renal vein and the left common iliac vein, whilst the right remains as the lower part of the inferior vena cava. The left division of the upper part of the inferior vena cava, which crosses the aorta below the superior mesenteric artery, remains as the inner portion of the left renal vein, which therefore receives the left spermatic and left suprarenal veins as tributaries.

### The Veins of the Limbs.

Two sets of veins are developed in each limb, the **superficial** and the **deep**; the former are the primary vessels, and as a rule they are quite apart from the limb arteries; the deep veins are secondary, and they accompany the arteries of the limb.

At the peripheral extremity of each limb a venous arch is developed, which is subsequently connected with the digital veins. In the upper extremity the arch terminates on the ulnar (post-axial) side of the limb in a trunk which afterwards becomes the posterior ulnar, basilic, axillary, and subclavian veins. At a latter period additional superficial vessels are formed, and of these a median vein which drains the palm, and a radial which commences on the radial side of the dorsum of the hand, are the most important. The radial passes up the preaxial border of the limb, becomes the cephalic, and for a time terminates in the primitive jugular vein;[1] this connexion is usually lost,[2] and a new communication is formed with the axillary vein. The median vein ends in an anastomosing vessel between the basilic and cephalic veins at the elbow, and through which it also communicates with the deep veins.

In the lower extremity the peripheral venous arch terminates in a fibular or post-axial trunk, which remains in the adult as the external saphenous vein; its connexion with the sciatic vein, which was its original continuation upwards, is soon lost, and a new communication is formed with the popliteal vein.

The internal saphenous vein is a later development which appears on the pre-axial border of the limb, and terminates in the femoral vein.

The deep veins appear as a series of anastomosing channels at the sides of the arteries.

### The Pulmonary Veins.

The pulmonary veins develop simultaneously with the lungs, and at first the veins from both lungs unite to form a single trunk, which enters the left auricle posteriorly, close to the auricular septum; subsequently the single trunk is absorbed, and two veins, one from each lung, enter the left auricle, and eventually, as the result of further absorption, two veins from each lung terminate in that cavity.

**The Lymphatic Vessels.**—The lymph vessels commence as outgrowths from the large veins at the root of the neck and gradually extend throughout the body by a process of budding, at least this appears to be the case in the pig. The growth therefore is from the centre to the periphery, and the communications with the large serous cavities must be formed secondarily.

## MORPHOLOGY OF THE VASCULAR SYSTEM.

In conformity with the general plan of the vertebrate body, the vascular system is essentially segmental in character. This is obvious, even in the adult, in the intercostal and lumbar vessels. It is distinguishable, though less obvious, in the vessels of the head and neck and of the pelvis.

The segmental arteries and veins form a series of bilaterally symmetrical vessels, each of which is united to the vessels of adjacent segments by intersegmental channels, which anastomose with one another, through the portions of the segmental vessels which they connect together, and thus form longitudinal trunks. The longitudinal trunks are mainly, though not exclusively, intersegmental. From them the main stem vessels of the individual are formed, and from or to these latter the segmental vessels appear to proceed as branches or tributaries.

In the course of development the longitudinal trunks become the most important trunks in the individual, and they are formed before the segmental vessels make their appearance.

[1] See note on page 937.

[2] In certain cases it remains, and then the cephalic vein crosses the front of the clavicle and terminates in the external jugular vein.

## The Segmental Arteries and their Anastomoses.

The main longitudinal trunks are the primitive aortæ. The descending aorta is formed, in

the greater part of its extent, by the fusion of the dorsal parts of the primitive aortæ, and from it the segmental arteries arise in pairs.

In a typical segment of the body of the embryo there are three segmental arteries on each side. One rises from the dorsal surface of the primitive dorsal aorta, *i.e.* from the dorsal longitudinal trunk, and runs outwards in the tissues developed from the somatic mesoderm; it is distributed to the body wall, including the spinal column and its contents, and is termed a **somatic segmental artery.** A second vessel rises from the side of the primitive dorsal aorta; it is distributed to the structures developed from the intermediate cell mass, viz. the suprarenal body, the kidney, and the ovary or testicle, and it is accordingly termed the **intermediate visceral artery.** The third artery, which is known as the **splanchnic segmental artery,** springs from the ventral surface of the descending aorta. It runs in the tissues developed from the splanchnic mesoderm, and supplies the wall of the alimentary canal.

V.V. Vitelline vessels.

The **somatic segmental arteries** form in the early embryo a regular series of paired vessels throughout the cervical, dorsal, lumbar, and sacral regions. It is, however, only in the dorsal and lumbar regions that their original characters are retained. The paired vessels pass backwards

by the sides of the vertebræ, and divide into dorsal and ventral branches which accompany the corresponding anterior and posterior primary divisions of the spinal nerves.

The **ventral branches** run outwards between the ribs in the dorsal region, and in corresponding positions in the lumbar region. They are connected together, near their commencements, by a series of precostal anastomoses which pass in front of the necks of the ribs, and they are also connected together near their terminations by ventral anastomosing channels which run in the thoracic region behind the costal cartilages, and in the lumbar region behind or in the substance of the rectus abdominis muscle. Each ventral branch gives off a lateral offset which is distributed like the lateral cutaneous branch of a spinal nerve.

The **dorsal branches** run backwards between the transverse processes of the vertebræ; they are connected behind the necks of the ribs by post-costal anastomoses, and again behind the transverse processes of the vertebræ by post-transverse anastomosing channels. Moreover, each dorsal branch, as it passes by the corresponding intervertebral foramen, gives off a spinal offset which enters the spinal canal along the corresponding nerve-root, and divides into a dorsal, a ventral, and a neural branch. The dorsal branches of these spinal arteries are connected together along the ventral surfaces of the laminæ by pre-laminar anastomoses, and the ventral branches are united on the dorsal surfaces of the vertebral centra with their fellows above and below by post-central anastomoses; they are also united with their fellows of the opposite side by transverse communicating channels. The neural branches of the spinal arteries divide similarly into dorsal and ventral branches; the dorsal branches of each side are connected together by post-neural anastomoses, and the ventral branches unite in the middle line both with their fellows above and below and with those of the opposite side, forming a single longitudinal pre-neural trunk.

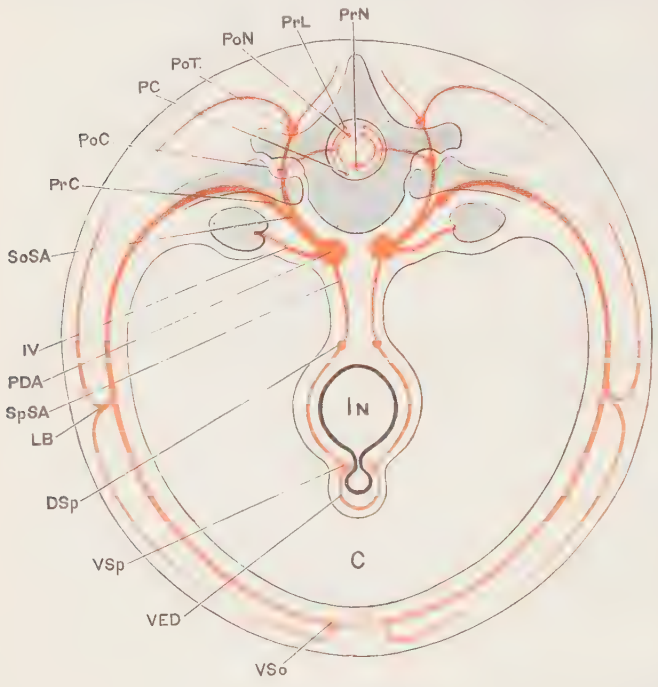

FIG. 677.—DIAGRAM SHOWING THE ARRANGEMENT AND COMMUNICATIONS OF THE SEGMENTAL AND INTERSEGMENTAL ARTERIES AT AN EARLY STAGE OF DEVELOPMENT.

C, Cœlom; D.Sp, Dorsal splanchnic anastomosis; IN, Intestine; I.V, Intermediate visceral artery; L.B, Lateral branch of the ventral division of a somatic segmental artery; P.C, Post-central anastomosis; P.D.A, Primitive dorsal aorta; Po.C, Post-costal anastomosis; Po.N, Post-neural anastomosis; Po.T, Post-transverse anastomosis; Pr.C, Pre-costal anastomosis; Pr.L, Pre-laminar anastomosis; Pr.N, Pre-neural anastomosis; So.S.A, Somatic segmental artery; Sp.S.A, Splanchnic segmental artery; V.E.D, Branch to a ventral enteric diverticulum; V.So, Ventral somatic anastomosis; V.Sp, Ventral splanchnic anastomosis.

In the dorsal and lumbar regions of the body the somatic segmental arteries persist and form the intercostal and lumbar arteries. These vessels spring from the dorsal aspect of the descending aorta, usually in pairs. The corresponding vessels of opposite sides, however, occasionally fuse together at their origins, simultaneously with the fusion of the dorsal longitudinal trunks to form the descending aorta, and then they arise by common stems.

The precostal anastomoses between the ventral branches of the somatic segmental arteries are only represented in the dorsal region by the superior intercostal arteries; in the lumbar region they disappear entirely. The anastomoses between the anterior ends of the ventral branches of the somatic segmental arteries persist as the internal mammary and deep epigastric arteries.

The lateral offsets of the ventral branches are represented by the cutaneous arteries which accompany the lateral cutaneous branches of the spinal nerves.

The post-costal and post-transverse anastomoses usually disappear in the dorsal and lumbar regions, but the post-costal anastomoses occasionally persist in the upper dorsal region, and take part in the formation of the vertebral artery, which in such cases arises from the first or second intercostal artery. In some carnivores the post-costal longitudinal vessels persist in the upper dorsal region, and form, on each side, a trunk which is connected with the first aortic intercostal, and which supplies the five anterior intercostal spaces.

The pre-laminar, the post-central, and the pre- and post-neural anastomoses persist, the two

latter aiding in the formation of the dorsal and lumbar portions of the pre- and post-spinal arteries respectively.

It is in the cervical region, however, that the most interesting changes occur. The first six pairs of somatic segmental arteries lose their connexions with the dorsal roots of the aortic arches, *i.e.*, in other words, with the longitudinal anastomosing channels in this region. The seventh pair, however, persist in their entirety; and from them are formed, on the right side, a portion of the subclavian trunk, and on the left side the whole of the subclavian stem from its commencement up to the origin of the vertebral artery. On each side the ventral branch of the seventh segmental artery forms that portion of the subclavian artery which lies between the origins of the vertebral and internal mammary arteries, and also the trunk of the internal mammary artery as far as the upper border of the first costal cartilage. The remainder of the internal mammary artery represents the ventral longitudinal anastomoses between the ventral branches of the seventh and the following somatic segmental arteries. The continuation of the subclavian artery, beyond the inner margin of the first rib, is the persistent and enlarged lateral offset of the ventral branch of the seventh somatic segmental artery, which is continued outwards into the upper limb behind, or postaxial to the shoulder girdle. The thyroid axis and the superior intercostal artery, both branches of the subclavian artery, are persistent pre-costal anastomoses, and the ascending cervical artery belongs to the same series of vessels. The vertebral artery, which appears as a branch of the subclavian in the adult, is morphologically somewhat complex. The first part represents the dorsal branch of the seventh somatic segmental artery; the second part, that passing through the cervical transverse processes, consists of the persistent post-costal anastomoses between the first seven segmental arteries; a third part, that lying on the arch of the atlas, is the spinal branch of the first somatic segmental artery and its neural continuation; whilst finally the upper part of the vertebral artery, that in the cranial cavity, appears to represent a prolongation of the preneural anastomoses, which still farther upwards are probably represented by the basilar artery. As already stated, the post-costal anastomoses below the seventh segmental artery occasionally persist, and in such cases the vertebral may lose its connexion with the subclavian, and spring from one or other of the dorsal branches of the upper intercostal arteries.

The profunda cervicis artery is to be regarded as a remnant of the post-transverse longitudinal anastomoses.

The origin of the seventh somatic segmental artery from the dorsal longitudinal trunk is at first some distance

behind the fifth aortic arch, but, simultaneously with the elongation of the neck and the retraction of the heart into the thoracic region, it is shifted forward until it is opposite the dorsal end of the fourth aortic arch.

The middle sacral artery is formed by the fusion of two vessels, each of which springs from the primitive aorta in exactly the same manner as a somatic segmental artery; it may therefore be looked upon as consisting of fused somatic segmental vessels which have been prolonged backward for the supply of the caudal appendage. It is, however, commonly regarded as the direct continuation of the descending aorta, and consequently as being mainly intersegmental. Its mode of origin and general nature do not lend much support to the latter view.

The **intermediate visceral arteries** supply the organs derived from the intermediate cell mass. They form a somewhat irregular series of vessels in the adult, but presumably in the primitive condition there was a pair in each segment of the body; many of these disappear, however, and the series is only represented in the adult by the suprarenal, the renal, and the spermatic or ovarian arteries—possibly, also, by some of the branches of the internal iliac arteries.

The **splanchnic segmental arteries** arise in the embryo from the ventral aspects of the primitive dorsal aortæ, and are distributed to the walls of the alimentary canal. They anastomose with their fellows in front and behind in the dorsal wall of the gut; those in front of the umbilicus also communicate together on the ventral wall of the gut, whilst those behind the umbilicus terminate ventrally in the posterior sections of the ventral aortæ.

After the fusion of the dorsal longitudinal trunks to form the descending aorta, the origins of the splanchnic arteries in each segment fuse into a common stem, or either the right or left artery altogether disappears, whilst at a later period the majority of the splanchnic segmental arteries lose their direct connexion with the descending aorta; those which retain their connexion are the left bronchial arteries, the œsophageal branches of the aorta, the cœliac axis, and the superior and inferior mesenteric arteries, the three latter vessels greatly increasing in size.

The coronary or gastric branch of the cœliac axis, as it passes from its origin to the small curvature of the stomach, represents a right splanchnic artery; the remainder of the coronary artery and the pyloric branch of the hepatic are remnants of the ventral anastomoses between the splanchnic arteries in front of the umbilicus.

The splenic artery is a branch given off from a splanchnic artery to an organ developed in the gastric mesentery, and the hepatic is a branch from the ventral splanchnic anastomoses to the hepatic diverticulum from the wall of the duodenal portion of the fore-gut.

The superior and inferior mesenteric arteries represent at their origins splanchnic branches, and in the remainder of their extent the dorsal anastomoses on the gut wall.

## The Aorta, Pulmonary Artery, and other Chief Stem Vessels.

The heart and the majority of the great arterial trunks of the body, including the aorta, the innominate, part of the right subclavian, the common, external, and greater parts of the internal carotids, the common and internal iliacs, and the pulmonary arteries, are all modified portions either of the primitive aortæ or of the aortic arches. The developmental changes, which result in the formation of the vessels named, are described in the preceding chapter, and the morphology of these vessels is obviously the same as that of the trunks from which they are derived.

It will be sufficient, therefore, to point out that the primitive aortæ are to be regarded as the greatly enlarged pre-central or pre-vertebral longitudinal anastomoses between the successive segmental arteries of each side; obviously, therefore, each primitive aorta, like the rest of the longitudinal anastomoses, consists chiefly of intersegmental elements. The origins of the segmental vessels only enter into its formation in so far as they connect the intersegmental vessels together, and so complete the longitudinal anastomoses.

The first cephalic aortic arches and the primary caudal arches are simply portions of the primitive aortæ. The other aortic arches have possibly a different morphological significance, but their exact nature is not definitely settled.

The second, third, fourth, and fifth cephalic aortic arches of each side are developed in the undivided mesoderm of the head region behind the first arch. They spring from the anterior part of the primitive aorta which, after the head fold is formed, lies on the ventral aspect of the fore-gut, and they extend at the side of the pharyngeal part of the fore-gut to the dorsal aorta. Thus in some respects they resemble segmental vessels. Behind the umbilicus some of the segmental splanchnic arteries pass from the dorsal to the ventral aorta in the splanchnic mesoderm on the wall of the alimentary canal. In addition to the vessels already mentioned, there are given off from the ventral aortæ and the aortic arches a series of branches which supply ventral and lateral diverticula from the alimentary canal; these are represented in the adult by the superior thyroid, the thyroidea ima, and the terminal branches of the hypogastric arteries.

**Iliac Arteries and their Branches.** The common iliac arteries are undoubtedly formed from the primitive aortic longitudinal vessels; they are simply those portions of the right and left primitive aortæ respectively which lie immediately beyond or caudal to the permanent descending aorta. The direct continuation of each is the primary caudal arch, which forms the origin of the superior vesical artery, and is prolonged as the hypogastric artery; these continuous channels are for the most part made up of intersegmental vessels. So also are the permanent vessels into which they are transformed. Reference has already been made to the fact that the primary caudal arch almost entirely disappears, and that a secondary caudal arch is developed in lieu of it (p. 928).

The internal iliac arteries are almost entirely formed from the secondary caudal arches. The

primary caudal arch, beyond doubt, is not a segmental vessel; the secondary arch may be, but this is still unproved. The branches of the internal iliac artery which represent offsets of the "caudal arch" portion of the primitive aortæ are arranged in two groups—(1) a visceral set which supplies the walls of the hind-gut and the genital organs, and (2) a parietal set which is distributed to the body wall and to the hind-limbs. The branches distributed to the gut probably represent the segmental splanchnic vessels given off from the dorsal longitudinal vessels; those to the genital organs appear to correspond with the intermediate visceral branches, for they are distributed to organs derived from the intermediate cell mass.

The parietal set are to be regarded as modified somatic segmental branches of the dorsal longitudinal trunks. The lateral sacral arteries which belong to this group represent, in the greater parts of their extent at least, the pre-costal anastomoses.

### The Limb Arteries.

In all probability the vessels of both the anterior and the posterior extremities are derived from several somatic segmental arteries, the majority of which, however, in the course of phylogenetic development, have atrophied. The upper limb is supplied in man by the lateral offset from the ventral branch of the seventh somatic segmental artery. It passes out into the extremity behind the shoulder girdle, courses through the upper arm, enters the antecubital fossa, and is continued through the forearm, in the early stages, as the anterior interosseous artery, to the deep part of the palm, where it terminates in the deep palmar arch. At a later period a median artery is given off from the parent stem, and it terminates in a superficial palmar arch; still later the radial and ulnar branches are given off. The latter grow rapidly, soon exceeding in size the parent stem, and they terminate in the superficial and deep palmar arches. The interosseous and median arteries decrease, and generally lose their direct connexions with the palmar arches. The posterior interosseous artery is also a secondary branch from the parent stem, and the digital arteries are offsets from the palmar arterial arches.

The chief arteries of the lower extremities spring directly from the caudal arches, and may be looked upon as being essentially segmental; whether they represent the whole or only parts of typical somatic segmental arteries, however, is not clear.

The arteries of the hind-limbs certainly show no very obvious indications of division into dorsal and ventral branches, though such indications are not entirely wanting. In their comparative absence it is supposed that the dorsal branches have been either suppressed or incorporated with the common stems; that similarly the ventral branches and their lateral offsets are indistinguishably fused, and that probably both are represented in a limb artery.

The original stem vessel of the lower limb is the sciatic artery, which is continued downwards behind the pelvic girdle into the popliteal and peroneal arteries, and so to the plantar arch. Subsequently the external iliac artery is given off from the caudal arch above the origin of the sciatic, and, passing into the limb in front of the pelvic girdle, it becomes the femoral artery. This vessel ultimately unites with the upper part of the popliteal artery, and after this communication is established the lower part of the sciatic atrophies and loses its connexion with the popliteal, which henceforth appears to be the direct continuation of the femoral trunk; therefore, whilst the main artery of the upper limb is formed by the prolongation of the lateral branch of one segmental artery, the corresponding vessel of the lower extremity is developed from representatives of two somatic segmental arteries, the external iliac and femoral trunks being the representatives of one, whilst the popliteal and its continuation, the peroneal, are parts of another.

The first main artery of the leg is the peroneal, which is continued into the plantar arch; after a time, however, the posterior and anterior tibial branches are given off from the stem, over which, as a rule, they soon preponderate in size, and they terminate in the plantar arch, whilst the parent trunk diminishes and loses its direct connexion with the arch.

The peroneal artery corresponds in position and development with the interosseous trunk and the anterior interosseous artery in the forearm. The posterior tibial apparently corresponds with the median artery; it develops in a similar way, and has similar relations to homologous nerves, the posterior tibial nerve representing the combined median and ulnar nerves of the upper extremity.

The anterior tibial artery represents the posterior interosseous, whilst the radial and ulnar arteries of the upper extremity are not represented in the lower limb.

## MORPHOLOGY OF THE VEINS.

Two dorsal longitudinal vessels, one on each side, connect the successive segmental veins together. They do not, however, in any part of their course, fuse together to form a single vessel comparable to the descending aorta.

Of these dorsal longitudinal vessels, that on the right side greatly enlarges, and from it the main stem vessels which return blood from the body walls, the head and neck, and the limbs, are almost entirely formed. The left dorsal longitudinal vessel remains relatively small—in parts, indeed, it altogether disappears—and the blood conveyed to it by the corresponding segmental veins is transmitted across the middle line to the chief functional stem by later developed and superadded transverse communicating channels, which are formed between the more primitive longitudinal anastomoses.

The primitive dorsal longitudinal anastomosing channels include on each side (1) the primitive jugular vein, (2) the primitive cardinal vein, and (3) the duct of Cuvier; the last-named vessel, however, is not so much a longitudinal anastomosis as a communicating channel between the longitudinal anastomoses and the heart, for it is formed by the junction of the primitive jugular and cardinal veins, and opens into the sinus venosus of the primitive heart.

From these vessels, and from the transverse communications which are established between the primitive jugular and cardinal veins of opposite sides, the chief veins of the head and neck and the body are formed; there are in addition, however, three later-formed vessels from which some, or portions of some, of the main stem vessels of the body are evolved. These later-formed vessels are the two internal jugular veins,[1] and the upper part of the inferior vena cava, whilst from the latter of these portions of the renal veins, the suprarenal veins and the spermatic or ovarian veins are possibly developed as offsets; moreover, it must not be forgotten that the veins of the extremities are, like the extremities themselves, secondary structures, and that they are developed at a later period than the veins of the trunk, with which, however, they ultimately communicate.

In the light of these facts the morphology of the chief veins of the trunk and limbs may now be considered.

The external jugular vein is obviously a portion of an intersegmental anastomosis, for it is part of the primitive jugular vein, which originally extended from the internal occipital protuberance to the post-condyloid foramen, and thence to the duct of Cuvier. During the course of development the intracranial part of the primitive jugular, on each side, is converted into the horizontal portion of the lateral sinus and the occasionally persistent squamo-petrosal sinus; outside the cranium the trunk of the temporo-maxillary vein, the whole of the external jugular vein, and that portion of the subclavian vein which intervenes between the external and internal jugular veins, are formed from the primitive jugular. On the right side the right innominate vein and the upper part of the superior vena cava are also formed from the primitive jugular vein, whilst on the left side the lower portion of the vessel becomes the upper part of the left superior intercostal vein.[2]

After the formation of the limbs the primitive jugular receives the pre-axial and post-axial veins of the fore-limb of the same side, which pass respectively along the radial and ulnar borders of the limb; both join the primitive jugular vein, the former above and the latter below the clavicle.[3] Subsequently, however, the pre-axial vein of the fore-limb loses its connexion with the primitive jugular vein, and opens below the clavicle into the post-axial vein, and the upper part of that vessel becomes the outer part of the subclavian vein, *i.e.* that portion of the subclavian vein which extends from the outer border of the first rib to the entrance of the external jugular vein, the remainder of the subclavian being formed by the portion of the primitive jugular vein which intervenes between the entrance of the pre-axial vein and the junction with the internal jugular vein.

The internal jugular vein is a newly formed anastomosing vessel which commences from the primitive jugular vein at the root of the neck and grows upwards to the base of the skull, where it passes through the jugular foramen, and ascends along the inner surface of the mastoid portion of the temporal bone to join the lateral sinus, of which it becomes the sigmoid portion. It probably represents a dorsal splanchnic intersegmental venous anastomosis.[1]

The innominate vein of the left side is an enlarged transverse anastomosis between the two primitive jugular veins, and the corresponding vessel on the right side is the portion of the right primitive jugular vein which lies between the origin of the right internal jugular vein and the transverse anastomosis between the two primitive jugular veins.

The superior vena cava is also formed from the primitive longitudinal anastomosis on the right side; the upper portion, which lies above the entrance of the azygos vein, being the lower part of the right primitive jugular vein, and the lower portion, which is enclosed within the pericardium, is the persistent right duct of Cuvier.

The only other vein formed from the jugular portion of the dorsal longitudinal anastomosis is the upper part of the left superior intercostal vein, which represents the part of the left primitive jugular vein lying below the transverse anastomosis which becomes the left innominate vein; occasionally this part of the left primitive jugular vein becomes enlarged, and forms a vertical left innominate vein which terminates in a left superior vena cava, the latter being formed from the left duct of Cuvier. This arrangement is the regular and normal condition in many mammals.

The internal iliac veins, the right common iliac vein, the lower part of the inferior vena cava, the vena azygos major, and the vertical portions of the upper and lower left azygos veins, and part of the left superior intercostal vein, are all parts of the primitive cardinal veins. They represent, therefore, portions of the dorsal longitudinal intersegmental anastomoses.

The internal iliac veins are the persistent lower sections of the cardinal veins, and their visceral and parietal tributaries probably represent more or less modified splanchnic and somatic segmental veins.

The left common iliac vein may, in the lower part of its extent, represent the part of the left cardinal vein immediately above the junction of the pre-axial hind-limb vein with the latter vessel, but the greater part of it is an enlarged transverse anastomosis between the cardinal veins at the level of the pelvic brim. The right common iliac vein, on the other hand, is the portion

[1] See note on p. 937. [2] *Ibid.*

[3] If the observations recorded on p. 937 are correct, then the external jugular vein is not the primitive jugular vein but a newly-formed vessel into which the pre-axial vein opens.

of the right cardinal vein which lies between the entrance of the limb vein and the transverse anastomosis which becomes the left common iliac vein. The inferior vena cava, from its commencement to the entrance of the renal veins, is a portion of the right cardinal vein, and the right lumbar veins which terminate in it are the somatic segmental veins of the right side of the lumbar region; whilst the left lumbar tributaries are the left lumbar segmental veins, which have been transmitted across the middle line by transverse anastomosing channels which connected the lumbar sections of the cardinal veins together.

The upper part of the inferior vena cava is a new anastomosing channel formed between the upper end of the right hepatic vein and the right cardinal vein. This section of the inferior vena cava grows downwards from the right hepatic vein.

The right and left renal veins originally terminated in the corresponding cardinal veins, and are therefore probably intermediate visceral segmental veins, but that part of the left renal vein which crosses the middle line is either an enlarged transverse anastomosis between the cardinal veins, or an outgrowth from the lower end of the upper part of the inferior vena cava; apparently the latter, for as the upper section of the inferior vena cava grows downwards from the right hepatic vein it divides into two branches, right and left, each of which joins the corresponding cardinal vein close to the termination of the renal vein. Before it fuses with the cardinal vein of its own side, each of the terminal branches of the upper section of the inferior vena cava gives off branches which ultimately become the suprarenal and spermatic veins; there can be no doubt, however, that both the suprarenal and spermatic veins are intermediate visceral segmental veins, and in all probability they originally terminated in the corresponding cardinal veins, their development from the upper section of the inferior vena cava being due to the production in the embryo of a condition which has been secondarily acquired during the development of the species. If this is the case, it is extremely probable that the left spermatic vein represents not only an elongated intermediate visceral segmental vein, but also a portion of the left cardinal into which it opened.

The vena azygos major is the persistent upper portion of the left cardinal vein, a fact which is emphasised by its frequent connexion with the inferior vena cava at the level of the right renal vein. The right intercostal veins which open into the vena azygos major are somatic segmental veins, the upper three or four of which have united together by pre-costal anastomoses to form a right superior intercostal vein.

The vertical portions of the left azygos veins are remnants of the left primitive cardinal vein, and their transverse portions are enlarged transverse anastomoses comparable to the left innominate and left common iliac veins. The left, like the right intercostal veins, are segmental somatic veins; but whilst the right superior intercostal vein is formed by pre-costal anastomoses between the upper three or four dorsal somatic segmental veins, the left superior intercostal vein (Fig. 674) represents the upper part of the left cardinal vein and the part of the left primitive jugular vein below the transverse anastomosis, which becomes the left innominate vein; moreover, the left superior intercostal vein frequently retains in the adult a connexion with the oblique vein of Marshall, which represents the left duct of Cuvier, by means of which both the left primitive jugular and the left cardinal veins originally communicated with the heart.

**Visceral Veins.**—The portal vein represents portions of the ventral longitudinal anastomosing vessels, being derived from the vitelline veins.

The pyloric vein is a splanchnic intersegmental ventral longitudinal anastomosing vein. The coronary vein is partly a ventral and partly a dorsal splanchnic intersegmental longitudinal anastomosis, and the superior and inferior mesenteric veins are dorsal splanchnic longitudinal intersegmental venous anastomoses, the splenic vein being merely a tributary from a lymphoid organ developed in the dorsal mesentery.

The facial vein is a combination of somatic and splanchnic veins of several segments, and the internal maxillary vein is probably of similar nature. The thyroid and bronchial veins return blood from organs developed from diverticula from the walls of the alimentary canal; they are, therefore, more or less modified segmental splanchnic veins; so also apparently are the vesical and the middle and inferior hæmorrhoidal veins.

The cardiac veins are simply "vasa vasorum," and they belong therefore to the splanchnic group of vessels, but it is impossible to say whether they are segmental or intersegmental. The coronary sinus into which they open is a portion of the sinus venosus of the heart, and therefore of an originally intersegmental vessel.

The hepatic and pulmonary veins are new vessels which return blood to the heart after the liver and lungs have been interposed in the vascular system.

It is noteworthy that some parts of the splanchnic venous system, *i.e.* the portal vein and the coronary sinus, are portions of the most primitive vascular system, and that others, *i.e.* the thyroid, bronchial, mesenteric, vesical, and hæmorrhoidal veins, appear to belong to a somewhat secondary group of splanchnic veins of combined segmental and intersegmental character; moreover, some of the secondary group of veins open into the primary splanchnic veins, *e.g.* the superior and inferior mesenteric into the portal vein; some open into the dorsal longitudinal anastomosing veins, *e.g.* the vesical and hæmorrhoidal veins open into the cardinal veins, which are intersegmental anastomoses; others again open into an entirely new vein, viz. the internal jugular,[1] which is developed along the dorso-lateral border of the fore-gut, and which is therefore comparable to the dorsal venous splanchnic intersegmental anastomosis, which in the abdominal region becomes converted, after fusion of the vessels of opposite sides, into the greater parts of the superior and inferior mesenteric veins; the latter, however, open into a ventral longitudinal

[1] See note on p. 937.

anastomosing vessel, the portal vein, whilst the former joins a dorsal longitudinal anastomosing trunk.

**Veins of the Limbs.**—The veins of the limbs, like the arteries, were probably at one time segmental in character, but we have no absolute proof that this was the case. Looked at from an embryological standpoint, the most primitive limb veins are a superficial distal arch and a post-axial trunk vein in each extremity; at a later period digital veins are connected with the distal arch, and a pre-axial trunk is formed. In the upper extremity the distal arch and its tributaries remain as the dorsal venous arch and the digital veins, and the post-axial vein becomes the posterior ulnar, the basalic and axillary veins, and also that part of the subclavian vein which lies external to the termination of the external jugular vein, the remainder of the subclavian vein being formed from the primitive jugular vein itself. The pre-axial vein of the upper extremity is represented in the adult by the radial and cephalic veins; the latter vessel originally terminated in the external jugular vein above the clavicle, the union with the axillary portion of the post-axial vessel being a secondary condition; the primary condition is, however, frequently retained in man, and is constant in many monkeys. The anastomosis between the pre-axial and post-axial veins in the region of the elbow, and the connexion of the anastomosing channels, is brought about by newly-formed vessels of secondary character.

The distal arch in the lower extremity and the tributaries connected with it remain in the adult as the dorsal venous arch of the foot and the digital veins. The post-axial vein becomes the external saphenous vein, which was originally continued upwards as the sciatic vein to the internal iliac portion of the cardinal vein; its connexion with the popliteal vein, and its more occasional connexion with the internal saphenous vein, being brought about by the formation of secondary anastomoses.

The pre-axial vein of the lower limb becomes the long saphenous vein, which is continued upwards to the cardinal portion of the left common iliac vein as the upper part of the femoral and the external iliac veins.

The venæ comites of the arteries in both the upper and lower extremities are secondarily developed vessels which become connected with the upper portions of the pre-axial venous trunks.

## ABNORMALITIES OR VARIATIONS OF THE VASCULAR SYSTEM.

Abnormalities are of special interest to the anatomist because of their morphological significance, and the vascular system is, perhaps more than any other, rich in such abnormalities, many of which are of great practical importance.

With the exception of those irregularities which are directly due to the effect of morbid conditions and external influences, all abnormalities are the result of modifications of normal developmental processes. The exceptions referred to are, however, very numerous; thus disease and external influences may lead to the obliteration of vessels, a condition which is invariably associated with the enlargement of collateral vessels, and it will be obvious that abnormalities so produced may occur in almost any situation.

Abnormalities which are determined by, or are dependent upon, modifications of the usual developmental processes are of greater interest. In the human subject they are generally due either to the retention of conditions which normally are only transitory, or to the acquirement of conditions which, though not as a rule present at any time in man, occur normally in other animals.

There are in addition other variations from the normal, such as the division of the axillary artery into radial and ulnar branches; the higher or lower division of the brachial artery; the formation of "vasa aberrantia," *e.g.* of long slender vessels connecting the axillary or brachial to the radial, ulnar, or interosseous arteries; the altered position of certain vessels, as *e.g.* the transference of the subclavian artery to the front of the scalenus anticus, or of the ulnar artery to the front of the superficial flexor muscles; all of which, though undoubtedly due to alterations of ordinary developmental processes, still do not represent conditions met with, either temporarily or permanently, in man or in other animals. Their occurrence cannot at present be adequately explained, and their retention is entirely dependent upon their utility.

To the first and last of these different groups of abnormalities it is not necessary to refer further, whilst with regard to the rest it will be sufficient to indicate those of greatest importance. They can only, however, be fully understood and explained on the basis of a comprehensive knowledge of the development and morphology of the vascular system, to the chapters on which the reader is referred.

### ABNORMALITIES OF THE HEART.

The **heart** may be transposed from the left to the right side of the body, a condition which is usually associated with general transposition of the viscera, and with the presence of a right instead of a left aortic arch.

The external form of the heart does not as a rule vary much, but occasionally the apex is slightly bifid, a character it normally possesses at an early stage of its development, and which is

retained in the adult in many cetaceans and sirenians. The internal conformation of the heart deviates from the normal much more frequently; more particularly is this the case with regard to the septa which separate the right from the left chambers. The interauricular septum may be entirely absent, as in fishes; it may be fenestrated and incomplete, as in some amphibians; or the foramen ovale may remain patent, as in amphibians and reptiles.

The interventricular septum may be absent, as in fishes and amphibians, or incomplete, as in reptiles; when incomplete, it is usually the "pars membranacea septi" which is deficient.

## ABNORMALITIES OF ARTERIES.

The **pulmonary artery** and the **aorta** may arise by a common stem, as in fishes and some amphibians, and the common stem may spring either from the right or the left ventricle, or from both. In these cases the aortic bulb has remained undivided, and the normal position of the interventricular septum in relation to the lower orifice of the aortic bulb has been altered.

Again, owing to malposition of the aortic septum, the pulmonary artery may spring from the left ventricle and the aorta from the right ventricle. In some cases the root of the pulmonary artery is obliterated, and the blood passes to the lungs along the patent ductus arteriosus.

Occasionally the arch of the aorta is on the right side instead of the left, a condition which is normal in birds. More rarely there are two permanent aortic arches, right and left, as in reptiles; the œsophagus and trachea in these cases are enclosed in a vascular collar, the two arches unite dorsally, and the beginning of the descending aorta is double. Quite independent of this condition, however, the two primitive dorsal aortæ sometimes fail, either altogether or partially, to unite together, and the descending aorta is accordingly represented, to a corresponding extent, by two tubes. A more common, though still rare, form of double aorta is that due to the persistence, in whole or in part, of the septum formed by the fused walls of the primitive dorsal aortæ from which the descending aorta is developed.

The length of the descending aorta is determined largely by the extent to which fusion of the two primitive aortæ takes place. Accordingly, when this deviates from the normal, the termination of the descending aorta is at a correspondingly higher or lower level than usual, and resulting from this the lengths of the common iliac arteries are almost invariably proportionately modified. The bifurcation[1] of the aorta may be as low as the fifth lumbar vertebra, less frequently it is higher than usual; it is rare, however, to find it higher than the third or second lumbar vertebra.

The aorta, instead of bifurcating into two common iliac arteries, may terminate in a common iliac artery on one side and an internal iliac artery on the opposite side, the external iliac artery on the irregular side arising, at a higher level, as a branch of the aortic stem. This arrangement approaches the condition met with in carnivores and many other mammals, in which the aorta bifurcates into two internal iliac arteries, the external iliacs arising from the aorta at a higher level as lateral branches; it is due either to a more extensive fusion than usual of the primitive dorsal aortæ, or to the origin of the external iliac arteries from the primitive dorsal aortæ being at a higher level than is ordinarily the case; if the condition is due to the latter cause, it may be that the external iliac arteries in carnivores, and the external iliac arteries which occasionally rise from the aorta in man, are somatic segmental arteries of a higher segment than the normal external iliac arteries of the human subject.

### The Branches of the Aorta.

The **coronary or cardiac arteries** may arise by a single stem. When arising separately both may spring from the same sinus of Valsalva; or again, their interventricular and transverse branches may all arise as distinct vessels from a single sinus of Valsalva. This variability is not so remarkable, seeing that the arteries in question are merely enlarged "vasa vasorum" raised to a position of special importance by the development of the heart.

The **branches of the arch of the aorta** are sometimes increased and sometimes decreased in number.

The highest number recorded is six, viz., right subclavian, right vertebral, right common carotid, left common carotid, left vertebral, and left subclavian. Apparently this condition is the result of the absorption of the innominate artery and of the roots of the subclavian arteries, to points beyond the origins of the vertebrals, into the arch. By variations of this process of absorption other combinations may be produced; thus, instead of the roots of the subclavian arteries being absorbed, the right common carotid and innominate arteries may alone be absorbed, in which case the five following branches spring separately from the arch of the aorta: right subclavian, right external carotid, right internal carotid, left common carotid, and left subclavian. The trunk most commonly absorbed is the initial part of the left subclavian; the number of branches then arising from the arch of the aorta is four, the additional vessel being the left vertebral, which arises between the left common carotid and the left subclavian. Occasionally the usual three branches from the arch are increased to four by the formation of a new vessel, the "thyroidea ima." This may be placed between the innominate and left carotid trunks, in which case it represents a persistent ventral visceral branch from the ventral root of the fourth left aortic arch; in other cases the thyroidea ima springs from the innominate artery and

[1] It is to be observed that the exact point of bifurcation of the aorta, in relation to the vertebral column, is not entirely determined by the length of the descending aorta.

represents a ventral visceral branch of the ventral root of the fourth *right arch.* Very rarely the right vertebral artery arises separately, and forms a fourth branch of the arch of the aorta, the rest of the branches being normal. This condition cannot be accounted for by any modification of the ordinary developmental processes. It may possibly be due to the persistence of an irregular or unimportant anastomosis between the ventral root of an aortic arch and the seventh somatic segmental artery.

Decrease in the number of branches from the arch of the aorta is most frequently due to fusion of the ventral roots of the fourth aortic arches, the result being that a stem is formed common to the right subclavian and the right and left common carotid arteries; whilst the left subclavian, arising separately, is the only other branch which springs from the arch of the aorta.

If the fusion of the ventral roots proceeds further and includes those of the third arches, the result as regards the branches given off from the arch of the aorta is the same, viz. there is a common stem for the right subclavian and both carotids, and a separate left subclavian trunk; but the common stem now gives off the right subclavian artery, and then continues as a single vessel for some distance before it divides into the two common carotids, of which the left crosses in front of the trachea. This arrangement is common in many quadrumana and in some other mammals.

It is only very occasionally when the number of branches from the arch of the aorta is reduced to two, that these consist of a right subclavian artery and of a single stem common to the two carotids and the left subclavian arteries. In such cases, however, the right common carotid crosses in front of the trachea, and the variation is one of practical importance. It does not appear to exist as a normal condition in any mammal. Probably it is due to fusion of the ventral roots of the fourth aortic arches, with absorption of the left fourth arch and the left subclavian into the stem so formed, whilst the right subclavian is relatively displaced. The two common carotids may arise by a common stem, and the left subclavian arise separately from the arch of the aorta, whilst the right subclavian springs from the descending aorta. This arrangement probably results from the disappearance of the fourth right arch and the fusion of the ventral roots of the fourth arches of opposite sides.

Sometimes two innominate arteries, right and left, replace the three usual branches of the arch of the aorta. This is the normal arrangement in bats, moles, and hedgehogs. It is obviously the result of the disappearance of that portion of the arch which intervenes between the left carotid and left subclavian arteries, and the consequent fusion of these two vessels.

In a similar way may be explained the rarer condition in which the three ordinary branches of the arch arise by one single stem, which divides into right and left innominate arteries. In most ruminants, in the horse and in the tapir, this arrangement is constant.

It will be evident that other combinations and modifications may be met with in the branches of the arch of the aorta as the result of fusions and absorption.

The **bronchial arteries** obviously correspond to splanchnic segmental arteries and their continuations to diverticula from the walls of the gut, therefore the usual origin of the right bronchial artery from the first right aortic intercostal artery must result from the persistence of an anastomosis between a splanchnic segmental artery and the first part of a somatic segmental artery; the origin of the right from the upper left bronchial artery, which sometimes occurs, is due to the fusion of the roots of two splanchnic segmental arteries. The occasional origin of a bronchial vessel from an internal mammary artery can only result from the persistence and enlargement of an anastomosis between a splanchnic segmental artery and the ventral branch of a somatic segmental artery. The origin of a bronchial branch from a subclavian artery may have the same or a different significance on opposite sides of the body. A bronchial artery arising from the left subclavian artery corresponds with the origin of the right bronchial artery from the first aortic intercostal artery; it is due to the persistence of an anastomosis between a splanchnic segmental artery and the root of a somatic segmental artery, and the origin of a bronchial artery from a right subclavian artery may be due to a similar cause. It may, on the other hand, be due to the enlargement of an anastomosis between a splanchnic branch of the descending aorta and a splanchnic branch of the fourth right aortic arch. When, as occasionally happens, the bronchial artery arises from the inferior thyroid, it is due to the persistence and enlargement of an anastomosis between splanchnic arteries.

**Intercostal Arteries.**—Variations of the intercostal arteries are not very common, but they are significant and interesting. Corresponding vessels of opposite sides may arise from a common stem which has been formed by the fusion of the roots of two somatic segmental arteries after or simultaneously with the fusion of the primitive dorsal aortæ. The number of intercostal arteries may be reduced, one artery supplying two or more intercostal spaces; in these cases the roots of origin of some of the somatic segmental arteries in the dorsal region have disappeared, and the precostal anastomoses between their ventral branches have persisted.

Occasionally the number of the aortic intercostal arteries is increased, an additional artery being given to the second intercostal space, which is usually supplied by the superior intercostal artery; this is brought about by the persistence of the root of the tenth somatic segmental artery and the disappearance of the precostal anastomosis between the ventral branches of the ninth and tenth somatic segmental arteries. Very rarely the first aortic intercostal artery sends a branch upwards between the necks of the ribs and the transverse processes of the upper dorsal region; this branch supplies the upper intercostal spaces, the superior intercostal artery being small or absent, and it terminates by becoming the profunda cervicis artery. It is due to the persistence of the postcostal anastomoses in the upper dorsal region, and is a repetition of a condition regularly present in some carnivores.

There are no very important variations of the œsophageal, pericardial, and mediastinal arteries.

**Lumbar Arteries.** — Variations of the lumbar arteries are very similar to those of the intercostal arteries, and they are due to similar causes. The lumbar arteries of opposite sides may arise by common stems from the back of the aorta; and the last pair of lumbar arteries may arise in common with the middle sacral artery. Further, a lumbar artery may have its area of distribution increased to the adjacent segment.

The **inferior phrenic arteries** are very variable; they may arise by a common trunk either from the cœliac axis or from the aorta; they may arise separately either from the aorta or from the cœliac axis, and more commonly from the latter vessel; or again, one may spring from the aorta or cœliac axis, and the other from the coronary, renal, or even from the superior mesenteric artery.

The **middle sacral artery** usually springs from the back of the aorta above its bifurcation; it may be considerably above, or more rarely it may spring directly from the bifurcation. Not infrequently it arises from the last lumbar artery or from a stem common to the two last lumbar arteries, and occasionally it arises from a common or internal iliac artery. Sometimes it apparently gives off the last pair of lumbar arteries, and very occasionally an accessory, renal, or a hæmorrhoidal branch arises from it. The vessel is not always present, it may be double, entirely or in part, and it may bifurcate at its termination.

The **renal arteries** frequently deviate from the normal arrangement. The arteries of opposite sides may spring from a common stem, or there may be two or more renal arteries on one or both sides. The accessory arteries are more common on the left than on the right side, and an accessory artery rising below the ordinary vessel is more common than one rising above it.

Accessory renal arteries may be derived not only from the aorta, but also from the common or internal iliac arteries; they have also been described as arising from the inferior phrenic, spermatic, lumbar, or middle sacral arteries, and even from the external iliac artery. As the kidney is developed in the region of the first sacral vertebra, and afterwards ascends to its permanent position, it is not surprising that it occasionally receives arteries from the main stem of more than one of the segments of the body through which it has passed, and it is usually found that the lower the position of the kidney in the abdomen the more likely it is to receive its arteries from the lower part of the aorta or from the common iliac arteries. The accessory renal arteries which spring from the inferior phrenic, the spermatic, and lumbar arteries can only be the result of the persistence and enlargement of anastomosing channels between the renal and either another intermediate visceral, or a somatic artery.

The **spermatic or ovarian arteries** may be double on one or both sides; the arteries of opposite sides may spring from a common trunk, or they may rise from the renal or suprarenal arteries. The right artery may pass behind instead of in front of the inferior vena cava. The spermatic and ovarian arteries arise from the upper lumbar portion of the aorta, because the testicles and ovaries are developed in and obtain their arterial supply in that region, and the vessels are elongated as the testicles and ovaries descend to their permanent positions. The occurrence of two spermatic arteries on one side is probably an indication that the testicle was developed in at least two segments of the body, and the origin of a spermatic artery from a renal or suprarenal artery is due to the obliteration of the root of the original vessel and the enlargement of an anastomosis between the intermediate visceral arteries of adjacent segments.

The **cœliac axis** may be absent, its branches arising separately from the aorta or from some other source. Sometimes it gives off only two branches, usually the coronary and splenic, and occasionally it gives four branches, the additional branch being either a second coronary artery or a separate gastro-duodenal artery.

The **hepatic artery** may spring directly from the aorta or from the superior mesenteric artery, and the left hepatic artery occasionally arises from the coronary artery. Accessory hepatic arteries are not uncommon, and they originate either from the coronary, superior mesenteric, renal, or inferior mesenteric artery.

The **coronary artery** is occasionally double; it may spring directly from the aorta, and it may give off the left hepatic or an accessory hepatic artery.

The **splenic artery** may arise from the middle colic, from the left hepatic, or from the inferior mesenteric artery.

The **superior mesenteric artery** may be double, and it may supply the whole of the alimentary canal from the second part of the duodenum to the end of the rectum, the inferior mesenteric artery being absent. In addition to its ordinary branches it may give off a hepatic, a splenic, a pancreatic, a gastric, a gastro-epiploic or a gastro-duodenal branch. Very rarely it gives off an omphalo-mesenteric branch, which passes to the region of the umbilicus and becomes connected with capillary vessels in the falciform ligament of the liver.

The **inferior mesenteric artery** may give hepatic, renal, or middle colic branches; occasionally it is absent, being replaced by branches of the superior mesenteric, and sometimes, as in ruminants and some rodents, its left colic branch does not anastomose with the middle colic artery.

All these variations of the unpaired visceral branches of the abdominal aorta are merely due to modifications of the usual processes by which these vessels are developed.

The origin of the branches which usually rise from the cœliac axis, from the trunk of the aorta is the result of the retention of a greater number of the splanchnic segmental arteries than usual. A double superior mesenteric artery results from the persistence of both the right

and left splanchnic vessels from which the superior mesenteric artery is formed, these remaining separate instead of fusing together. All the other variations are the results of the obliteration of the usual channels, combined with the enlargement of anastomoses which exist both between the splanchnic arteries of adjacent segments and the splanchnic and intermediate visceral arteries.

## The Arteries of the Head and Neck.

**Innominate Artery.**—From what has already been said with reference to the branches of the arch of the aorta, it will be seen that the innominate artery may be absent. On the other hand there may be two innominate arteries, a right and a left, each ending in corresponding common carotid and subclavian trunks, and the two vessels may themselves arise by a common stem.

The branches given off by the innominate artery may be increased in number, or the innominate may only vary from the normal as regards length. As a consequence of such modifications in length, the origins of the right common carotid and right subclavian arteries may be situated at a higher or lower level than usual, whilst, in the absence of the innominate artery, both these branches may arise directly from the aorta.

**Common Carotid Arteries.**—When the right common carotid artery arises separately from the arch of the aorta, it may be the first, or much more rarely the second branch. In the former case the fourth right aortic arch has been obliterated, and the right subclavian artery springs from the descending aorta; in the latter case either the innominate stem has been absorbed into the arch of the aorta, or the ventral root of the fourth right aortic arch has fused with part of an elongated fourth left arch.

Whether arising as the first or second branch, the origin may be to the left of the mesial plane, and the trunk may pass in front of the trachea, or behind the œsophagus, before it ascends in the neck.

The left common carotid artery varies as regards its origin much more frequently than the right vessel; not uncommonly, and apparently because of the fusion of the ventral roots of the fourth aortic arches, it arises from a stem common to it and to the right common carotid and right subclavian arteries.

Both common carotids may vary as regards their termination. They may divide at a higher or lower level than usual, the former more commonly than the latter; whilst in a few exceptional cases the common carotid does not divide, but is continued directly into the internal carotid, and from this the branches usually given off by the external carotid are derived.

This arrangement is probably due to obliteration of the ventral roots of the first and second aortic arches, the arches persisting and being divided into the branches which generally arise from their ventral extremities.

Usually the common carotids give off no branches, but not infrequently one or more of the branches of the external carotids arise from them.

The **external carotid artery** may be absent, or it may, in rare cases, arise directly from the arch of the aorta. The number of its branches may be diminished either by fusion of their roots or by transference to the internal or common carotid arteries. On the other hand, the number of its branches may be increased; thus the sterno-mastoid artery, the hyoid branch usually given off by the superior thyroid artery, or the ascending palatine branch of the facial, may arise from it. Sometimes the branches may arise in the usual way, but may deviate from the course generally taken; more particularly is this the case with the internal maxillary artery, which may pass either between the heads or entirely external or internal to both heads of the external pterygoid muscle.

The **internal carotid artery** is rarely absent. Occasionally it springs from the arch of the aorta, and in its course through the neck it may vary somewhat in length and in tortuosity. One or more of the branches usually derived from the external carotid artery may arise from it, and it sometimes gives off a large meningeal branch to the posterior fossa of the skull. Its posterior communicating branch may replace the posterior cerebral artery; on the other hand, the upper part of the internal carotid may be absent, and the posterior communicating artery may become the middle cerebral artery. The anterior cerebral branch of the internal carotid may be absent, or rather it may arise from the corresponding artery of the opposite side; or there may be three anterior cerebral arteries, the third arising from the anterior communicating artery which connects the two anterior cerebrals together. The ophthalmic artery, as it traverses the orbit, may pass either over or under the optic nerve. It is occasionally replaced by a branch of the middle meningeal artery.

The **vertebral artery** may have a double origin—one from the subclavian, and one from the inferior thyroid artery or from the aorta.

The right vertebral may arise from the common carotid or from the arch of the aorta. Occasionally it springs from the descending aorta, an arrangement associated with the persistence of the dorsal roots of the fourth and fifth right arches.

The left vertebral artery not infrequently springs from the arch of the aorta, arising between the left common carotid and left subclavian arteries; this is evidently due to the absorption of the stem of the seventh segmental artery into the aortic arch. Very exceptionally the left vertebral is a branch of an intercostal artery.

In its course upwards either vertebral artery may enter the vertebrarterial foramen of any of the lower six cervical vertebra.

The cases in which it does not enter one of the lowest of these are apparently associated with its formation in part from the precostal instead of from the postcostal anastomosing channels.

The artery may enter the spinal canal with the second instead of with the first cervical nerve, or, after leaving the foramen in the transverse process of the third vertebra, it may divide into two branches, one of which accompanies the second and the other the first cervical nerve; the two branches unite together again in the spinal canal to form a single trunk.

Sometimes, though rarely, it gives off superior intercostal and inferior thyroid branches. The upper end of one of the vertebrals is sometimes very small, or it may be entirely wanting; in the latter case the basilar artery is formed by the direct continuation of the opposite vertebral.

The **basilar artery** may be double in part or the whole of its extent, or its cavity may be divided by a more or less complete septum. It may terminate in one instead of two posterior cerebral arteries, the missing vessel being supplied by the enlargement of the posterior communicating branch of the internal carotid.

## The Arteries of the Upper Limb.

**Subclavian Arteries.**—The variations, so far as regards the origins of the subclavian arteries, have already been mentioned (p. 947). Other interesting modifications are met with in respect of its position and branches.

The subclavian artery may reach as high as one or even one-and-a-half inches above the clavicle, though as a rule it does not reach higher than three-quarters of an inch above that bone. On the other hand, it may not rise even to the level of the upper border of the clavicle. These differences appear to be associated with the descent of the clavicle and sternum, which occurs as age increases.

The artery may pass in front of or through the scalenus anticus instead of behind it, or the vein may accompany it behind the muscle.

The branches of the subclavian artery may be modified with reference to their points of origin; thus those of the first part may be further in or out than usual, the suprascapular or some other branch of the thyroid axis may arise separately from the third part of the artery, and not uncommonly the posterior scapular artery is a branch of this part. The abnormalities of the vertebral branch have already been described; those of the thyroid axis and its branches are numerous but not important.

The **internal mammary artery**, usually a branch of the first part of the subclavian, is very variable as regards its origin. It may arise from the second or third parts, or from the thyroid axis, or it may spring from the aorta, or from the innominate or axillary arteries. All these variations are due to obliteration of the normal origin and the opening up of anastomoses. The internal mammary artery sometimes descends in front of the cartilages of one or more of the lower true ribs, and occasionally it gives off a large lateral branch (a. mammaria lateralis) which descends on the inner side of the chest wall nearly in the mid-axillary line, a point of importance in paracentesis.

A few cases have also been noticed in which a bronchial artery has arisen from the internal mammary.

The **superior intercostal branch** of the subclavian may be absent. In any case its deep cervical branch may rise directly from the subclavian trunk. The superior intercostal is sometimes formed from a postcostal instead of a precostal primitive channel, and in this case it passes between the necks of the ribs and the transverse processes of the vertebræ instead of, as usual, in front of the necks of the ribs.

The **axillary artery** does not vary much as regards its origin or course. Its relations may be modified by the existence of a muscular or tendinous "axillary arch," which, passing from the latissimus dorsi to the pectoralis major, crosses the lower part of the artery superficially; and a further interesting modification is associated with an anomalous arrangement of its branches. Occasionally the sub-scapular, circumflex, and superior and inferior profunda arteries arise from the axillary by a common stem. In these cases the chief branches of the brachial plexus are grouped round the common stem instead of round the main trunk, and it is suggested that the common stem in question was originally the trunk artery of the upper limb, the lower part of which has been obliterated, the circulation being carried on by a vas aberrans which anastomoses below either with the brachial artery or with one of the arteries of the forearm. It is also said that a rudiment of this artery exists in a muscular branch which passes between the heads of the median nerve.

Sometimes the axillary artery divides into the radial and ulnar arteries, and more rarely the interosseous artery may spring from it.

Obviously when the radial and ulnar arteries are formed by the division of the axillary, there is no brachial artery; its place is taken by the two abnormal vessels which, as a rule, are separated by the median nerve as they run through the upper arm; the radial is usually more superficial than the ulnar, and crosses outwards in front of it at the bend of the elbow.

The **brachial artery** is rarely prolonged beyond its usual point of bifurcation, not uncommonly, however, it bifurcates at a higher level. Of the two terminal branches of the brachial, one may divide into radial and interosseous, the other forming the ulnar; or one may divide into radial and ulnar, whilst the other is the interosseous artery. Occasionally the brachial artery terminates by dividing into three branches—viz. the radial, the ulnar, and the interosseous. In any case, the branch which gives origin to or becomes the interosseous was in all probability the original trunk.

Division of the brachial artery at a higher level than usual occurs most commonly in the upper third of the arm, and least commonly in the lower third; the resulting trunks are often united near the bend of the elbow by a more or less oblique anastomosis.

In cases of high division of the brachial artery the radial branch may pierce the deep fascia of the arm near the bend of the elbow, and descend in the forearm immediately beneath the skin; in other cases the radial runs deeper, and passes behind the tendon of the biceps. The ulnar branch sometimes runs, on the internal intermuscular septum, towards the inner condyle, and then outwards towards the middle of the bend of the elbow under a band of fascia, from which the upper fibres of the pronator teres arise, or round the supracondylar process of the humerus if it is present. More commonly the ulnar branch descends towards the inner condyle, and crosses superficial to the flexor muscles or beneath the palmaris longus; and in a few cases it is subcutaneous. Very occasionally the ulnar artery accompanies the ulnar nerve behind the inner condyle; in these cases it has obviously been formed by enlargement of the ordinary inferior profunda and posterior ulnar recurrent arteries.

Instead of following its usual course along the brachialis anticus, the brachial artery may accompany the median nerve behind a supracondylar or epicondylic process, or ligament, as in many carnivores; it may pass in front of the median nerve instead of behind it. It may give off a "vas aberrans" or a median artery, and any of its ordinary branches may be absent.

The vas aberrans given off from the brachial artery usually ends in the radial artery, sometimes in the radial recurrent, and rarely in the ulnar artery.

The **ulnar artery** may be absent, being replaced by the "comes nervi mediani" or the interosseous artery, and it may terminate in the deep instead of in the superficial palmar arch. It rarely rises at a lower level than usual, and when it rises at a higher level it most commonly passes superficial to the muscles which spring from the internal epicondyle. Moreover, in these cases it frequently has no interosseous branch, the latter vessel springing from the radial artery, and in all probability variations of this description are produced by the ulnar artery taking origin from the main trunk, which is represented by the radio-interosseous vessel, at a higher level than usual. Even when it commences in the usual way the ulnar artery may pass superficial to the muscles from the internal epicondyle, and in these cases its interosseous and recurrent branches spring from the radial artery.

The anterior and posterior interosseous arteries may arise separately from the ulnar instead of by a common interosseous trunk. The recurrent branches of the ulnar may spring from the interosseous, and the interosseous itself may be a branch of the radial.

The small median artery, the companion artery of the median nerve, usually a branch of the anterior interosseous, may spring from the axillary, brachial, or ulnar arteries; it may be much larger than usual, and terminate either by breaking up into digital branches, or by joining one or more digital branches of the superficial palmar arch or the palmar arch itself.

The **radial artery** may be absent, its place being taken by branches of the ulnar or interosseous arteries; it may arise from the axillary, or, higher than usual, from the brachial. It may terminate in muscular branches in the front of the forearm, or in the superficialis volæ, or in carpal branches; the lower portion of the artery, in these cases, is usually replaced by branches of the ulnar or interosseous arteries. Occasionally the radial divides some distance above the wrist into two terminal branches, one of which gives off the carpal branches, and becomes the superficialis volæ, whilst the other crosses superficial to the extensor tendons and passes to the back of the wrist.

The radial artery may run a superficial course, or, and especially when it commences at a lower level than usual, it may pass beneath the pronator radii teres and the radial origin of the flexor sublimis digitorum. In some cases it passes to the back of the wrist across the supinator longus, and in others it lies upon, instead of beneath, the extensor tendons of the thumb.

Its branches may be diminished or increased in number. The radial recurrent may spring from the brachial or ulnar arteries, or may be represented by several branches from the upper part of the radial. The dorsalis indicis may be large, and may replace the princeps pollicis and the radialis indicis. On the contrary, the dorsal carpal artery and dorsal digital branches of the radial may be small, or the former may be replaced by branches of the interosseous arteries, and the latter by the superior perforating branches of the deep palmar arch.

The **princeps pollicis** and **radialis indicis** arteries may be absent, their places being taken either by branches of the superficial palmar arch or by the dorsalis indicis artery.

The **superficial palmar arch** is sometimes absent; its branches are then given off from the deep arch. Conversely, it may be larger than normal, and it may be completed on the ulnar side by the radialis indicis, the princeps pollicis, or the comes nervi mediani arteries.

The **deep palmar arch** is much more rarely absent than the superficial arch. When absent its branches are supplied by the superficial arch, the superior perforating arteries, or the palmar carpal arch.

## The Iliac Arteries and their Branches.

The **common iliac artery** may be longer or shorter than usual, a modification which is largely though not altogether determined by the point at which the bifurcation of the aorta takes place. If exceptionally long, it is usually tortuous. In rare cases in man the artery is absent. It occasionally gives off the middle or a lateral sacral artery, and ilio-lumbar, spermatic, or accessory renal branches may arise from it.

The **internal iliac artery** varies as regards length. It is usually longer, and rises at a higher level when the common iliac is short. In rare cases it has been found to arise from the

aorta without the intervention of a common iliac. Frequently it does not, even in appearance, end in anterior and posterior divisions, but obviously forms a single trunk, as in the fœtus, from which the several branches are given off.

The visceral branches vary much in number and size, and the middle hæmorrhoidal may not be present, its place being taken by branches from the vesical arteries. A renal branch sometimes arises from the internal iliac.

The ilio-lumbar branch may rise from the common instead of from the internal iliac; the gluteal and sciatic may rise by a common stem, or the gluteal may be absent, and its place taken by a branch from the femoral artery; the sciatic artery may, as in the fœtus, constitute the main artery of the hind limb, and run down to become continuous with the popliteal artery. Probably the "comes nervi ischiadici" represents the original continuity of these two vessels. Occasionally the lateral sacral arteries do not arise from the internal iliac trunks.

In some few instances the **obturator artery** arises from the deep epigastric artery instead of from the internal iliac. The condition is apparently due to obliteration of the usual origin of the obturator artery and to the subsequent enlargement of the anastomosing pubic branches of the obturator and deep epigastric arteries. The course of the abnormal obturator artery is of importance. From its origin it descends into the pelvis on the inner side of the external iliac vein, and in the majority of cases on the outer side of the crural ring, but in three-tenths of the cases, and more frequently in males than in females, it descends on the inner side of the ring.

The obturator artery sometimes gives off an accessory pudic branch which passes along the side of the prostate, pierces the triangular ligament, and terminates by dividing into the artery of the corpus cavernosum and the dorsal artery of the penis. When this occurs the pudic artery is small, and it terminates in the artery to the bulb. Occasionally the accessory pudic arises from the pudic artery in the pelvis, or from one of the vesical arteries.

The **external iliac artery** may be much smaller than usual, especially if the sciatic artery persists as the main vessel of the lower limb. It may give off two deep circumflex iliac branches, a dorsal artery of the penis, an internal circumflex artery of the thigh, or a vas aberrans, and its deep circumflex iliac and deep epigastric branches may arise at higher or lower levels than usual.

## The Arteries of the Lower Limb.

The **femoral artery** is small, and ends in the profunda and circumflex branches, when the sciatic artery forms the principal vessel of the lower limb. The profunda branch, which usually arises from the outer side of the femoral trunk, about one-and-a-half inches below Poupart's ligament, may commence at a higher or a lower level, and from the back or the inner side of the femoral trunk. Absence of the profunda has been noted, and in these cases the branches usually given off by it spring directly from the femoral artery.

The femoral artery may be double for a portion of its extent, or it may be joined by a vas aberrans given off from the external iliac artery. In addition to its ordinary branches, it may furnish one or both of the circumflex arteries of the thigh, and sometimes it gives off, near the origin of the profunda, a great saphenous artery, such as exists normally in many mammals. This vessel descends through Scarpa's triangle and Hunter's canal, and accompanies the internal saphenous nerve to the inner side of the foot.

The deep circumflex iliac, the obturator, and the deep epigastric arteries are occasionally given off from the femoral.

The **popliteal artery** may exceptionally form the direct continuation of the sciatic artery. It sometimes divides at a higher or lower level than usual, and the division may be into either two or three branches; if three terminal branches are present, they are the anterior and posterior tibial and the peroneal arteries, and if only two, either the anterior and posterior tibial, or the anterior tibial and the peroneal arteries.

Occasionally the artery is double for a short portion of its course, and it has been found to cross first behind the inner head of the gastrocnemius to the inner side of the knee, and then in front of the inner head of the gastrocnemius to regain the popliteal space. The number of its branches may be reduced, or they may be increased by the addition of a vas aberrans which connects it with the posterior tibial artery. Its superficial sural branch may enlarge to form a well-marked small saphenous artery.

The **posterior tibial artery** may be small or altogether absent, its place being taken by branches of the peroneal artery; again, it may be longer or shorter than usual, in conformity with the higher or lower division of the popliteal trunk. The peroneal artery is large if either the anterior or posterior tibial arteries are small. The anterior terminal branch of the peroneal is almost invariably large when the anterior tibial artery is small; in some cases, indeed, it replaces the whole of the dorsalis pedis continuation of the latter vessel; in others, however, only the tarsal and metatarsal branches are so replaced. The peroneal sometimes arises from a stem common to it and the anterior tibial artery.

The **anterior tibial artery** may be absent, its place being taken by branches of the posterior tibial and peroneal arteries. It is longer than normal when the popliteal artery divides at a higher level than usual, and in these cases it may pass either behind or in front of the popliteus muscle. Occasionally the anterior tibial artery and its dorsalis pedis continuation are larger than normal, and the terminal part of the dorsalis pedis takes the place, more or less completely, of the external plantar artery.

The **internal plantar artery** is sometimes very small, and it may be absent; its place is

taken by branches of the dorsalis pedis or external plantar arteries. The **external plantar artery** also may be small or absent, the plantar arch being formed entirely by the dorsalis pedis.

## ABNORMALITIES OF VEINS.

Abnormalities or variations of veins are as frequently met with as those of arteries, and they are due to similar causes.

### The Superior Vena Cava.

The **superior vena cava** may develop on the left side instead of the right. This peculiarity is due to the persistence of the left duct of Cuvier instead of that on the right side, and it is associated with absence of the coronary sinus, which is replaced by the lower part of the left superior vena cava. An exceptional case is recorded in which the opening of the coronary sinus into the heart was obliterated, and the cardiac veins terminated in a trunk which passed upwards to the left innominate vein. This trunk was obviously formed by enlargement of the left duct of Cuvier and the lower part of the left primitive jugular vein. Not very uncommonly, as the result of the persistence of both ducts of Cuvier, there are two superior venæ cavæ, the transverse anastomosis which usually forms the left innominate vein being small or entirely absent. In these cases the left innominate vein descends in the left part of the superior mediastinum, crosses the aortic arch, is joined by the left superior intercostal vein, and becomes the left superior vena cava; this latter vessel descends in front of the root of the left lung, and terminates in the lower and back part of the right auricle. It receives the great cardiac vein, and, turning to the back of the heart, replaces the coronary sinus. This arrangement is normal in many mammals. Occasionally in man the left superior vena cava terminates in the left auricle, and the coronary sinus, which represents a part of the sinus venosus, has been seen to have a similar ending; both these abnormal endings must be the result of malposition of the interauricular septum.

The vena azygos major may be formed on the left side; it then arches over the root of the left lung, and terminates in the left end of the coronary sinus. This is the normal arrangement in some mammals, and it is due to the persistence of the left cardinal vein and the left duct of Cuvier.

The **azygos veins** may be reduced or increased in number. In the former case there may be only one azygos vein which receives the intercostal veins of both sides, or there may be two azygos veins, a right and a left, the left usually being divided into upper and lower sections which are connected by a smaller intermediate portion, and united to the right vein by one or more transverse anastomoses, or it may terminate by joining either the left innominate vein or the left superior vena cava. The small intermediate section on the left side may form a separate vessel, and then the number of the azygos veins is increased to four, each of the three left veins terminating in the right vein. When there is only one azygos vein the portion of the left cardinal vein, from which, usually, the vertical portions of the left azygos veins are formed, has disappeared, and the left intercostal veins open into the right azygos vein by separate transverse anastomoses, as in the case of the left lumbar veins and the inferior vena cava. On the other hand, when there is only one left azygos vein the intermediate sections of the thoracic part of the left cardinal vein and one or more of the transverse anastomoses have persisted, whilst, when the left azygos terminates in the left innominate vein, the transverse anastomoses have disappeared, and the lower part of the left primitive jugular vein has remained patent.

Occasionally the vena azygos major takes the place of the upper part of the inferior vena cava, and the whole of the left cardinal vein is enlarged; in these cases the upper portion of the normal inferior vena cava is absent or exceptionally small.

The **internal jugular vein** is sometimes smaller or larger than normal. In either case compensatory changes in size occur in the lateral sinus and internal jugular vein of the opposite side, or in the external and anterior jugular veins of the same side.

The **external jugular vein** is sometimes absent, or it may be smaller than usual; in both cases either the anterior or internal jugular veins are enlarged. In some of the cases in which the external jugular vein is small it receives no communication from the temporo-maxillary vein, but is merely the continuation of the posterior auricular vein. On the other hand, it may be enlarged, and receive the whole of the temporo-maxillary vein.

The **anterior jugular vein** may be absent, or it may be unusually large, especially in the lower part of its extent, and after it has received an occasional tributary from the common facial vein.

The **temporo-maxillary vein** may terminate entirely in the common facial vein, or in the external or the internal jugular vein. It may be very small, and occasionally it is absent.

Variations of the **cranial blood sinuses** are not numerous. One lateral sinus may be absent or very small when, as a rule, that of the opposite side is enlarged. The inferior longitudinal, the occipital, or the spheno-parietal sinuses may be absent, and there may be an additional petro-squamous tributary to the lateral sinus. The petro-squamous sinus, when present, is the remains of that portion of the primitive lateral sinus which crossed the temporal bone, passed through the post-condyloid foramen and terminated in the primitive jugular vein. Very occasionally in the human adult it still pierces the skull behind the condyle of the jaw, and terminates in the temporo-maxillary vein, and this is the normal arrangement in some mammals.

### The Veins of the Upper Extremity.

The **superficial veins** of the forearm are extremely variable; any of them may be absent, but most commonly it is the median or the radial vein which is wanting. The median cephalic and the cephalic veins may be small or absent, and on the other hand the cephalic vein may be larger than usual. Moreover the cephalic vein may end in the external jugular vein, its original termination; or it may be connected with the external jugular vein by an anastomosing channel which sometimes passes over the clavicle and sometimes through that bone.

The basilic vein is sometimes larger and sometimes smaller than usual, and it may pierce the fascia of the arm at a higher or at a lower level than is customary.

The **venæ comites** of the arteries of the upper extremity generally terminate at the lower border of the subscapularis, where they join the axillary vein, but they may end above or below the position of their usual termination.

The **subclavian vein** sometimes passes behind instead of in front of the scalenus anticus muscle, and it has been seen passing between the clavicle and the subclavius muscle.

### The Inferior Vena Cava.

The lower part of the inferior vena cava is sometimes absent, in which case the common iliac veins ascend, one on the right and the other on the left of the aorta, to the level of the second lumbar vertebra, where the left common iliac vein receives the left renal vein, and then crosses in front of or behind the aorta to fuse with the right corresponding vein; in these cases, therefore, the inferior vena cava commences at the level of the second lumbar vertebra, and it represents only the upper and last-formed part of the ordinary vessel; the common iliac veins, each of which receives the lumbar veins of its own side, are exceptionally long, and they may or may not be united at the pelvic brim by a small transverse anastomosing channel.

Occasionally the inferior vena cava does not terminate in the right auricle, but is continuous with the vena azygos major, which is much enlarged, all the inferior caval blood being then carried to the superior vena cava. In these cases the hepatic veins open directly into the right auricle without communicating with the inferior vena cava.

The lower part of the inferior vena cava sometimes lies to the left instead of to the right of the aorta; this condition is associated with a long right common iliac vein, which crosses obliquely from right to left to join the shorter left common iliac vein. After receiving the left renal vein the misplaced inferior vena cava crosses in front of the aorta, reaching the right side at the level of the second or first lumbar vertebra. In other cases, however, the left inferior vena cava continues upwards through the left crus of the diaphragm, usurping the place of a greater or smaller part of the left azygos vein; having entered the thorax, it may cross to the opposite side and terminate in the vena azygos major, or it may continue upwards on the same side, and after arching over the root of the left lung, descend behind the left auricle, to terminate in the right auricle in the situation of the coronary sinus. In this group of cases also the hepatic veins open separately into the right auricle.

The tributaries of the inferior vena cava are also subject to variation. Additional renal, spermatic, ovarian, or suprarenal veins may be present. Two or three lumbar veins of one or both sides may unite into a common trunk which terminates in the inferior vena cava, and the hepatic veins may open separately, or after fusing into a common trunk, into the right auricle near the opening of the inferior vena cava.

No explanation of the variations of the inferior vena cava and its tributaries is necessary, beyond the statement that they are due to persistence of portions of the cardinal veins which usually disappear, and to the persistence of transverse anastomoses and tributaries which usually atrophy, or to modifications of those which ordinarily take part in the formation of the inferior vena caval system.

The **left common iliac vein** is short and the right long when the inferior vena cava lies on the left side. The common iliac veins may be absent, the internal iliac veins uniting to form the commencement of the inferior vena cava, into which the external iliac veins open as lateral tributaries.

### The Veins of the Lower Extremity.

The **long saphenous vein** is not subject to much variation, but the **short saphenous vein** may terminate by joining the long saphenous, or, after piercing the deep fascia in the lower part of the thigh, it may ascend and join the sciatic vein or one of the tributaries of the profunda vein.

The **venæ comites** are generally described as terminating in the lower extremity, at the lower part of the popliteal space, but they may ascend as far as Scarpa's triangle; as a matter of fact, although as a rule there is only one large popliteal and one large femoral vein, one or more small additional veins usually accompany the popliteal and femoral arteries.

In a few cases the popliteal vein does not pierce the lower part of the abductor magnus, but ascends behind that muscle and becomes continuous with the profunda vein, the femoral artery being unaccompanied by any large vein during its passage through Hunter's canal.

## ABNORMALITIES OF THE LYMPHATICS.

Variations of the glands and smaller vessels of the lymphatic system are so common that they can hardly be regarded as abnormalities; variations of the larger vessels, however, are

comparatively rare. This is especially the case with respect to the two terminal trunks, the thoracic duct and the right lymphatic duct, the abnormalities of which are interesting and important.

When the arch of the aorta is on the right instead of on the left side, the thoracic duct usually terminates in the right innominate vein, in which case it receives the tributaries which usually open into the right lymphatic duct, whilst the corresponding area on the left side is drained by lymphatics terminating in a left lymphatic duct which opens into the commencement of the left innominate vein. A similar arrangement of the terminal lymphatic trunks sometimes occurs even when the arch of the aorta is in its normal position on the left side. In either case the thoracic duct may commence in the usual way, and after reaching the level of the fifth dorsal vertebra continue upwards on the right side, instead of crossing to the left side, of the vertebral column; more rarely it commences on the left side and crosses over to the right at a higher level.

In one case in which the thoracic duct opened into the right innominate vein, instead of the left, no trace of a lymphatic duct was discovered on the left side.

Occasionally the thoracic duct commences and terminates in the usual manner, but crosses the vertebral column immediately after its origin and ascends on the left side.

Not uncommonly there is no distinct receptaculum chyli, in which case the terminal lymphatic vessels of the abdomen merely unite to form a larger vessel which does not present any obvious dilatation, and from which the thoracic duct is continued. The terminal lymphatic trunk may open into the internal jugular vein previous to its junction with the subclavian, instead of into the commencement of the innominate vein.

Occasionally the thoracic duct is double, either on the whole or in part of its extent, and sometimes it breaks up into a plexus of vessels which may reunite into a single trunk in the upper part of the thorax. Both the thoracic duct and the right lymphatic duct may before terminating divide into branches which, though sometimes reuniting on each side into a single trunk, not infrequently open separately into the great veins at the root of the neck.

As a rule the thoracic duct joins the commencement of the left innominate vein, but it may end in the internal jugular, vertebral, or subclavian veins of the left side; whilst very rarely, it opens into the vena azygos major.

# THE RESPIRATORY SYSTEM.

## THE ORGANS OF RESPIRATION AND VOICE

By D. J. Cunningham.

The organs of respiration are the larynx and trachea, which together constitute a median air-passage; the two bronchi or branches into which the lower end of the trachea divides; and the two lungs to which the bronchi conduct the air. In connexion with the lungs we have likewise to consider the pleural membranes—two serous sacs which line the portions of the thoracic cavity which contain the lungs, and at the same time give a thin coating to these organs.

The larynx opens above into the lower part of the pharynx, and the air which passes in and out from the air-passages likewise traverses the pharynx, the nasal fossæ, and also the buccal cavity if the mouth is open. This connexion between the digestive and respiratory systems is explained by the fact that the respiratory apparatus is secondarily developed as an outgrowth from the front aspect of the primitive fore-gut of the embryo. In most mammals the upper aperture of the larynx opens into the part of the pharynx which lies behind the nasal chambers. In man, however, the upper opening of the larynx is placed lower down, below the communication between the mouth and pharynx, and both nasal and buccal breathing may be carried on with very nearly equal ease.

### THE LARYNX OR ORGAN OF VOICE.

The larynx is the upper part of the air-passage, specially modified for the production of the voice. Above, it opens into the pharynx, whilst below, its cavity becomes continuous with the lumen of the trachea or windpipe.

**Position and Relations of the Larynx.**—In the natural position of the neck, and whilst the organ is at rest, the larynx is placed in front of the bodies of the fourth, fifth, and sixth cervical vertebræ. Its highest point, represented by the tip of the epiglottis, reaches as high as the lower border of the body of the third cervical vertebra, whilst its lower limit, or the lower border of the cricoid cartilage usually corresponds to the lower border of the body of the sixth cervical vertebra. From the vertebral column the larynx is separated, not only by the prevertebral muscles and prevertebral layer of cervical fascia, but also by the posterior wall of the pharynx—indeed the posterior surface of the larynx forms the lower part of the anterior wall of the pharynx, and is covered by the lining mucous membrane of that section of the alimentary canal.

The larynx lies below the hyoid bone and the tongue, and in the interval between the great vessels of the neck. It forms a more or less marked projection on the front of the neck, and in the median line it approaches very close to the surface, being merely covered by skin and the two layers of fascia. Laterally it is more deeply placed. Thus it is overlapped by the sterno-mastoid muscle, covered by the two strata of thin ribbon-like muscles which are attached to the thyroid cartilage and the hyoid bone, and hidden to some extent by the upward prolongations of the lateral lobes of the thyroid body.

The position of the larnyx is influenced by movements of the head and neck. Thus it is elevated when the head is thrown back, and depressed when the chin is carried

downwards towards the chest. Again, if the finger is placed upon it during deglutition, it will be seen that the larynx moves to a very considerable extent. The pharyngeal muscles attached to it, and more especially the stylo-pharyngeal muscles, are chiefly responsible for bringing about these movements. During singing, changes in the position of the larynx may also be noted, a high note being accompanied by a slight elevation, and a low note by a slight depression of the organ.

The position of the larynx is not the same at all periods of development and growth. In the fœtus, shortly before birth, it lies much higher up in the neck. Thus its lower border corresponds to the lower border of the fourth cervical vertebra. Its permanent position is not reached until the period of puberty is attained (Symington). This descent of the larynx has been stated to be due to the rapid and striking growth of the facial part of the skull which lies above it (Symington). It is very doubtful, however, if the facial growth has any influence in this direction. In the anthropoid ape, in which the face forms a much greater part of the skull than in man, and in which, in the transition from the infantile to the adult condition, the facial growth is even more striking than it is in man, the larynx occupies a relatively higher position in the neck. In the early stages of growth all the thoracic viscera undergo a gradual subsidence. The larynx in its descent follows these. Indeed it cannot do otherwise, seeing that the bifurcation of the trachea between infancy and puberty moves downwards more than the depth of one thoracic vertebra.

**General Construction of the Larynx.**—The wall of the larynx is constructed upon a somewhat complicated plan. There is a frame-work composed of several cartilages. These are connected together at certain points by distinct joints and also by elastic membranes. Two elastic cords, which stretch in an antero-posterior direction from the front to the back wall of the larynx, form the ground-work of the true vocal cords. Numerous muscles are likewise present. These operate upon the cartilages of the larynx, and thereby not only bring about changes in the relative position of the true vocal cords, but also produce different degrees of tension of these cords. The cavity of the larynx is lined with mucous membrane, under which, in certain localities, are collected masses of mucous glands.

## CARTILAGES OF THE LARYNX.

There are three single cartilages and three pairs of cartilages entering into the construction of the laryngeal wall. They are named as follows:—

Single cartilages { Thyroid. Cricoid. Epiglottis.

Paired cartilages { Arytenoid. Cornicula laryngis, or the cartilages of Santorini. Cuneiform cartilages.

**Thyroid Cartilage** (cartilago thyreoidea).—The thyroid cartilage, the largest of the laryngeal cartilages, is formed of two quadrilateral plates termed the **alæ**, which meet in front at an angle, and become fused along the mesial plane. Behind, the alæ diverge from each other, and enclose a wide angular space which is open behind. The *anterior borders* of the alæ are only fused in their lower parts. Above they are separated by a deep, narrow V-shaped median notch, called the **incisura thyroidea**. In the adult male the angle formed by the meeting of the anterior borders of the two alæ, especially in its upper part, is very projecting, and with the margins of the thyroid notch, which lies above, constitutes a marked subcutaneous prominence in the neck, which receives the name of the **pomum Adami**.

The angle which is formed by the meeting of the two alæ of the thyroid cartilage varies to some extent in different individuals of the same sex, and shows marked differences in the two sexes and at different periods of life. In the adult male the average angle is said to be 90°: in the adult female it is 120°; whilst in the infant the alæ meet in the form of a gentle curve convex to the front.

The *posterior border* of each ala of the thyroid cartilage is thick and rounded, and is prolonged beyond the superior and inferior borders in the form of two slender cylindrical processes, termed cornua. The **superior cornu** is longer than the inferior cornu. It is directed upwards, with a slight inclination inwards and backwards, and it ends in a rounded extremity, which is joined to the tip of the great cornu of

the hyoid bone by the lateral thyro-hyoid ligament. The **inferior cornu** is shorter and stouter than the superior cornu. As it proceeds downwards it curves slightly inwards, and upon the inner face of its extremity it shows a circular flat facet, by means of which it articulates with a similar facet on the lateral aspect of the cricoid cartilage. The *superior border* of the ala is for the most part slightly convex, and in front it dips suddenly down to become continuous with the margin of the thyroid notch. Posteriorly, where it joins the superior cornu, it exhibits a shallow notch or concavity. The *inferior border* is to all intents and purposes horizontal, but it is marked off by a projection, termed the **inferior tubercle**, into a short posterior part, which shows a shallow concavity in front of the inferior cornu, and a longer part which lies in front of the tubercle, which is also concave, but to a less degree. The *external surface* of the ala is divided into two unequal areas by an **oblique line** or ridge. This line begins above at the **superior tubercle**, a prominence situated immediately below the superior border, and a short distance in front of the root of the superior cornu. From this the oblique line proceeds downwards and forwards, to end inferiorly in the inferior tubercle on the lower border of the ala. The area which lies behind the oblique line is much smaller than that which lies in front. It is covered by the inferior constrictor muscle of the pharynx. The larger anterior area is for the most part covered by the thyro-hyoid muscle. To the oblique line are attached the sterno-thyroid and thyro-hyoid muscles. The *inner surface* of the ala of the thyroid cartilage is smooth and slightly concave.

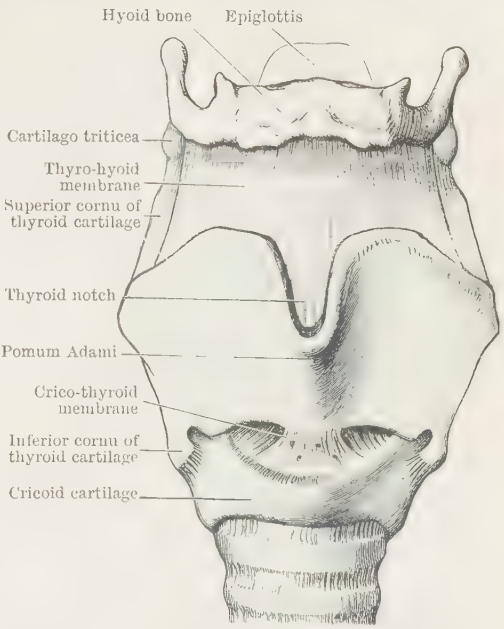

FIG. 680.—THE CARTILAGES AND LIGAMENTS OF THE LARYNX VIEWED FROM THE FRONT.

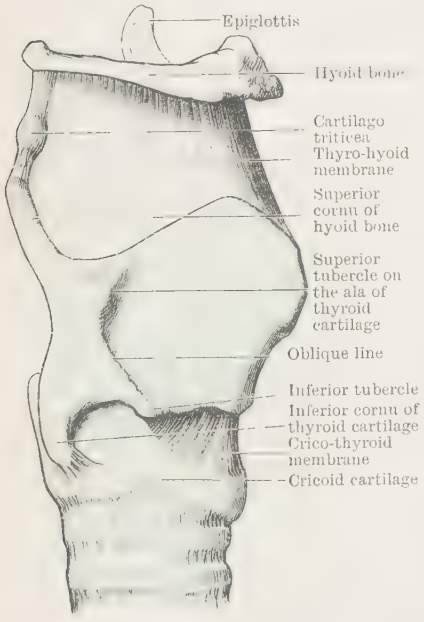

FIG. 681.- PROFILE VIEW OF THE CARTILAGES AND LIGAMENTS OF THE LARYNX.

**Cricoid Cartilage** (cartilago cricoidea).—The cricoid cartilage is shaped like a signet-ring. Behind, there is a broad, thick plate somewhat quadrilateral in form and termed the **posterior lamina**; whilst in front and laterally, the circumference of the ring is completed by a curved band, called the **anterior arch**. The lumen of the ring enclosed by these parts is circular below, but above the ring is compressed laterally, so that the lumen becomes elliptical. The superior border of the **posterior lamina** presents a faintly-marked median notch. On either side of this there is an oval convex facet which looks more outwards than upwards, and which articulates with the base of the arytenoid cartilage. The posterior surface of the lamina is divided by an elevated median ridge into two depressed areas which give attachment to the posterior crico-arytenoid muscles. The front part of the **anterior arch** of the cricoid is in the form of a narrow band, but as it proceeds backwards towards the posterior

lamina its superior border rises rapidly, and in consequence the arch becomes much broader. The *inferior border* of the cricoid is nearly horizontal, although it frequently presents a median projection in front, and a lateral projection on either side. It is joined to the first ring of the trachea by an intervening elastic membrane. On the *outer surface* of the cricoid cartilage, at the place where the anterior arch joins the posterior lamina, a vertical ridge descends from the arytenoid articular facet. On this, a short distance from the lower border of the cartilage, a prominent circular articular facet is visible for articulation with the inferior cornu of the thyroid cartilage (Fig. 683, p. 963). The *inner surface* of the cricoid cartilage is smooth, and is lined by mucous membrane.

The narrow band-like part of the anterior arch of the cricoid cartilage lies below the lower border of the thyroid cartilage, whilst the posterior lamina is received into the interval between the posterior portions of the alæ of the thyroid cartilage.

**Arytenoid Cartilages** (cartilagines arytænoideæ).—The arytenoid cartilages are placed one on either side of the mesial plane, and rest upon the upper border of the posterior lamina of the cricoid cartilage, in the interval between the posterior portions of the alæ of the thyroid cartilage. They present a somewhat pyramidal form. The pointed **apex** or summit of each is directed upwards, and at the same time curves backwards and inwards. It supports the corniculum laryngis. Of the three surfaces, one looks directly inwards towards the corresponding surface of the opposite cartilage, from which it is separated by a narrow interval; another looks backwards; whilst the third is directed outwards and forwards. The *internal surface*, which is the smallest of the three, is triangular in outline. It is narrow, vertical, and even, and is clothed by the lining mucous membrane of the larynx. The *posterior surface* is smooth and concave from above downwards; it lodges and gives attachment to the arytenoideus transversus muscle. The *antero-external* surface is the most extensive of the three (Fig. 683, p. 963). Its middle part is marked by a deep depression in which is lodged a mass of mucous glands. Upon this surface of the arytenoid cartilage the powerful thyro-arytenoid muscle is inserted, whilst a small tubercle a short distance above the base gives attachment to the superior thyro-arytenoid ligament—the feeble supporting ligament of the false vocal cord. The three surfaces of the arytenoid cartilage are separated from each other by an anterior, a posterior, and an external border. The *external border* is the longest, and it pursues, as it is traced from the apex to the base, a sinuous course. Reaching the base of the cartilage, it is prolonged outwards and backwards in the form of a stout prominent angle or process, termed the **processus muscularis**. Into the front of this process is inserted the crico-arytenoideus lateralis muscle; whilst into its posterior aspect the crico-arytenoideus posticus muscle is inserted. A small nodule of yellow elastic cartilage, called the **sesamoid cartilage**, is frequently found on the external border of the arytenoid cartilage, where it is held in position by the investing perichondrium. The *anterior border* of the arytenoid is vertical, and at the base of the cartilage is

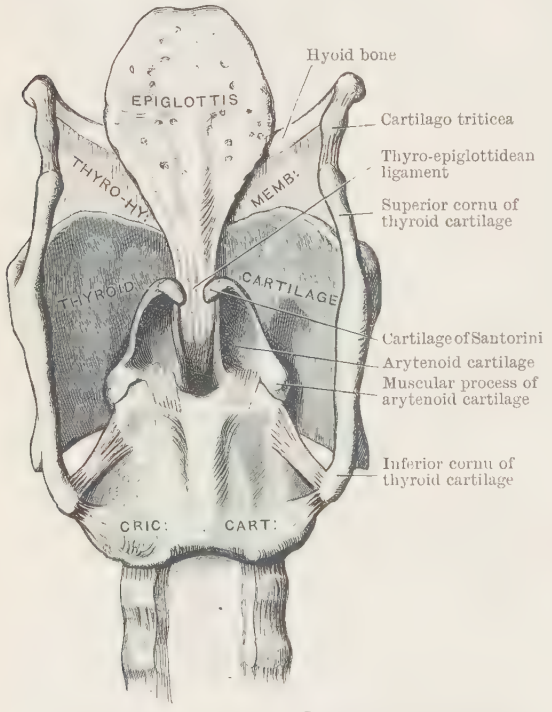

FIG. 682.—CARTILAGES AND LIGAMENTS OF LARYNX, as seen from behind.

prolonged horizontally forwards into a small sharp-pointed process called the **processus vocalis**. It receives this name because it gives attachment to the inferior thyro-arytenoid ligament or supporting band of the true vocal cord. The **base** of the arytenoid cartilage presents on its under surface, and more particularly on the under surface of the processus muscularis, an elongated concave facet for articulation with the upper border of the posterior lamina of the cricoid cartilage.

**Cartilages of Santorini** (cartilagines corniculatæ).—The cartilages of Santorini, or the cornicula laryngis, are two minute conical nodules of yellow elastic cartilage which surmount the apices of the arytenoids, and prolong the upper curved ends of these cartilages in a backward and inward direction. Each cartilage of Santorini is enclosed within the posterior part of the corresponding aryteno-epiglottidean fold of mucous membrane.

**Cuneiform Cartilages** (cartilagines cuneiformes).—The cuneiform cartilages are not invariably present. They are two minute rod-shaped pieces of yellow elastic cartilage, each of which occupies a place in the corresponding aryteno-epiglottidean fold of mucous membrane immediately in front of the arytenoid cartilage and the cartilage of Santorini. On the superficial surface of each a collection of mucous glands is present, and this tends to make the cartilage stand out in relief under the mucous membrane.

**Epiglottidean Cartilage** (cartilago epiglottica).—The epiglottis is supported by a thin leaf-like lamina of yellow fibro-cartilage which is placed behind the root of the tongue and the body of the hyoid bone, and in front of the superior aperture of the larynx. When divested of the mucous membrane, which covers it behind and also to some extent in front, the epiglottidean cartilage is seen to present the outline of a bicycle-saddle, and to be indented by pits and pierced by numerous perforations. In the former, glands are lodged, whilst through the latter, blood-vessels and in some cases nerves pass. The broad end of the cartilage is directed upwards, and is free. Its margins are, to a large extent, enclosed within the aryteno-epiglottidean folds of mucous membrane. The anterior surface is only free in its upper part. This part is covered with mucous membrane, and looks towards the pharyngeal part of the tongue. The posterior surface is covered throughout its whole extent by the lining mucous membrane of the laryngeal cavity. The lower pointed extremity of the cartilage is carried downwards in the form of a strong fibrous band, termed the thyro-epiglottidean ligament.

**Ossification of the Cartilages of the Larynx.**—The thyroid and cricoid cartilages and the greater part of the arytenoid cartilages are composed of the hyaline variety of cartilage. The apical parts, and also the vocal processes of the arytenoid cartilages, the cartilages of Santorini, the cuneiform cartilages, and the epiglottis, are formed of yellow fibro-cartilage, and at no period of life do they exhibit any tendency towards the ossific change. The thyroid, cricoid, and basal portions of the arytenoids, as life advances, become more or less completely transformed into bone. In males over twenty years of age, and in females over twenty-two years of age, the process will usually be found to have begun (Chievitz). It is impossible, however, by an examination of the laryngeal cartilages, to form an estimate of the age of the individual, although in old age it is usual to find the thyroid, cricoid, and the hyaline part of the arytenoid completely ossified. It would appear that the process is somewhat slower in the female than in the male. The thyroid is the first to show the change; then, but almost at the same time, the cricoid, and lastly, a few years later, the arytenoid.

## JOINTS, LIGAMENTS, AND MEMBRANES OF THE LARYNX.

**Crico-thyroid Joints** (articulationes cricothyreoideæ).—These are diarthrodial joints, and are formed by the apposition of the circular facets on the tips of the inferior cornua of the thyroid cartilage with the elevated circular facets on the sides of the cricoid cartilage. A capsular ligament is thrown around each articulation, and this is lined by synovial membrane. On the posterior aspect of the joint a strengthening band is present in the capsule. The movements which take place at the crico-thyroid joints are of a twofold character, viz. gliding and rotatory. In the first case the thyroid facets glide upon the cricoid surfaces in different directions.

The rotatory movement is one in which the thyroid cartilage rotates to a slight extent around a transverse axis which passes through the centre of the two joints.

**Crico-arytenoid Joints** (articulationes cricoarytænoideæ).—These also are diarthrodial articulations. In each case there is a joint cavity surrounded by a capsular ligament, which is lined by a synovial membrane. The cricoid articular surface is convex, whilst that of the arytenoid is concave; both are elongated or elliptical in form, and they are applied to each other, so that the long axis of the one intersects or crosses that of the other at an acute angle. In no position of the joint do the two surfaces accurately coincide—a portion of the cricoid facet is always left uncovered. The capsule of the joint is strengthened behind by a band which is inserted into the inner and back part of the base of the arytenoid cartilage, and plays a somewhat important part in the mechanism of the joint; it arrests effectually excessive forward movement of the arytenoid cartilage.

The movements which take place at the crico-arytenoid joint are of a twofold kind, viz. gliding and rotatory. The ordinary position of the arytenoid during easy, quiet breathing is one in which it rests upon the outer part of the cricoid facet. By a gliding movement it can ascend upon the cricoid facet, and advance towards the median plane and its fellow of the opposite side. The gliding movements, therefore, are of such a character that the two arytenoid cartilages approach or retreat from each other and the mesial plane. In the rotatory movement the arytenoid cartilage revolves around a vertical axis. By this movement the vocal process is swung outwards or inwards, so as to open or close the rima glottidis.

The **joint between the arytenoid and the cartilage of Santorini** may either partake of the nature of an amphiarthrosis or of a diarthrosis. The tips of the two cornicula laryngis can generally be made out to be connected to the upper border of the posterior lamina of the cricoid cartilage by a delicate Y-shaped ligament termed the **ligamentum jugale.**

**Thyro-hyoid Membrane** (membrana hyothyreoidea).—This is a broad membranous and somewhat elastic sheet which occupies the interval between the hyoid bone and the thyroid cartilage. It is not equally strong throughout. It presents a central thick portion and a cord-like right and left margin, whilst in the intervals between these it is thin and weak (Figs. 680 and 681, p. 959). The central thickened part (ligamentum thyro-hyoideum medium) is largely composed of elastic fibres. Below, it is attached to the margins of the thyroid notch, whilst above, it is fixed to the posterior aspect of the upper margin of the body of the hyoid bone. The upper part, therefore, of its anterior surface is placed behind the posterior hollowed-out surface of the body of the hyoid bone; a synovial bursa of variable extent is placed between them, and in certain movements of the head and larynx the upper border of the thyroid cartilage slips upwards behind the hyoid bone. On either side of the strong central part, the thyro-hyoid membrane is thin and loose. It is attached below to the upper border of the thyroid cartilage, and above to the posterior aspect of the great cornu of the hyoid bone. It is pierced by the internal laryngeal nerve and the superior laryngeal vessels. The posterior border of the thyro-hyoid membrane on each side is thickened, round, and cord-like, and is chiefly composed of elastic fibres. It is termed the **ligamentum thyro-hyoideum laterale**, and extends from the tip of the great cornu of the hyoid bone to the extremity of the superior cornu of the thyroid cartilage. In this ligament there is usually developed a small oval cartilaginous or bony nodule which receives the name of the **cartilago triticea**. The deep surface of the lateral part of the thyro-hyoid membrane is covered by the pharyngeal mucous membrane. Behind its central part lies the epiglottis, but separated from it by a mass of adipose tissue (Fig. 686, p. 966).

**Crico-thyroid Membrane** (membrana cricothyreoidea).—This is a very important structure, which must be considered in three parts, viz. a central and two lateral, all of which are directly continuous with each other, and differ only in the nature of their superior connexions. The **central part** of the crico-thyroid membrane is strong, tense, and elastic. It is triangular in shape, and is attached by its broad base to the upper border of the anterior arch of cricoid cartilage, whilst above, it is fixed to the middle part of the lower border of the thyroid cartilage (Fig. 680, p. 959). It is pierced by minute apertures, and is crossed superficially by the crico-thyroid

branch of the superior laryngeal artery. The central part of the crico-thyroid membrane, therefore, closes in front the interval between the cricoid and thyroid cartilages. The **lateral part** on each side presents very different connexions. It is not attached to the lower border of the thyroid cartilage, but slopes upwards and inwards within the thyroid ala, and thus diminishes materially the transverse width of the lower subdivision of the laryngeal cavity. Its attachments are very definite. *Below*, it is fixed to the upper border of the cricoid cartilage, immediately subjacent to the lining mucous membrane of the larynx; *above*, it is directly continuous with the inferior thyro-arytenoid ligament or supporting band of the true vocal cord. This ligament, indeed, may be looked upon as constituting the upper thickened free border of the lateral part of the crico-thyroid membrane. *In front*, the lateral part of the crico-thyroid membrane is attached to the lower half of the inner surface of the ala of the thyroid cartilage, close to the angle, and *behind*, to the lower border of the processus vocalis of the arytenoid cartilage. In contact with the *outer surface* of the lateral part of the crico-thyroid membrane, and separating it from the thyroid ala, are the lateral crico-arytenoid and the thyro-arytenoid muscles; the *inner surface* is clothed by the lining mucous membrane of the larynx.

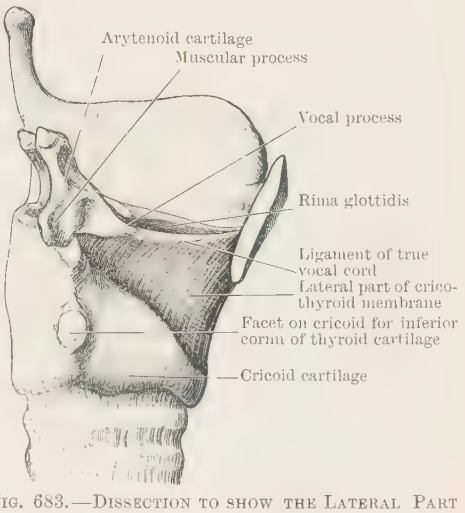

FIG. 683.—DISSECTION TO SHOW THE LATERAL PART OF THE CRICO-THYROID MEMBRANE. The right ala of the thyroid cartilage has been removed.

**Inferior Thyro-arytenoid Ligament** (ligamentum vocale).—This is formed in connexion with the upper border of the lateral part of the crico-thyroid membrane, and it constitutes the supporting ligament of the true vocal cord. It is attached *in front*, close to its fellow of the opposite side, to the middle of the angular depression between the two alæ of the thyroid cartilage. From this it stretches backwards, and becomes incorporated with the tip and upper border of the processus vocalis which projects forwards from the base of the arytenoid cartilage. The inferior thyro-arytenoid ligament is composed of yellow elastic fibres, and embedded in its anterior extremity there is frequently a minute nodule of elastic cartilage. Its inner border is sharp and free, and is clothed by mucous membrane, which in this position is very thin and tightly bound down to the ligament.

The **superior thyro-arytenoid ligament** (ligamentum ventriculare) supports the false vocal cord. It is weak and indefinite, but somewhat longer than the preceding ligament. In front it is attached to the angular depression between the two alæ of the thyroid cartilage, above the true vocal ligaments and close to the attachment of the thyro-epiglottidean ligament, and it extends backwards to be fixed to a tubercle on the antero-external surface of the arytenoid cartilage, a short distance above the processus vocalis. It is composed of connective tissue and elastic fibres which are continuous with the fibrous tissue in the aryteno-epiglottidean fold.

**Epiglottidean Ligaments.**—The epiglottis is bound by ligaments to the base of the tongue, to the wall of the pharynx, to the hyoid bone, and to the thyroid cartilage. The **glosso-epiglottidean ligament** (plica glosso-epiglottica mediana) is a prominent mesial fold of mucous membrane which proceeds from the middle of the anterior free surface of the epiglottis to the base of the tongue. The **pharyngo-epiglottidean ligaments or folds** (plicæ glosso-epiglotticæ laterales) are similar mucous folds which proceed from the margins of the epiglottis in an upward direction on the side wall of the pharynx. Between the two layers of mucous membrane which form the glosso-epiglottidean and pharyngo-epiglottidean folds there is a certain amount of elastic tissue. By the three folds the depression between the root of the tongue and the epiglottis is marked off into two fossæ termed the **valleculæ**.

The **hyo-epiglottidean ligament** (ligamentum hyoepiglotticum) is a short, broad elastic band, somewhat broken up by adipose tissue, which connects the anterior face of the epiglottis to the upper border of the hyoid bone (Fig. 686, p. 966). The **thyro-epiglottidean ligament** (ligamentum thyreoepiglotticum) is strong and thick (Fig. 682, p. 960). Composed mainly of elastic tissue, it proceeds downwards from the lower pointed extremity of the epiglottis, and is attached to the angular depression between the two alæ of the thyroid cartilage below and behind the median notch.

A triangular interval is left between the anterior face of the epiglottis and the thyro-hyoid membrane. This is imperfectly closed above by the hyo-epiglottidean ligament, and contains a pad of soft fat (Fig. 686, p. 966).

## INTERIOR OF THE LARYNX.

The cavity of the larynx is smaller than might be expected from an inspection of its exterior. On looking into its interior through the superior aperture it is seen to be subdivided into three portions by two elevated folds of mucous membrane which extend from before backwards, and project inwards from each side-wall of the cavity. The upper pair of folds are the **false vocal cords**; the lower, more definite pair, are the **true vocal cords** (Fig. 684). The latter are the chief agents in the production of the voice, and the larynx is so constructed that changes in their relative position and in their degree of tension are brought about by the action of the muscles and the recoil of the elastic ligaments.

**Superior Aperture of the Larynx** (aditus laryngis).—This is a large obliquely-placed opening which slopes rapidly from above downwards and backwards and looks backwards into the upper part of the laryngeal portion of the pharynx. Somewhat triangular in outline, the basal part of the aperture, placed above and in front, is formed by the free border of the epiglottis. Behind, the opening rapidly narrows, and finally ends in the interval between the two arytenoid cartilages. The sides of the aperture are formed by two sharp and prominent folds of mucous membrane called the **aryteno-epiglottidean folds** (plicæ aryepiglotticæ), which stretch between the lateral margins of the epiglottis in front and the arytenoid cartilages behind.

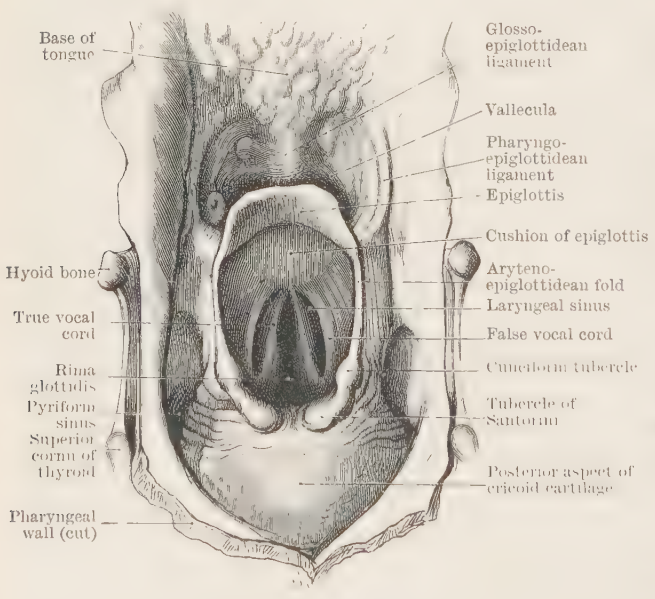

FIG. 684.—SUPERIOR APERTURE OF LARYNX, exposed by laying open the pharynx from behind.

The aryteno-epiglottidean folds enclose between the two layers of mucous membrane which compose them some connective tissue, muscular fibres belonging to the aryteno-epiglottidean muscles, and in their posterior parts the cuneiform cartilages and the cornicula laryngis which surmount the arytenoid cartilages. These small nodules of cartilage raise the hinder part of the aryteno-epiglottidean fold in the form of two rounded eminences, termed respectively the **cuneiform tubercle** (tuberculum cuneiforme) and the **tubercle of Santorini** (tuberculum corniculatum).

On either side of the posterior and lower part of the laryngeal opening there is, in the pharynx, a small downwardly-directed recess which presents a wide entrance,

but rapidly narrows towards the bottom. It is termed the **sinus pyriformis** and is of importance to the surgeon, because foreign bodies introduced into the pharynx are liable to be caught in this little pocket. On the inner side the sinus pyriformis, is bounded by the arytenoid cartilage and the aryteno-epiglottidean fold, whilst on the outer side it is limited by the inner surface of the ala of the thyroid cartilage, clothed by the pharyngeal mucous membrane.

**Upper Subdivision of the Laryngeal Cavity** (vestibulum laryngis).—The upper subdivision of the laryngeal cavity extends from the superior opening of the larynx down to the false vocal cords. In its lower part it exhibits a marked lateral compression. Its width, therefore, diminishes from above downwards, whilst, owing to the obliquity of the upper aperture of the larynx, its depth rapidly diminishes from before backwards. *In front* it is bounded by the posterior surface of the epiglottis, clothed by mucous membrane. This wall descends obliquely from above downwards and forwards, and becomes narrower as it approaches the anterior ends of the false vocal cords. The upper part of the posterior surface of the epiglottis is convex, owing to the manner in which the upper margin is curved forwards towards the tongue; below this there is a slight concavity, and still lower a marked bulging or convexity over the upper part of the thyro-epiglottidean ligament. This swelling is called the **cushion** or **tubercle of the epiglottis** (tuberculum epiglotticum), and it forms a conspicuous object in laryngoscopic examinations of the larynx. The *lateral wall* of the upper compartment or vestibule of the larynx is formed by the inner surface of the aryteno-epiglottidean fold. For the most part it is smooth and slightly concave, and it diminishes considerably in vertical depth as it passes backwards. In its posterior part the mucous membrane stands out in two elongated vertical elevations placed one behind the other (Fig. 686, p. 966). The anterior elevation is formed by the subjacent cuneiform cartilage with the mass of glands associated with it; the posterior elevation is produced by the anterior margin of the arytenoid cartilage and the cartilage of Santorini. A shallow groove (philtrum ventriculi of Merkel) descends between these rounded elevations, and terminates below by running into the interval between the false and true vocal cords. The anterior elevation comes to an end below in the posterior extremity of the false vocal cord; the arytenoid or posterior elevation, in its inferior part, bends round the hinder end of the ventricle of the larynx and becomes lost in the true vocal cord. The *posterior wall* of the laryngeal vestibule is narrow, and corresponds to the interval between the upper parts of the two arytenoid cartilages. Its width, to a large extent, depends on the position of these cartilages, and when they are placed near each other the mucous membrane which covers this wall is thrown into longitudinal folds.

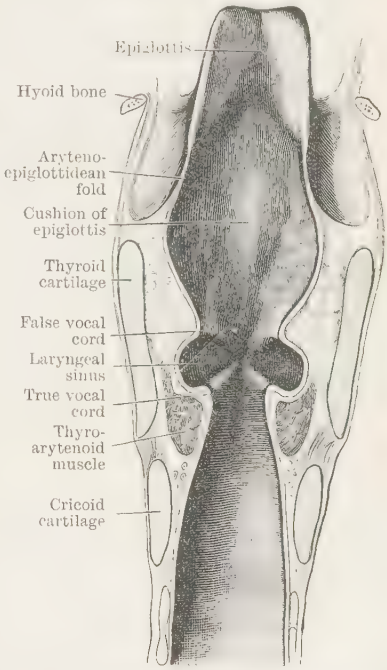

FIG. 685. CORONAL SECTION THROUGH LARYNX, to show its three compartments.

**Middle Subdivision of the Laryngeal Cavity.**—The middle compartment of the larynx is much the smallest of the three. It is bounded above by the false vocal cords and below by the true vocal cords, whilst it communicates between these folds with the vestibule on the one hand and the inferior compartment of the larynx on the other.

The **false vocal cords** (plicæ ventriculares) are two prominent mucous folds which extend from before backwards on the side walls of the laryngeal cavity. In front they reach the angle between the two alæ of the thyroid cartilage, but behind they do not extend so far as the posterior wall of the larynx. They come to an end on each side at the lower end of the elongated swelling produced by cuneiform

cartilage. The false vocal cord is soft and somewhat flaccid, and presents a free border which is slightly arched—the concavity looking downwards. Within the fold of mucous membrane which forms this cord are contained: (1) the feeble superior thyro-arytenoid ligament; (2) numerous glands which are chiefly aggregated in its middle part; and (3) a few muscle fibres.

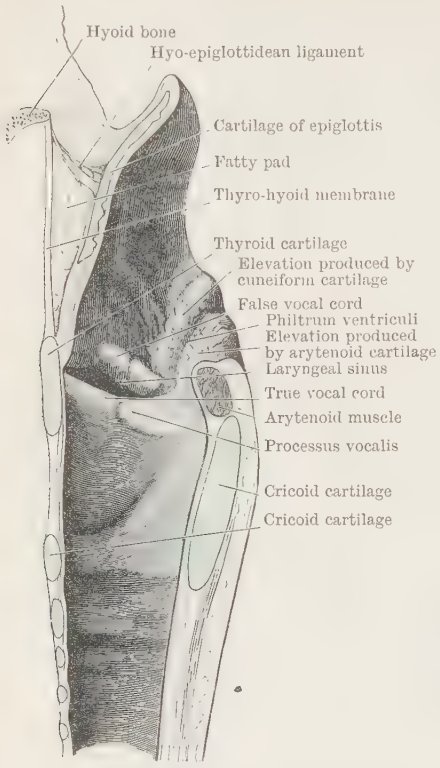

FIG. 686.—MESIAL SECTION THROUGH LARYNX to show the outer wall of the right half.

The interval between the false vocal cords is sometimes termed the **false glottis** (glottis spuria), and is considerably wider than the interval between the true vocal cords, which is called the **true glottis** (glottis vera) or **rima glottidis**. It follows from this that when the cavity of the larynx is examined from above the four cords are distinctly visible, but when examined from below the true vocal cords alone can be seen.

The **true vocal cords** (plicæ vocales), placed below the false cords, extend from the angle between the alæ of the thyroid cartilage in front to the vocal processes of the arytenoid cartilages behind. The true vocal cord is sharp and prominent, and the mucous membrane which is stretched over it is very thin and firmly bound down to the subjacent ligament. In colour it is pale, almost pearly white, whilst posteriorly the point of the processus vocalis of the arytenoid, which stands out clearly in relief, presents a yellowish tinge. In cross-section the true vocal cord is prismatic in form, and its free border looks upwards as well as inwards.

The true vocal cords are the agents by means of which the voice is produced. The false vocal cords are of little importance in this respect; indeed, they can in great part be destroyed and no appreciable difference in the voice result.

**Glottis vera** (rima glottidis).—This name is applied to the elongated fissure by means of which the middle compartment of the larynx communicates with the lower compartment. It is placed somewhat below the middle of the laryngeal cavity, of which it constitutes the narrowest part. In front it corresponds to the interval between the true vocal cords; behind, it corresponds to the interval between the bases and vocal processes of the arytenoid cartilages. It is composed, therefore, of two distinct parts: (1) a narrow anterior portion, between the true vocal cords, involving more than half of its length, and called the **glottis vocalis** (pars intermembranacea); (2) a broader, shorter portion, between the arytenoid cartilages, and termed the **glottis respiratoria** (pars intercartilaginea). By changes in the position of the arytenoid cartilages the form of the rima glottidis undergoes constant alterations. In

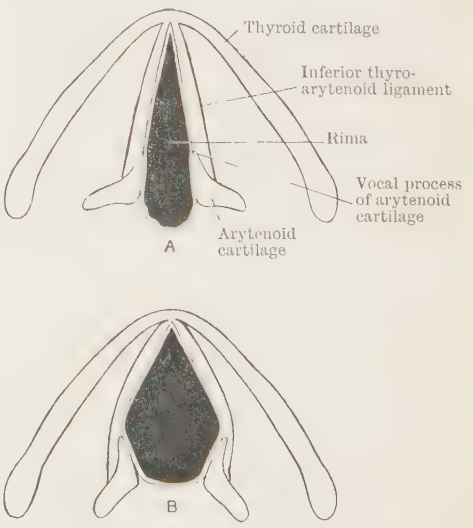

FIG. 687.—DIAGRAM OF RIMA GLOTTIDIS.
A. During ordinary easy breathing. B. Widely open.

ordinary easy breathing it is somewhat lanceolate in outline. The glottis vocalis presents under these conditions the form of an elongated triangle with the base directed backwards, and corresponding to an imaginary line drawn between the points of the vocal processes of the arytenoid cartilages, whilst the glottis respiratoria is somewhat quadrangular. When the glottis is opened widely the broadest part of the fissure is at the extremities of the vocal processes of the arytenoids, and here the side of the rima presents a marked angle. The two vocal cords, on the other hand, may be approximated to each other so closely, as in singing a high note, that the glottis vocalis is reduced to a linear chink.

The length of the rima glottidis differs very considerably in the two sexes, and upon this depends the different character of the voice in the male and female. According to Moura, the following are the average measurements in the quiescent condition of the rima :—

| | |
|---|---|
| Male—Length of entire rima glottidis, 23 mm. | glottis vocalis, 15·5 mm.<br>glottis respiratoria, 7·5 mm. |
| Female—Length of entire rima glottidis, 17 mm. | glottis vocalis, 11·5 mm.<br>glottis respiratoria, 5·5 mm. |

By stretching the vocal cords, however, the length of the rima glottidis in the male may be increased to 27·5 mm., and in the female to 20 mm.

The position of the rima glottidis may be indicated on the surface by marking a point on the middle line of the neck 8·5 mm. below the bottom of the thyroid notch in the male and 6·5 mm. in the female. This is the average position (Taguchi).

**Laryngeal Sinus** (ventriculus laryngis).—The side wall of the larnyx, in the interval between the false and the true vocal cords, exhibits a marked pocket-like depression or recess called the laryngeal sinus. The recess passes upwards so as to undermine somewhat the false vocal cord, and its mouth is somewhat narrower than its cavity. In front it reaches forwards to the angle between the alæ of the thyroid cartilage, whilst behind it ends at the anterior border of the arytenoid cartilage.

Under cover of the forepart of the false vocal cord a small slit-like aperture may be detected ; this leads upwards from the laryngeal sinus into a small diverticulum of mucous membrane, termed the **laryngeal saccule** (appendix ventriculi) which ascends between the false vocal cord and the ala of the thyroid cartilage. The laryngeal saccule is of variable extent, but as a rule it ends blindly at the level of the upper border of the thyroid cartilage.

Sometimes the saccule extends much higher, and may even reach the hinder part of the great cornu of the hyoid bone. This is of interest when considered in connexion with the extensive larnygeal pouches of the anthropoid apes.

Fig. 688.—Specimen showing a great Extension of the Saccule of the Larynx.

**Lower Compartment of the Laryngeal Cavity.**—This leads directly downwards into the trachea. Above it is narrow and compressed laterally, but it gradually widens out until, in its lowest part, it becomes circular, in correspondence with the trachea with which it is continuous. It is bounded by the sloping inner surfaces of the crico-thyroid membrane and by the inner aspect of the cricoid cartilage—both covered by smooth mucous membrane. In the operation of laryngotomy the opening is made through the anterior wall of this compartment.

**Mucous Membrane of the Larynx.**—The mucous membrane which lines the larynx is continuous above with that lining the pharynx, and below with mucous membrane of the trachea. Over the posterior surface of the epiglottis it is closely adherent, but elsewhere, above the level of the true vocal cords, it is loosely attached by submucous tissue which extends into the aryteno-epiglottidean folds. As it passes over the true vocal cords the mucous membrane is very thin, and is tightly bound down.

It is important to bear these facts in mind, because in certain inflammatory conditions the lax submucous tissue in the upper part of the larynx is liable to become infiltrated with fluid, pro-

ducing what is known as œdema glottidis. This may proceed so far as to cause occlusion of the upper part of the cavity. The close adhesion of the mucous membrane to the true vocal cords, however, prevents the œdema extending beyond the level of the rima glottidis, and the surgeon is thus able to relieve the patient by making an opening through the front part of the crico-thyroid membrane into the lower compartment of the larynx.

Above the level of the rima glottidis the laryngeal mucous membrane is extremely sensitive, and when touched by a foreign body there is an immediate response in the shape of an explosive cough. In the lower compartment of the larynx the mucous membrane is lined by columnar ciliated epithelium. Over the true vocal cords this is replaced by squamous epithelium. In the middle compartment and in the lower part of the vestibule of the larynx the columnar ciliated epithelium again reappears. The upper part of the epiglottis and the upper parts of the side walls of the vestibule are covered by squamous epithelium similar to that present in the mouth and pharynx.

The mucous membrane of the larynx has a plentiful supply of acinose glands, and in only one place, viz. over the surface of the true vocal cords, are these completely absent. For the most part the glands are aggregated in groups. The following are the localities in which these groups are especially noticeable:—(1) On the dorsal surface of the epiglottis, many of the glands piercing the cartilage; (2) around the cuneiform cartilage, where they are chiefly responsible for the elongated elevation seen in this part of the wall of the vestibule; (3) in the false vocal cord, and over the wall of the laryngeal sinus and the laryngeal saccule.

## LARYNGEAL MUSCLES.

Under this heading we do not include all the muscles which are attached to the cartilages of the larynx. Thus the inferior constrictor muscles of the pharynx, although attached to both cricoid and thyroid cartilages, and the stylo-pharyngeus muscle on each side, although inserted in part into the thyroid cartilage, properly belong to the pharynx. Of the laryngeal muscles proper two are attached to the oblique line of the thyroid cartilage (viz. the sterno-thyroid and thyro-hyoid), and are concerned in producing movements of the larynx as a whole. These are termed the *extrinsic muscles* of the larynx, and have been already described (p. 412). The *intrinsic muscles* of the larynx are a group of small muscles which help to build up the laryngeal wall, and which, by their contraction, move the laryngeal cartilages on each other. One passes between the cricoid and thyroid cartilages—the **crico-thyroid muscle**; two pass between the cricoid and arytenoid cartilages—the **crico-arytenoideus posticus** and **crico-arytenoideus lateralis**: one, in each lateral wall of the larynx, under cover of the ala of the thyroid cartilage, passes between the thyroid and the arytenoid cartilages—the **thyro-arytenoid**. These muscles are in pairs. One muscle only, which connects the two arytenoid cartilages, and which is termed in consequence the **arytenoideus**, is single. In addition to these, some muscular fibres which enter the aryteno-epiglottidean fold and reach the epiglottis require to be considered. These constitute the **thyro-ary-epiglottidean muscle**.

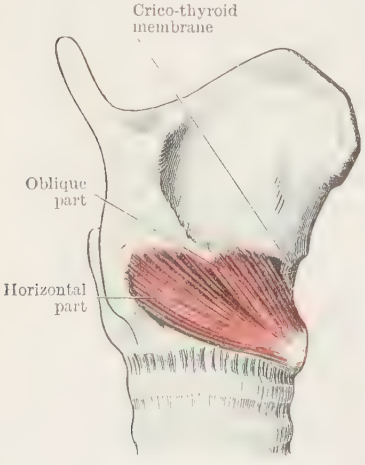

FIG. 689.—THE CRICO-THYROID MUSCLE.

The **crico-thyroid muscle** (musculus crico-thyreoideus) is placed on the cricoid cartilage, and bridges over the crico-thyroid interval. Taking origin from the lower border and outer surface of the anterior arch of the cricoid cartilage, its fibres spread out in an upward and backward direction, and are inserted into the inner surface and lower margin of the thyroid cartilage, and also into the anterior aspect of its inferior cornu. As a general rule it is divided into two parts, viz.: (1) an **anterior** or **oblique part**, composed of those fibres which are inserted into the ala of the thyroid cartilage; and (2) a **posterior** or **horizontal part** formed of those fibres which are inserted into the

inferior cornu of the thyroid cartilage. It is closely associated with the inferior constrictor muscle of the pharynx, and sometimes shows a certain amount of continuity with it.

The **posterior crico-arytenoid muscle** (musculus cricoarytænoideus posterior) is somewhat fan-shaped (Fig. 691, p. 970). It springs by a broad origin from the depression which is present on the posterior lamina of the cricoid cartilage on each side of the mesial ridge, and its fibres converge to be inserted into the posterior surface of the processus muscularis of the arytenoid cartilage. In pursuing its upward and outward course on the back of the cricoid cartilage its fibres show different degrees of obliquity. The uppermost fibres are short and nearly horizontal; the intermediate fibres are the longest, and are very oblique; whilst the lowest fibres are almost vertical in their direction.

The **lateral crico-arytenoid muscle** (musculus cricoarytænoideus lateralis) is triangular in form and smaller than the preceding muscle (Fig. 690). It springs from the upper border of the lateral part of the anterior arch of the cricoid as far back as the facet which supports the base of the arytenoid cartilage. A few of its fibres also take origin from the lateral part of the crico-thyroid membrane, to which its deep surface is applied. From this attachment its fibres run backwards and upwards, and converge to be inserted into the anterior surface of the processus muscularis of the arytenoid cartilage. The superficial or outer surface of this muscle is covered by the lower part of the ala of the thyroid cartilage and by the upper part of the crico-thyroid muscle.

The **thyro-arytenoid muscle** (musculus thyreoarytænoideus) is placed in the lateral wall of the larynx under cover of the ala of the thyroid cartilage (Fig. 690). Its lower border is contiguous with, and generally inseparably blended with, the upper margin of the lateral crico-arytenoid muscles, so that the two muscles form a more or less continuous sheet. The thyro-arytenoid muscle is usually described as consisting of a superficial and a deep part, termed respectively the thyro-arytenoideus externus and the thyro-arytenoideus internus. As a rule these parts are more or less completely united, and can only be isolated from each other by artificial means.

The **thyro-arytenoideus externus** is a broad muscular layer which lies immediately subjacent to the ala of the thyroid cartilage. Its lower border is in contact with the lateral crico-arytenoid muscle, whilst its upper border is placed at a higher level than the true vocal cord. The upper part of the muscle is therefore in relation to the wall of the sinus of the larynx. The thyro-arytenoideus externus arises in front from the lower half of the inner surface of the ala of the thyroid cartilage, close to the angle, and also from the lateral part of the crico-thyroid membrane, on which it to some extent lies. Its fibres pass backwards, and are inserted into the outer border and muscular process of the arytenoid cartilage, a certain number, however, turning round this cartilage, and becoming continuous with the transverse fibres of the arytenoideus muscle.

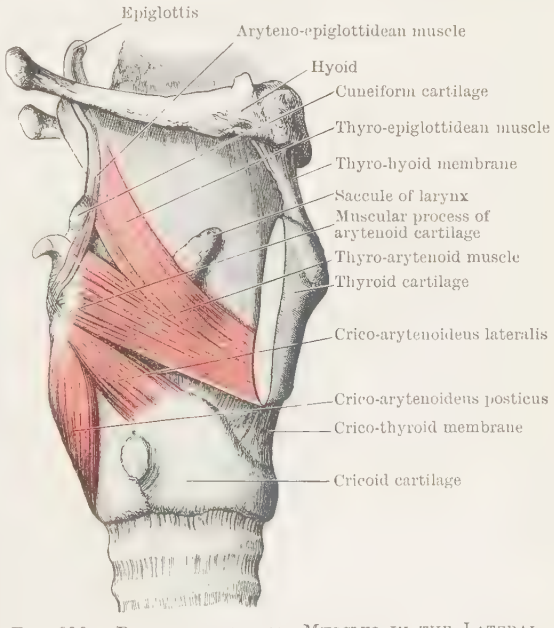

FIG. 690.—DISSECTION OF THE MUSCLES IN THE LATERAL WALL OF THE LARYNX.

The right ala of the thyroid cartilage has been removed.

A considerable number of the uppermost fibres of the thyro-arytenoideus externus, as they proceed backwards, curve upwards so as to form a thin band which reaches the

aryteno-epiglottidean fold and the margin of the epiglottis. These constitute the **thyro-epiglottidean muscle.**

The **thyro-arytenoideus internus** is a slender, three-sided, muscular band which is applied to the outer aspect of the true vocal cord, and receives its prismatic form from this adaptation. It arises in front from the angular depression between the two alæ of the thyroid cartilage, and is inserted behind into the outer aspect of the processus vocalis and also into the adjoining depressed part of the antero-external surface of the arytenoid cartilage. The thyro-arytenoideus internus is somewhat thicker behind than in front. This is due to the fact that, whilst all the fibres which compose it are attached to the arytenoid cartilage, only a certain proportion obtain attachment in front to the thyroid cartilage. A large number of the deeper fibres are directly fixed at different points to the outer side of the true vocal cord. These constitute the **ary-vocalis muscle** (Ludwig).

The thyro-arytenoideus is a complicated muscle, and the above description can only be regarded as conveying in a general way what may be regarded as the more usual arrangement of its fibres. It is subject to much variation and to very different degrees of development in different individuals. As a rule it is possible to trace from both parts of the muscle fibres which are carried obliquely upwards over the laryngeal sinus, and to some extent also over the sacculus laryngis. Further an additional part, termed the *small* or *superior* **thyro-arytenoideus,** is as a rule present (93 per cent according to Sewell). This is a slender band which arises from the inner aspect of the ala of the thyroid cartilage close to the notch, and passes backwards and downwards to find insertion into the lateral border of the arytenoid cartilage immediately above the processus muscularis.

The **arytenoideus muscle** is composed of two portions—a superficial part, termed the arytenoideus obliquus, and a deeper part, called the arytenoideus transversus.

The **arytenoideus obliquus** consists of two bundles of muscular fibres, each of which springs from the posterior aspect of the muscular process of the arytenoid cartilage. From these points the two fleshy slips proceed upwards and inwards, and cross each other in the mesial plane like the two limbs of the letter X. Reaching the summit of the arytenoid cartilage on each side, many of the fibres are inserted into it, whilst the remainder are prolonged round it into the aryteno-epiglottidean fold. Here they receive the name of the **aryteno-epiglottidean muscle**, and as they approach the epiglottis they are joined by the fibres of the thyro-epiglottidean muscle. The oblique arytenoid muscles may therefore be regarded as forming a rudimentary sphincter muscle for the superior aperture of the larynx. Each bundle, starting from the base of one of the arytenoid cartilages, is prolonged into the aryteno-epiglottidean fold of the opposite side, and within this to the margin of the epiglottis.

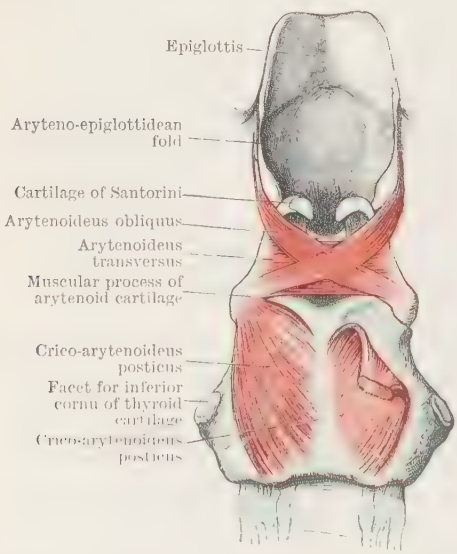

FIG. 691.—DISSECTION OF THE MUSCLES ON THE POSTERIOR ASPECT OF THE LARYNX.

The **arytenoideus tranversus** is an unpaired muscle. It is composed of transverse fibres which bridge across the interval between the two arytenoid cartilages, and occupy their posterior concave surfaces. To a large extent these fibres are inserted into the posterior aspect of the outer border of each arytenoid cartilage, but many turn round this border and become continuous with the fibres of the thyro-arytenoid muscle. It follows from this that the arytenoideus transversus and the two thyro-arytenoid muscles are sometimes spoken of as the sphincter of the glottis.

**Action of the Laryngeal Muscles.**—By the action of the laryngeal muscles the position and tension of the true vocal cords are so influenced that, during the passage of

air through the larynx, the tone and the pitch of the voice is determined. *Tension* of the true vocal cords is produced by the contraction of the two **crico-thyroid muscles**. The anterior or oblique portions of the muscles pull the lower border of the thyroid cartilage downwards, whilst the posterior horizontal portions, through their insertion into the inferior cornua, draw the thyroid cartilage forwards, thereby increasing the distance between the angle of the thyroid cartilage and the vocal processes of the arytenoid cartilages. When the crico-thyroid muscles cease to contract, the relaxation of the cords is brought about by the elasticity of the ligaments. The **thyro-arytenoid muscles** must be regarded as antagonistic to the crico-thyroid muscles. When they contract they approximate the angle of the thyroid cartilage to the arytenoid cartilages, and still further relax the true vocal cords; and when they cease to act the elasticity of the ligaments of the larynx again restore the state of equilibrium. The ary-vocales muscles, by the insertion of their fibres into the true vocal cords, may tighten portions of these cords, whilst they relax at the same time the parts behind.

The *width of the rima glottidis* is regulated by the **arytenoideus muscle**, which draws together the two arytenoid cartilages, and this may be done so effectually that the inner surfaces of these cartilages come into contact; the glottis respiratoria is thus completely closed. The lateral and posterior crico-arytenoid muscles also modify the width of the rima glottidis. When they act together they assist the arytenoideus muscle in closing the glottis, but when they act independently they are antagonistic muscles. Thus the **posterior crico-arytenoid muscles**, by drawing the muscular processes of the arytenoid cartilages outwards and backwards, swing the processus vocales and the vocal cords outwards, and thereby open the rima. The **lateral crico-arytenoid muscles** act in exactly the opposite manner. By drawing the muscular processes of the arytenoid cartilages forwards and inwards, they approximate the processus vocales and close the rima.

**Closure of the Larynx during Deglutition.**—But the muscles of the larynx have another function to perform besides vocalisation and regulating the amount of air passing to and fro through the glottis. During deglutition it is requisite that the communication between the pharynx and larynx should be closed, so as to prevent the fluid or solid parts of the food entering the respiratory passages. Formerly it was believed that this was effected by the folding back of the epiglottis; that in fact the epiglottis, during the passage of the food, is applied like a lid over the entrance into the vestibule of the larynx. The observations of Professor Anderson Stuart would seem to indicate that this view is incorrect. According to Professor Stuart it is not the anterior wall of the vestibule which moves; the epiglottis stands erect, whilst the posterior wall formed by the arytenoids is carried forwards. In the process of closing the laryngeal entrance the arytenoid cartilages are closely approximated, glide forwards, and are then inclined towards the epiglottis. The result of this is that the laryngeal opening is converted into a T-shaped fissure. The mesial limb of the T is formed by the interval between the closely-applied arytenoid cartilages, whilst the cross limb, which lies in front, is bounded anteriorly by the epiglottis and behind by the aryteno-epiglottidean folds. The apices of the arytenoid cartilages, with the cartilages of Santorini, are pressed against the cushion of the epiglottis, whilst the lateral margins of the epiglottis are pulled backwards so as to make the transverse limb of the fissure distinctly concave in a backward direction. The muscles chiefly concerned in producing these movements are the external thyro-arytenoid and the transverse arytenoid muscles. These form a true sphincter vestibuli. The thyro-ary-epiglottidean muscles also come into play. They pull upon the epiglottis so as to produce tight application of its cushion to the arytenoid cartilages and the cartilages of Santorini, and they also curve its margins backwards so as to increase its posterior concavity.

**Vessels and Nerves of the Larynx.**—Two branches of the vagus nerve, viz. the superior laryngeal and the recurrent laryngeal nerves, supply the larynx. The superior laryngeal divides into the internal and external laryngeal branches. The **external laryngeal nerve** supplies the crico-thyroid muscle; whilst the **internal laryngeal nerve** enters the larynx by piercing the lateral part of the thyro-hyoid membrane to supply the laryngeal mucous membrane. The **recurrent laryngeal nerve** reaches the larynx from below, and supplies all the intrinsic laryngeal muscles with the exception of the crico-thyroid.

The **superior laryngeal artery**, a branch of the superior thyroid, accompanies the internal laryngeal nerve; whilst the **inferior laryngeal artery**, which springs from the inferior thyroid, accompanies the recurrent laryngeal nerve. These two vessels ramify in the laryngeal wall and supply the mucous membrane, the glands, and muscles.

**Growth-Alterations and Sexual Differences in the Larynx.** A considerable amount of variation may be noticed in the size of the larynx in different individuals. This is quite independent of stature, and explains to a great extent the difference in the

pitch of the voice which is observable in different persons. But quite apart from these individual variations, there is a marked sexual difference in the size of the larynx. The male larynx is not only absolutely but also relatively larger than the female larynx. This is noticeable in all its diameters, but more particularly in the antero-posterior diameter, and to a large extent the increase in the latter direction is produced by the strong development of the laryngeal angle or pomum Adami in the male. The great antero-posterior diameter of the male larynx necessarily implies a greater length of the vocal cords and a lower or deeper tone of the voice than in the female.

In the newly-born child the larynx, in comparison with the rest of the body, is somewhat large (C. L. Merker), and it continues to grow slowly and uniformly up to the sixth year of childhood. At this period there is a cessation of growth, which persists until puberty is reached, and then a stage of active growth supervenes. Up to this time the larynx in both sexes is similar in its characters, and although the growth which now occurs affects both the male and the female larynx, it is much more rapid and much more accentuated in the male than in the female. As a result of this the voice of the male breaks and assumes its deep tone.

It is interesting to note that the growth activity of the larynx at puberty is intimately connected with the development of the sexual organs. In an individual who has been castrated when young the larynx attains a size which exceeds that of the female only to a very small degree, and the high pitch of the voice is retained.

**Appearance presented by the Interior of the Larynx when examined by the Laryngoscope.**—When the cavity of the larynx is illuminated and examined by the laryngoscopic mirror the parts which surround the superior aperture of the larynx, as well as the interior of the organ, come into view. Not only this, but when the vocal cords are widely separated it is possible to inspect the interior of the trachea as low down as its bifurcation.

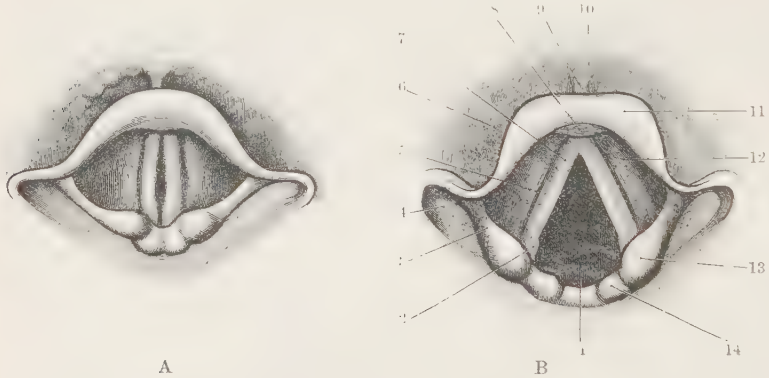

Fig. 692.—Cavity of the Larynx, as seen by means of the laryngoscope.

A. The rima glottidis closed. B. The rima glottidis widely open.

1. Rings of the trachea.
2. Processus vocalis of the arytenoid cartilage.
3. Aryteno-epiglottidean fold.
4. Sinus pyriformis.
5. Laryngeal sinus.
6. Vallecula.
7. True vocal cord.
8. Cushion of epiglottis.
9. Middle glosso-epiglottidean fold.
10. Base of tongue.
11. Epiglottis.
12. False vocal cord.
13. Cuneiform tubercle.
14. Tubercle of Santorini.

In such an examination the arched upper border of the epiglottis constitutes a conspicuous object, whilst, behind this, the bulging on the anterior wall of the vestibule, formed by the cushion of the epiglottis, may constitute a feature of the picture. The middle glosso-epiglottidean ligament, with the vallecular fossa on either side of it, can also be inspected in the interval between the epiglottis and the base of the tongue. The sharp ary-epiglottidean folds are clearly visible, and in the back portion of each of these can be seen the two prominent tubercles which are formed by the enclosed cuneiform cartilage and the cartilage of Santorini. Behind these tubercles is the posterior wall of the pharynx, whilst to their outer side the deep sinus pyriformis may be seen. In the interior of the larynx the false and the true vocal cords are easily recognised, and the interval between the false and the true cord, or, in other words, the entrance into the laryngeal sinus, appears as a dark line on the side wall of the larynx. The false vocal cords are red and fleshy-looking; the true vocal cords during phonation are tightly stretched and pearly white—the white colour being usually more apparent in the female than in the male. The outline and yellowish tinge of the processus vocalis at its attachment to the true vocal cord, as well as, to a slight extent, the outline of the fore part of the base of the arytenoid cartilage, can in a successful laryngoscopic examination be made out. The true vocal cords during ordinary inspiration are seldom at rest, and with the laryngoscope their movements may be studied. It should be borne in mind that the picture afforded by the laryngoscope does not give a true idea of the level at which the different parts lie. The cavity appears greatly shortened, and its depth diminished.

## THE TRACHEA.

The **trachea** or **windpipe** is a wide tube which is kept permanently patent by

a series of cartilaginous rings embedded in its wall. These rings are deficient posteriorly, and consequently the tube is not completely cylindrical: its hinder wall is flattened. The trachea begins above at the lower border of the cricoid cartilage, and opposite the lower margin of the sixth cervical vertebra. From this it extends downwards through the lower part of the neck into the superior mediastinum of the thorax, in which it ends at the level of the upper border of the fifth dorsal vertebra by dividing into the right and left bronchus. The length of the trachea in the male is from four to four and a half inches, and in the female from three and a half to four inches, but even in the same individual it varies considerably in length with the movements of the head and neck.

The lower end of the trachea is fixed in position. This is a necessary provision to prevent dragging on the roots of the lungs during movements of the head and neck. The remainder of the tube is surrounded by a quantity of loose areolar tissue, and possesses a considerable amount of mobility. Further, its wall is highly elastic, and thus when the head is thrown back the tube elongates through stretching, and when the chin is depressed its length is diminished by the recoil of its wall.

The trachea does not present an absolutely uniform calibre throughout its whole length. About its middle it exhibits a slight expansion or dilatation, and from this the calibre diminishes in an upward and a downward direction. Close to the bifurcation it is again slightly expanded (Braune and Stahel).

These differences in the calibre of the tube are determined by the surroundings of the trachea. The upper part is narrowed through its being clasped by the thyroid body. Further, a short distance above the bifurcation an impression, sometimes strongly marked, is usually seen on the left side of the trachea. This is due to the close contact of the aortic arch as it passes backwards against this part of the tube. It is evident therefore that the second slight diminution in calibre which is described by Braune and Stahel is produced by the proximity of the aorta. Lejars gives the average antero-posterior diameter of the trachea in the living person as 11 mm., and the transverse diameter as 12·5 mm. In the dead subject the lumen of the tube is considerably greater.

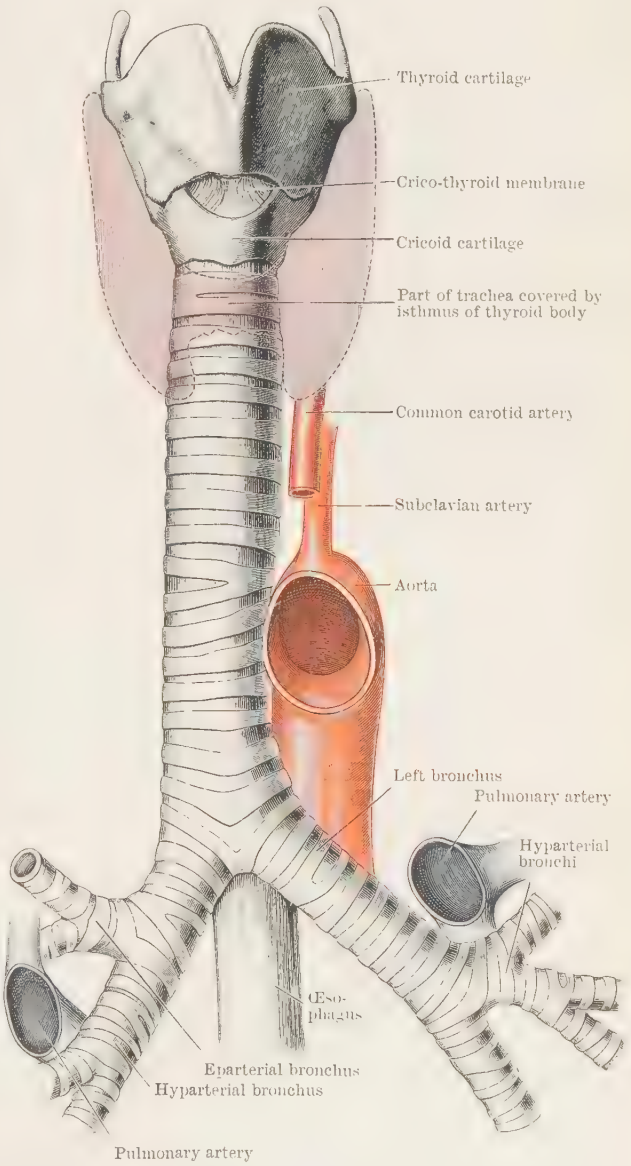

FIG. 693.—THE TRACHEA AND BRONCHI.

The thyroid body is indicated by a dotted line and a purple tint.

The trachea adheres rigorously to the median line except towards its lower end, where it deviates very slightly to the right. As it descends it recedes rapidly from the surface. This is due to its following the curvature of the vertebral column, from which it is separated by the œsophagus alone.

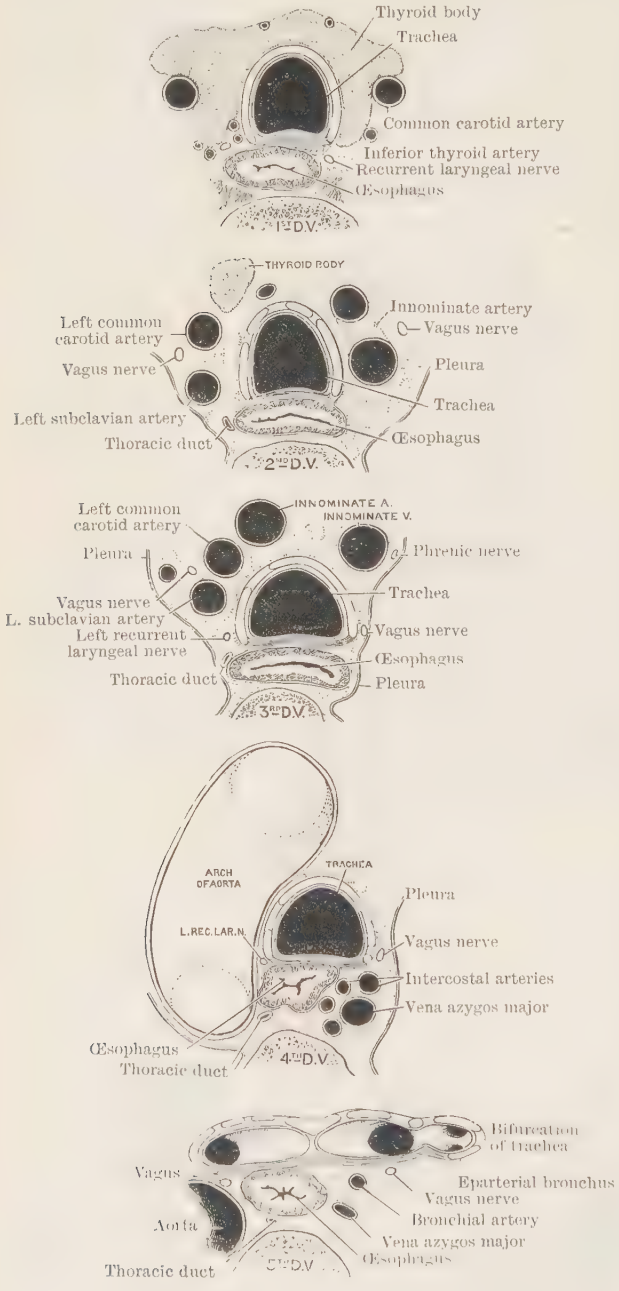

FIG. 694.—TRANSVERSE SECTIONS through the trachea and its immediate surroundings at the level of each of the upper five dorsal vertebræ.

**Relations of the Trachea.**—In the study of the relations of the trachea it is convenient to consider it in the two stages of cervical and thoracic.

When the chin is held so that the face looks forwards the **cervical part** of the trachea measures from 2 to $2\frac{1}{2}$ inches in length; but when the head is thrown back the length is considerably increased. In its upper part the trachea is clasped by the thyroid body, the isthmus of which is applied to its anterior surface, and covers the second, third, and fourth rings, whilst on each side the lateral lobe of the same body is applied to its lateral surface, and extends downwards as low as the fifth ring. On either side of the cervical trachea is the common carotid artery, whilst the recurrent laryngeal nerve ascends in the groove between the trachea and the œsophagus. Posteriorly the trachea is in relation to the œsophagus, which intervenes between it and the bodies of the vertebræ, and deviates somewhat to the left as it descends.

In addition to the isthmus of the thyroid body two thin muscular strata, composed of the sterno-hyoid and sterno-thyroid muscles, and also the deep fascia and integument, separate the cervical trachea from the surface. In the middle line of the neck there is a narrow diamond-shaped space between the inner margins of these muscles, within which the trachea is merely covered by the integuments and fasciæ. It is important to note that in the lower part of the neck the deep cervical fascia is in two layers—viz. a strong stratum applied to the anterior surface of the sterno-hyoid and sterno-thyroid muscles, and a weaker superficial layer stretching across between the two sterno-mastoid muscles. Beneath these muscular and fascial layers the inferior thyroid veins descend on the surface of the trachea,

and sometimes the occasional thyroidea ima artery passes upwards in front of the tube. At the upper border of the manubrium sterni the innominate artery may be seen crossing the trachea obliquely.

The **thoracic part** of the trachea is situated in the back part of the superior mediastinum, being separated from the bodies of the vertebræ by the œsophagus alone. Immediately above its bifurcation the deep cardiac plexus of nerves is placed in front and on either side of the trachea. At the level of the fourth dorsal vertebra the aortic arch is very intimately related to it. At first in front of the tube, the aortic arch passes backwards in close contact with its left side. The three great vessels which spring from the aortic arch are also placed in close proximity to the trachea. The innominate and left common carotid arteries, at first in front, gradually diverge as they proceed upwards and come to lie on either side of the tube—the innominate to the right, and the left common carotid to the left. In front of these vessels are the left innominate vein and the remains of the thymus body. On the right side the thoracic part of the trachea is in relation to the right vagus nerve, and is clothed by the right mediastinal pleura; on the left side are the left subclavian artery and the left recurrent laryngeal nerve.

**Structure of the Wall of the Trachea.**—The wall of the trachea and bronchi is composed of (1) a fibro-elastic membrane in which the cartilaginous rings are embedded; (2) within this, and on the posterior aspect of the tube, a layer of muscular tissue, termed the musculus trachealis; and (3) the lining mucous membrane.

The **fibro-elastic membrane** is strong and dense, and, passing round the whole circumference of the tube, it becomes continuous superiorly with the perichondrium which invests the cricoid cartilage. Embedded in its substance are the series of **cartilaginous rings.** These vary in number from 15 to 20, and are composed of hyaline cartilage. They are horseshoe-shaped, the posterior fourth of the circumference being deficient, so that behind, each ring ends in two rounded extremities. The external surface of a tracheal ring is flat and even, and does not project much beyond the level of the membrane in which it is embedded; the inner surface, however, is convex in the vertical direction, and consequently it bulges slightly into the lumen of the trachea. The intervals between the rings are somewhat narrower than the rings themselves, and neighbouring rings frequently show a more or less complete fusion, whilst others present other irregularities, such as a tendency to bifurcate. The lowest ring is specially adapted to the tracheal bifurcation. In the middle line in front it inclines downwards, and from this median peak a cartilaginous strip is carried backwards in the fork between the two bronchi.

The **musculus trachealis** is a continuous layer of involuntary muscular tissue placed in the posterior part of the wall in front of the fibro-elastic membrane. The muscular bundles are arranged transversely, and are attached to the extremities of the rings, and also to the deep surface of the rings for a short distance beyond their extremities. In the intervals between the rings the transverse muscular bundles are attached to the fibro-elastic membrane. It is evident that, by its contraction, this muscle will reduce in a marked degree the lumen of the tube.

The **mucous membrane** is laid smoothly over the interior of the tube upon a layer of submucous areolar tissue. Lymphoid tissue enters largely into the composition of the tracheal mucous membrane, and its inner surface is lined by columnar ciliated epithelial cells. The action of the cilia exercises an important influence in producing an upward movement of the mucus which is present on the surface of the mucous membrane.

Numerous longitudinal bundles of elastic tissue are present in the posterior wall of the trachea, more particularly in its lower part, between the mucous membrane and the musculus trachealis.

In connexion with the mucous membrane there is a plentiful supply of **acinose mucous glands.** These are placed in the submucous tissue, and also on the posterior aspect of the tube on the exterior of the musculus trachealis as well as amidst its muscular bundles. They send their ducts to the surface of the mucous membrane, where they open by trumpet-shaped mouths.

## THE BRONCHI.

The two **bronchi** proceed obliquely downwards and outwards from the termination of the trachea, each towards the hilum of the corresponding lung. Like the trachea they are kept permanently patent by the presence of cartilaginous rings in their walls. These rings are deficient posteriorly, so that the bronchi exhibit a

flattened posterior surface in every respect similar to the trachea. The two bronchi differ from each other, not only in the relations which they present to surrounding structures, but also in length, in width, and in the direction which they pursue (Fig. 693, p. 973).

The first collateral branch arises from the right bronchus, much nearer the trachea than in the case of the left bronchus. It is this which determines the length of these primary divisions of the trachea, and although there is much variation in this matter, it may be said that, as a rule, the left bronchus is at least twice as long as the right bronchus. According to Henle there are from six to eight rings in the right and from nine to twelve rings in the left bronchus. A marked difference is also noticeable in the calibre of the two tubes. The right bronchus is wider than the left in the proportion of 100 : 78·4 (Braune and Stahel), and this asymmetry is clearly due to the fact that the right lung is more bulky than the left. The right bronchus, as it passes towards the hilum of the right lung, takes a more vertical course than the left bronchus. It therefore lies more in the line of the trachea, and to this, as well as to its greater width, is due the greater tendency which foreign bodies exhibit, when introduced into the trachea, to drop into the right in preference to the left bronchus. The average angle which the right bronchus forms with the median plane is 24·8°, whilst the angle formed by the left bronchus with the median plane is 45·6°. The more horizontal course of the left bronchus is probably determined by the marked projection of the heart to the left side of the mesial plane (Merkel).

**Relations of the Bronchi.**—Arching forwards over the right bronchus is the vena azygos major, whilst arching backwards over the left bronchus there is the arch of the aorta. Occupying the interval between the bronchi there is a cluster of bronchial lymphatic glands, and an irregular chain of similar glands is carried along each tube towards the hilum of the lung. On the posterior aspect of each bronchus the vagus nerve breaks up into the posterior pulmonary plexus, whilst the left bronchus, as it proceeds downwards and outwards, crosses in front of the œsophagus and the descending thoracic aorta. But perhaps the most interesting relation is that presented on each side by the corresponding pulmonary artery. On the left side the pulmonary artery crosses in front of the left bronchus above the level of its first collateral branch, and then turns round its outer side to gain its posterior aspect. All the left bronchial branches, therefore, are placed below the left pulmonary artery, and are in consequence termed **hyparterial.** The right pulmonary artery, on the other hand, crosses in front of the continuation of the right bronchus below its first collateral branch. This branch is therefore termed the **eparterial bronchus**, whilst all the others are classified as hyparterial.

**Structure of the Walls of the Bronchi.**—The walls of the bronchi present a structure similar to that seen in the trachea.

## THE THORACIC CAVITY.

A central vertical partition, termed the **mediastinum thoracis**, which extends from the vertebral column behind to the anterior thoracic wall in front, subdivides the thoracic cavity into two large lateral chambers which contain the lungs. From the fact of each of these chambers being lined by an extensive and separate serous membrane called the **pleura**, they receive the name of the **pleural cavities.**

The mediastinum or intervening partition is built up of several structures which lie in or in close proximity to the mesial plane. The more important of these are the heart, enveloped in its pericardium, the thoracic aorta, with the great vessels which spring from its arch, the pulmonary artery, and the great veins in the neighbourhood of the heart, the thymus gland or its remains, the trachea, œsophagus, and thoracic duct, and the pneumogastric and phrenic nerves.

The pleural cavities in which the two lungs lie comprise much the largest part of the thoracic cavity. Each is bounded *below* by the corresponding cupola of the diaphragm; and as the right cupola rises to a higher level than the left, the right pleural cavity presents a smaller vertical depth than the left. *In front*, the wall of each pleural chamber is formed by the costal cartilages and the sternum;

*laterally*, by the shafts of the ribs and the intercostal muscles as far back as the angles of the ribs; *behind*, by the portions of the ribs, with the intervening intercostal muscles, which lie internal to the costal angles; and *internally*, by the bodies of the vertebræ and the mediastinal partition which completely shut off the one chamber from the other.

The mediastinum is not median in position. Owing to the marked projection of the heart to the left side, and to the position of the descending thoracic aorta on the left side of the mesial plane, the left pleural chamber, although it is deeper than the right, is greatly reduced in width. The two pleural cavities, therefore, are very far from being symmetrical in form.

Each pleural cavity is completely lined by a separate serous membrane termed the **pleura**. The portion of this membrane which clothes the mediastinum or intervening partition forms the lateral boundary of a space termed the **mediastinal** or **interpleural space**, within which the parts which build up the mediastinum are placed.

## THE TWO PLEURAL MEMBRANES.

The pleura or pleural membrane of each side not only lines the corresponding pleural cavity, but at the pulmonary root it is prolonged on to the lung so as to give it a complete investment. It is customary, therefore, to recognise a **visceral** or **investing part** (pleura visceralis) and a **parietal** or **lining part** (pleura parietalis). The inner surface of the membrane (*i.e.* that surface which is turned towards the interior of the cavity) is coated with squamous endothelium, and presents a smooth, glistening, and polished appearance; further, it is moistened by a small amount of serous fluid. In consequence of this the surface of the lung covered by visceral pleura can glide on the wall of the cavity, lined as it is by parietal pleura, with the least possible degree of friction. In the pathological condition known as pleurisy the surface of the membrane becomes roughened by inflammatory exudation, and the so-called "friction sounds" become evident when the ear is applied to the chest.

**Visceral Pleura.** — The visceral pleura is very thin, and is so firmly bound down to the surface of the lung that it cannot be detached without laceration of the pulmonary substance, and then only in small pieces. It dips into the fissures of the lungs, lines them down to the very bottom, and thus completely separates the different lobes of the lungs from each other. The visceral pleura becomes continuous with the mediastinal part of the parietal pleura over the root of the lung, and also through the ligamentum latum pulmonis.

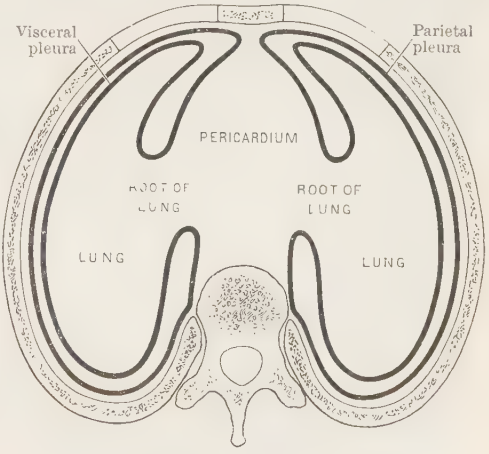

FIG. 695.—DIAGRAM SHOWING ARRANGEMENT OF PLEURAL SACS, as seen in transverse section.

**Parietal Pleura.**—Different names are applied to the parietal pleura as it lines the different parts of the wall of the cavity in which the lung lies. Thus there is the costal pleura, the diaphragmatic pleura, the mediastinal pleura, and the cervical pleura; but it must be borne in mind that these terms are merely used for convenience in description, and the portions of the membrane so designated are all directly continuous with each other.

The **cervical pleura** rises up into the root of the neck, through the superior aperture of the thorax, and forms a dome-shaped roof for the pleural cavity. Its summit or highest point reaches the level of the lower border of the neck of the first rib; but owing to the great obliquity of the first costal arch, this point is placed from one to two inches above the anterior extremity of the first rib, and from a half to one and a half inches above the clavicle. The cervical dome of

pleura is supported on the outer side by the scalenus anticus and scalenus medius muscles, whilst the subclavian artery arches over it, and lies in a groove on its inner and anterior aspect a short distance below its summit. At a lower level the innominate and subclavian veins also lie upon its inner and anterior aspects.

The cervical *cul de sac* of pleura is strengthened and held in place by an aponeurotic expansion, first described by Sibson, which is spread over it, and is attached to the inner concave margin of the first rib. This fascia is derived from a small muscular slip which takes origin from the transverse process of the seventh cervical vertebra.

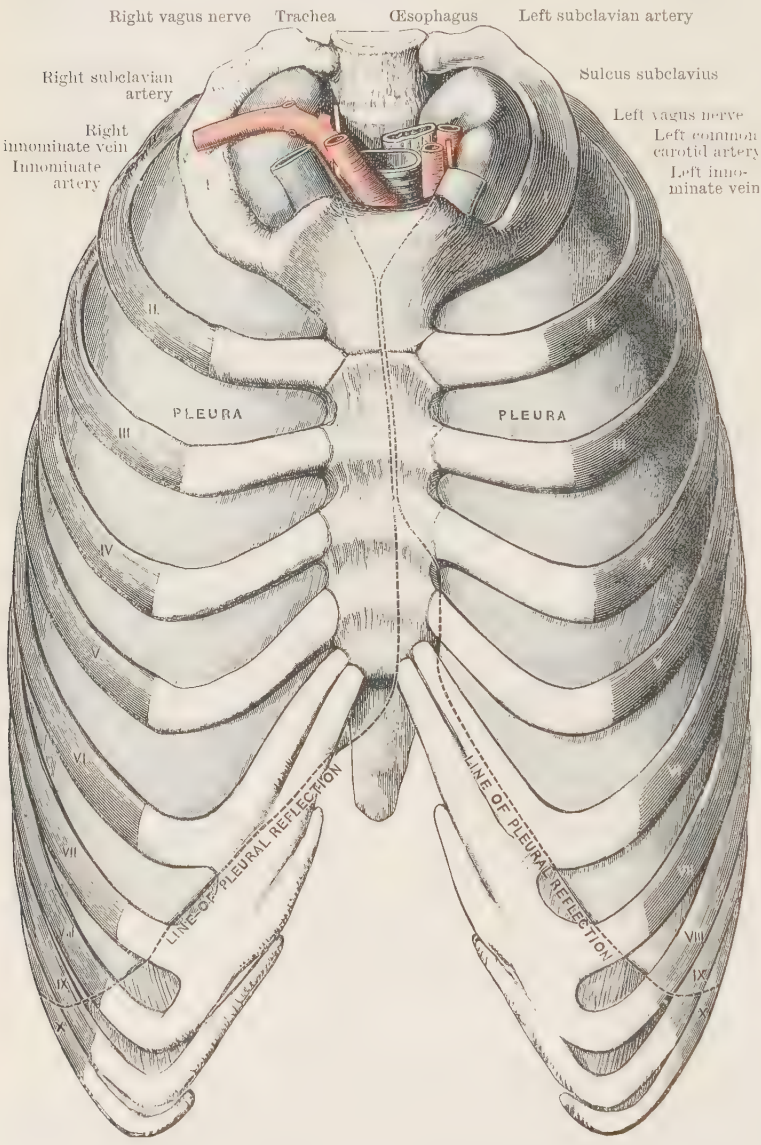

FIG. 696.—DISSECTION OF A SUBJECT HARDENED BY FORMALIN-INJECTION, to show the relations of the two pleural sacs as viewed from the front. The anterior and diaphragmatic lines of pleural reflection are exhibited by black dotted lines, whilst the outlines of the lungs and their fissures are indicated by the blue lines.

The **costal pleura** is the strongest and thickest part of the parietal pleura. It lines the deep surface of the costal arches and of the intervening intercostal muscles. In front it reaches the back of the sternum, whilst behind it is carried forwards on the bodies of the vertebræ. It is easily detached from the parts which it covers, except as it passes from the heads of the ribs on to the vertebral column. Here it is somewhat tightly bound down.

The **diaphragmatic pleura** covers the portion of the upper surface of the diaphragm which lies to the outer side of the base of the pericardium, but it does not dip down to the bottom of the narrow interval between the thoracic wall and the diaphragm. In other words, a strip of the upper surface of the diaphragm adjoining its costal attachment is left uncovered.

The **mediastinal pleura** extends backwards from the posterior surface of the anterior thoracic wall to the vertebral column, and it clothes the side of the mediastinum or partition intervening between the two pleural cavities. It is continuous with the pleura costalis of its own side, both in front and behind, along two lines which are respectively termed the **anterior** and **posterior lines of pleural**

**reflection**; whilst below it becomes continuous with the diaphragmatic pleura of its own side at the base of the pericardium.

Above the level of the root of the lung the mediastinal pleura passes directly backwards from the sternum to the vertebral column. In this region the *left mediastinal pleura* is applied to the arch of the aorta and the phrenic and vagus nerves; to the left innominate vein, the left superior intercostal vein, and the left common carotid and left subclavian arteries; to the œsophagus and the thoracic duct. The *right mediastinal pleura*, on the other hand, is applied, above the level of the root of the lung, to the upper part of the superior vena cava and right innominate vein; to the right innominate artery; to the vena azygos major, as it hooks forwards above the bronchus; to the vagus and phrenic nerves; and to the right side of the trachea.

Opposite the root of the lung, as well as in the region below it, the mediastinal pleura clothes the corresponding aspect of the pericardium, and is somewhat firmly attached to it. As the phrenic nerve passes downwards upon the pericardium it is likewise covered over by the pleura. In the region corresponding to the upper lateral aspect of the pericardium the mediastinal pleura is prolonged outwards, so as to form an investment for the root of the lung, and become continuous around the hilum of the lung with the visceral pleura. Below the root of the lung the two layers of pleura which invest it come into apposition with each other, and are prolonged downwards as a distinct fold, termed the **ligamentum latum pulmonis**. This fold stretches between the pericardium and the lower part of the inner surface of the lung, and ends below in a free border.

Behind the root of the lung and the ligamentum latum pulmonis the mediastinal pleura on the *right side* is carried backwards to the vertebral column on the œsophagus, whilst on the *left side* it is carried backwards over the descending aorta, and to a small extent, in the region immediately above the diaphragm and in front of the aorta, over the lower end of the œsophagus.

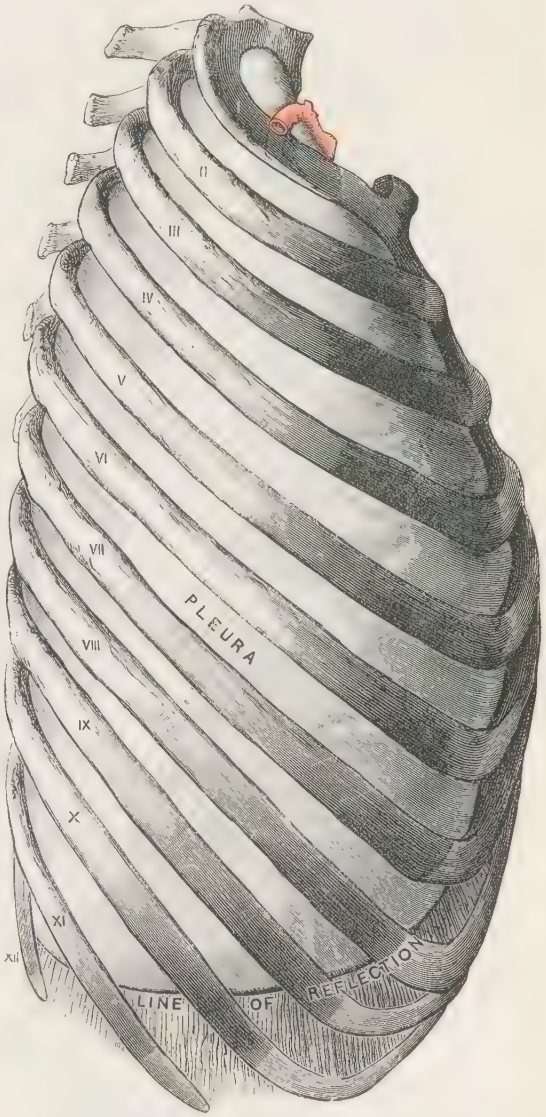

Fig. 697.—Lateral View of the Right Pleural Sac in a Subject hardened by Formalin-injection. The blue lines indicate the outline of the right lung, and also the position of its fissures.

**Lines of Pleural Reflection.**—These are three in number—viz. the anterior or sternal, the posterior or vertebral, and the lower or diaphragmatic. The pleural cavities are not symmetrical. The left is longer and narrower than the right, and it thus happens that the lines of pleural reflection do not accurately correspond on the two sides of the body. Further, although the posterior line of reflection is fairly constant, the other two

reflection-lines are subject to marked variations in different subjects. Consequently the following description must be regarded as merely giving the average condition.

The **posterior** or **vertebral line of pleural reflection** is that along which the costal pleura is continued forwards from the vertebral column to become the mediastinal pleura. On the *right side*, above the root of the lung, the pleura passes from the bodies of the vertebræ on to the right side of the trachea; whilst below this level, and behind the pericardium, it passes from the vertebral bodies on to the œsophagus. On the *left side*, and above the arch of the aorta the pleura along this line of reflection is carried from the vertebral column on to the œsophagus and thoracic duct; below that level it passes on to the descending thoracic aorta. In the upper part of the chest the right and left lines of reflection are placed well apart from each other, and about equidistant from the mesial plane. As they are traced downwards they approach more closely to each other and deviate to the left, so that whilst the reflection on the *right side* takes place from the front aspect of the vertebral bodies, on the *left side* it takes place from the left aspect of the vertebral column. This is due to the position of the descending thoracic aorta.

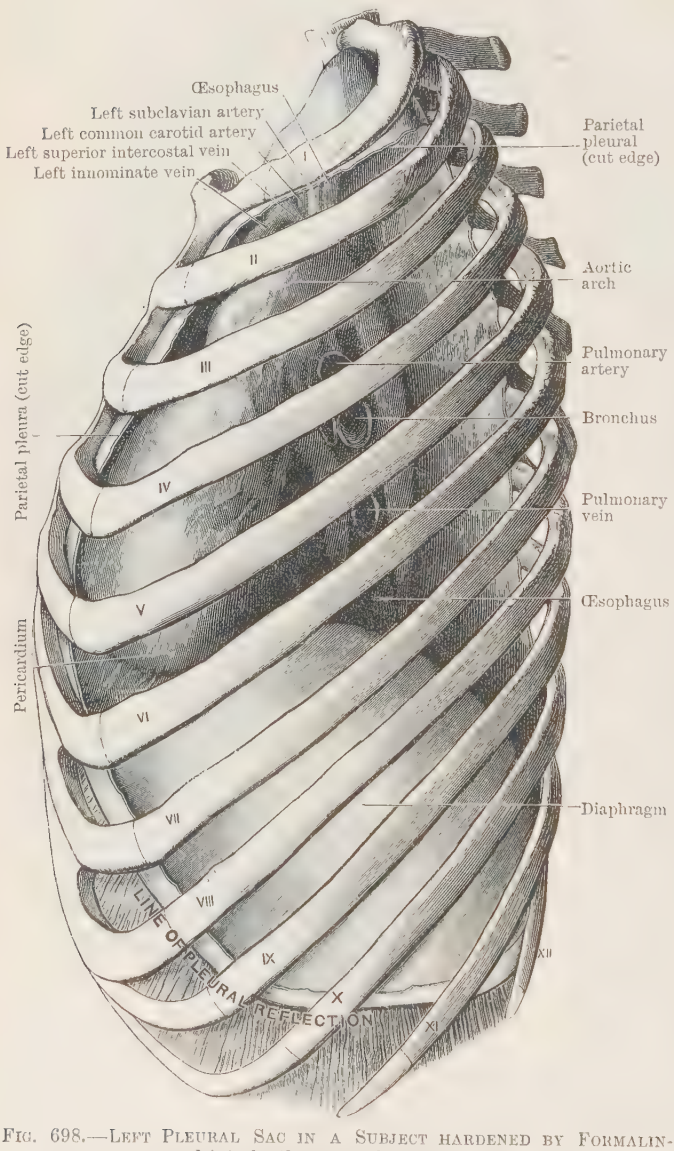

FIG. 698.—LEFT PLEURAL SAC IN A SUBJECT HARDENED BY FORMALIN-INJECTION, opened into by the removal of the costal part of the parietal pleura. The lung has also been removed so as to display the mediastinal pleura.

The **anterior line of pleural reflection** is that along which the costal pleura leaves the anterior thoracic wall to become the mediastinal pleura. The line differs somewhat on the two sides, and in both cases shows a tendency to deviate to the left (Fig. 696, p. 978). Behind the upper part of the manubrium sterni the two pleural sacs are separated from each other by an angular interval. The lines of reflection at the inlet of the thorax correspond to the sterno-clavicular joints. From these points, as they are traced downwards, they converge on the back of the manubrium, until at last they meet a short distance above the upper end of the gladiolus. Here the two sacs come into contact with each other, and the lines of reflection coincide. From this they proceed downwards on the back of the sternum, with a slight deviation to the left of the mesial plane, until a point immediately above the level of the sternal attachments of the fourth costal cartilages is reached, and here the two sacs part company. The line of reflection of the *right pleura* is continued downwards in a straight line behind the sternum until the back of the ensiform cartilage is reached, and here the sternal reflection-line passes into the right diaphragmatic

reflection-line. Opposite the sternal attachment of the fourth costal cartilage the reflection line of the *left pleura* deviates outwards on the back of the sternum, and is continued downwards at a variable distance from the right pleura. A small triangular area of pericardium is thus left uncovered by pleura, and therefore in direct contact with the anterior chest-wall. Leaving the sternum, the reflection-line of the left pleura descends parallel and close to the left margin of the sternum behind the fourth intercostal space, the fifth costal cartilage and the fifth intercostal space, to the back of the sixth costal cartilage. Here it turns outwards and downwards, and passes into the diaphragmatic reflection-line of the left side.

From the back of the sternum the *right pleura* is reflected in the upper part of the chest on to the remains of the thymus, the right innominate vein and the superior vena cava, and below this directly on to the front of the pericardium. The *left pleura* is reflected from the back of the manubrium sterni on to the left innominate vein and the aortic arch, and below this directly on to the front of the pericardium.

The **diaphragmatic line of reflection** is that along which the pleura leaves the thoracic wall and is reflected on to the upper surface of the diaphragm. This reflection takes place along a curved line, which, except behind as it approaches the vertebral column, is placed a short distance above the lower border of the thoracic wall. It differs somewhat on the two sides of the body.

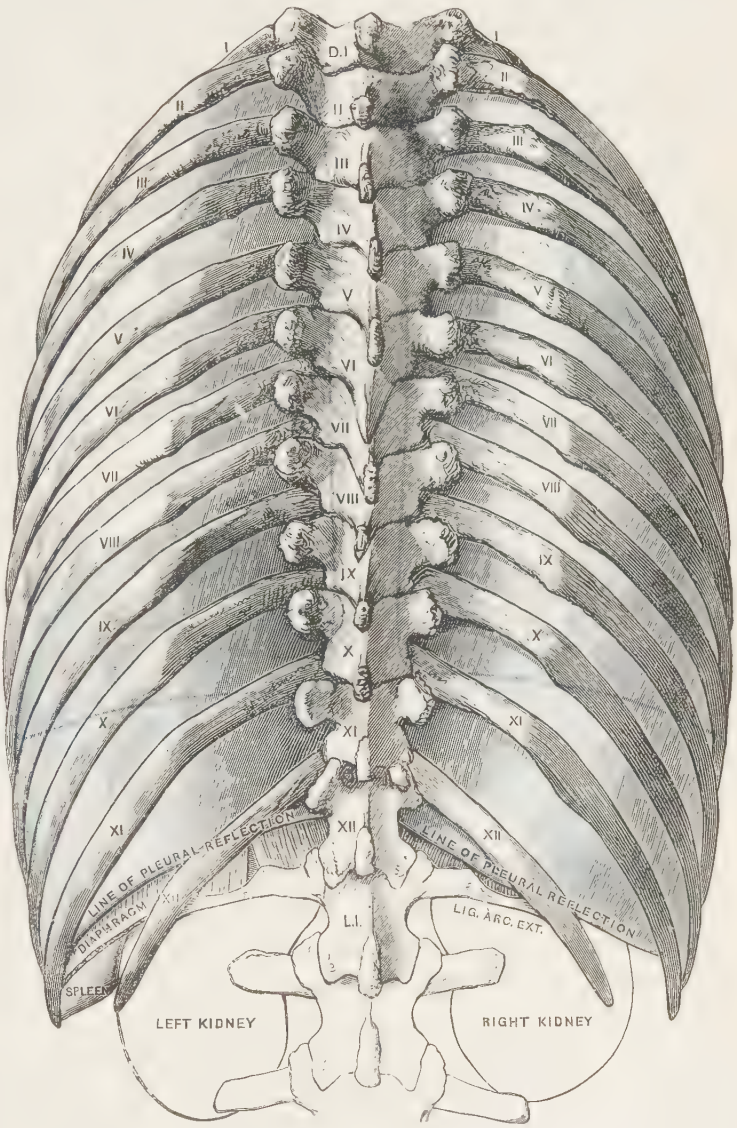

FIG. 699.—DISSECTION OF THE PLEURAL SACS FROM BEHIND.
The blue lines indicate the outlines and the fissures of the lungs.

On the *left side* the diaphragmatic line of reflection proceeds downwards behind the ascending part of the sixth costal cartilage, crosses behind the anterior end of the sixth intercostal space and the descending part of the cartilage of the seventh rib (Fig. 698). Still continuing to descend, it passes behind the eighth costal arch at the junction between its cartilaginous and bony portions. This is a fairly constant relation on both sides of the body, and it should be noted that a vertical line drawn downwards from the nipple (mammillary line) intersects the line of pleural reflection close to the point where it presents this relation to the eighth costal arch. Beyond this point the line of diaphragmatic reflection is carried downwards and outwards across the extremities of the bony portions

of the ninth and tenth ribs. As it passes under cover of the tenth rib, or it may be as it proceeds across the tenth intercostal space, the line of pleural reflection reaches its lowest point, and it is important to observe that this point lies in the mid-lateral line (*i.e.* a vertical line drawn downwards on the side of the chest midway between spine and sternum). From this it ascends slightly as it curves backwards towards the spine. Thus it cuts across the eleventh rib and reaches the twelfth rib. The relation which it presents to the twelfth rib varies in accordance with the length of that rib. When the last rib is not abnormally short the pleura clothes its inner half, and the line of reflection falls below this portion of the rib so as to reach the spine midway between the head of the last rib and the transverse process of the first lumbar vertebra (Fig. 699). Here, therefore, the line of diaphragmatic reflection falls below the lower border of the thoracic wall, and this is a point of high practical importance. In operations upon the kidney the incision cannot be carried above the level of the transverse process of the first lumbar vertebra and the ligamentum arcuatum externum without the risk of wounding the pleura.

On the *right side* the line of diaphragmatic pleural reflection differs from that on the left chiefly in front (Fig. 697, p. 979). Here it descends to a lower level. Thus it proceeds outwards and downwards from the back of the ensiform cartilage along the posterior aspect of the ascending part of the seventh costal cartilage, and it passes beneath the eighth costal arch, as a rule, at the same point as on the left side, viz. at the junction of its cartilaginous and bony parts. From this backwards to the spine the relations are so similar to those of the left side that a separate description is unnecessary.

It is commonly stated that the left pleural sac reaches a lower level than the right. In certain cases there is no doubt that it does, but this condition is by no means the rule. In those cases where the two pleural sacs do not reach the same level at their lowest points, it is sometimes the right and sometimes the left pleura which oversteps the mark.

As already stated, the lowest point to which the pleura descends is usually found, on both sides, in the mid-lateral line where the diaphragmatic reflection-line crosses the tenth rib or the tenth intercostal space. This point can be very readily ascertained on the surface by drawing a horizontal line round the trunk at the level of the lower part of the extremity of the spinous process of the first lumbar vertebra, and noting where it is intersected by the mid-lateral line. In the majority of cases the point of intersection will correspond with the lowest part of the pleural sac. Another horizontal line opposite the spine of the last dorsal vertebra will give the level of the diaphragmatic pleural reflection in the mammillary line.[1]

Along the line of the diaphragmatic reflection a strong fascia passes from the lower uncovered part of the diaphragm, and from the costal cartilages to the surface of the costal pleura, so as to hold it firmly in its place. It may be termed the **phrenico-pleural fascia**.

## MEDIASTINAL OR INTERPLEURAL SPACE.

The term mediastinal space is applied to the interval between the mediastinal portions of the two pleural sacs. In front it is bounded by the sternum, and behind by the vertebral column. It is customary to subdivide this space in a purely arbitrary manner into four portions, termed respectively superior, anterior, middle, and posterior, according to the relations which they present to the pericardium.

The **superior mediastinum** is the part of the general space which lies above the level of the pericardium. Its boundaries are the following:—*In front*, the manubrium sterni, to the posterior aspect of which are the attached lower ends of the sterno-hyoid and sterno-thyroid muscles; *behind*, the bodies of the upper four dorsal vertebræ; *below*, an imaginary and oblique plane, which extends from the lower border of the manubrium sterni backwards and upwards to the lower border of the fourth dorsal vertebra; *laterally*, the mediastinal pleura.

Within the superior mediastinal space are placed (1) the aortic arch and the three great arteries which spring from it; (2) the innominate veins and the upper part of the superior vena cava; (3) the trachea, gullet, and thoracic duct; (4) the phrenic, pneumogastric, left recurrent laryngeal and cardiac nerves; (5) the thymus gland.

[1] The above description represents the average results which have been obtained from the study of the pleura in a large number of subjects, eight of which were specially hardened by formalin or other re-agents for the purpose. For many of the dissections I have to thank my former assistant, Dr. H. St. J. Brooks, and for others I am indebted to Professor C. J. Patten of Sheffield.

The **middle mediastinum** is the wide part of the space which contains the pericardium, and lies below the superior mediastinum. In addition to the pericardium and its contents the middle mediastinum contains the phrenic nerves and their accompanying vessels.

The **anterior mediastinum** is that part of the interpleural space which lies between the pericardium behind and the sternum in front. In its upper part this space can hardly be said to exist, seeing that here the two pleural sacs come into contact with each other on the anterior aspect of the pericardium; but below the level of the sternal ends of the fourth costal cartilages the left pleura falls short of the right pleura, and an interval is apparent. The only contents to be noticed in the anterior mediastinum are a few lymphatic glands and some areolar tissue, in which ramify some lymphatic vessels, and some minute twigs from the internal mammary artery.

The **posterior mediastinum** is that part of the interpleural space which is situated behind the pericardium. It may be regarded as the continuation downwards of the posterior part of the superior mediastinum, and many of the structures in the one are prolonged downwards into the other. The arbitrary upper limit of the posterior mediastinum is the lower border of the fourth dorsal vertebra. *In front* it is bounded by the pericardium, except in its lowest portion, where the anterior wall is formed by the back of the diaphragm. *Behind* it is limited by the bodies of the eight lower dorsal vertebræ, and *on each side* by the mediastinal pleura. It contains the descending thoracic aorta with the left aortic intercostal arteries, the azygos veins, the thoracic duct and the œsophagus, with the two pneumogastric nerves.

**Structure of the Pleura.**—The pleura on each side is a closed sac, and, like other serous membranes, it is attached by its outer surface to the wall of the cavity which it lines and to the surface of the viscus which it covers. It is composed of a thin connective-tissue stratum in which bundles of fibres cross each other in various directions, and intermixed with which there is a considerable quantity of elastic tissue. On the inner surface of this there is a continuous coating of thin endothelial cells placed edge to edge. The pleura so formed is attached to the parts it lines and invests by a small amount of areolar tissue which forms a **subserous layer**. In the case of the visceral pleura the subserous tissue is continuous with the areolar tissue in the substance of the lung, and this accounts for the tight manner in which the membrane is bound down.

The pleura is plentifully supplied with blood. This is conveyed to it by minute twigs from the intercostal arteries, the internal mammary artery, and the bronchial arteries. Lymphatic vessels also are particularly abundant in the pleura and in the subserous layer, and it is by these that excess of fluid is conveyed from its cavity. Many lymphatic vessels communicate directly with the cavity by means of excessively minute orifices termed **stomata**. Dybkowsky has shown that the lymphatics and stomata of the pleura are not equally distributed throughout the membrane. Over the ribs and on the mediastinal pleura they are absent.

## THE LUNGS.

When healthy and sound each lung lies free within the corresponding pleural chamber, and is only attached by its root and the ligamentum latum pulmonis. It is not common, however, to meet with a perfectly healthy lung. Adhesions between the visceral and parietal layers of pleura, due to pleurisy, are generally present.

Like the cavities in which they are placed, the two lungs are not precisely alike. The right lung is slightly larger than the left, in the proportion of about 11 to 10. The right lung is also shorter and wider than the left lung. This difference is due to the great bulk of the right lobe of the liver, which elevates the right cupola of the diaphragm to a higher level than the left cupola, and likewise to the heart and pericardium projecting more to the left than to the right, and thus diminishing the width of the left lung.

The lung is light, soft, and spongy in texture; when pressed between the finger and thumb it crepitates, and when placed in water it floats. The elasticity of the pulmonary tissue is very remarkable. A striking demonstration of this is afforded when the thoracic cavity is opened, and the atmospheric pressure acting

upon the interior and exterior of the lung is equalised. Immediately the organ collapses to about one-third of its original bulk, and it becomes impossible in such a specimen to study its proper form and dimensions.

The surface of the adult lung presents a mottled appearance. The ground colour is a light slate-blue, but scattered over this there are numerous dark patches of various sizes, and also fine dark intersecting lines. The coloration of

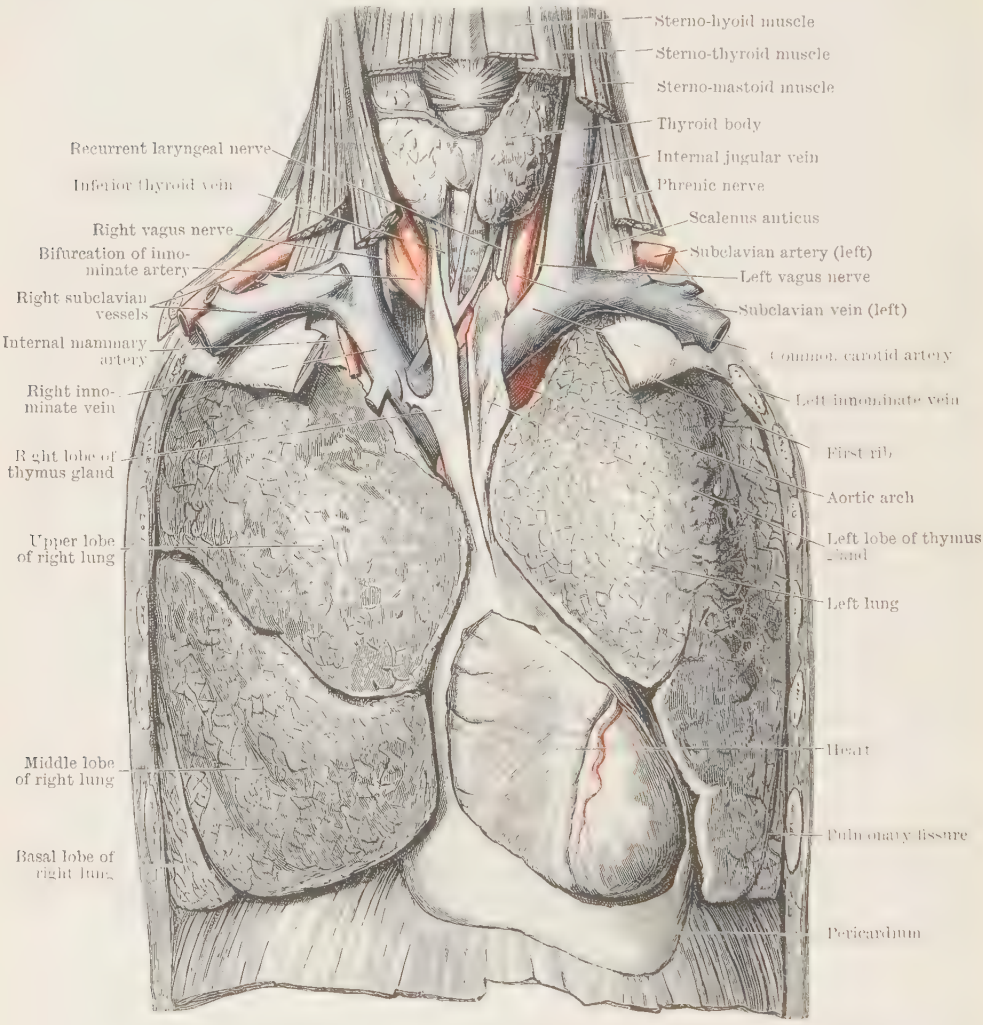

FIG. 700.—DISSECTION OF THORAX AND ROOT OF THE NECK FROM THE FRONT TO SHOW THE RELATIONS OF THE LUNGS, PERICARDIUM AND THYMUS GLAND.

the lung differs considerably at different periods of life. In early childhood the lung is rosy-pink, and the darker colour and the mottling of the surface which appear later are due to the pulmonary substance, and chiefly the interstitial areolar tissue becoming impregnated more or less completely with atmospheric dust and minute particles of soot.

At every breath foreign matter of this kind is inhaled, but only a small proportion of it reaches the lung tissue. The greater part of it becomes entangled in the slimy mucus which coats the mucous membrane of the larger air-passages, and is gradually got rid of along with the mucus through the activity of the cilia attached to the lining epithelium. By the constant upward sweep of these a current towards the pharynx is established. The fine dust and soot particles which reach the finer recesses of the lungs, and ultimately the interstitial issue, is partly conveyed away by the lymphatic vessels to the bronchial glands, which in consequence become in many cases absolutely black. The colour of the lung, therefore, depends to some

extent upon the purity of the atmosphere which is inhaled, and it thus happens that in coal-miners the surface of the lung may be very nearly uniformly black.

The fœtal lung differs in a marked degree from the lung in an individual who has breathed. After respiration is fully established, the lung soon comes to occupy almost the whole space allotted to it in the pleural cavity; in the fœtus, on the other hand, the lung is packed away at the back, and occupies a relatively much smaller amount of space in the thoracic cavity. Further, it is firm to the touch, and sinks in water. It is only when air and an increased supply of blood are introduced into the lung that it assumes the soft spongy and buoyant qualities which are characteristic of the adult lung.

**Form of the Lungs.**—The lungs are accurately adapted to the walls of the pleural chambers in which they are placed, and in the natural state they bear on

the surface impressions and elevations which are an exact counterpart of the irregularities on the walls of the cavity in which they lie.

When care has been taken to harden it *in situ*, each lung presents an apex and a base, an inner and an outer surface, and an anterior and a posterior border.

The **apex pulmonis** is blunt and rounded, and rises above the level of the oblique first costal arch to the full height of the cervical dome of pleura. It therefore protrudes upwards through the thoracic inlet into the root of the neck. The subclavian artery arches outwards on its inner and anterior aspects a short distance below its summit, and a groove (sulcus subclavius) corresponding to the vessel is apparent upon it. At a lower level on the apex pulmonis a shallower and wider groove upon its inner and anterior aspects marks the position of the innominate and subclavian veins. Although these vessels impress the lung they are separated from it by the cervical pleura.

The **basis pulmonis** presents a semilunar outline, being curved around the base of the pericardium. It is adapted to the upper surface of the diaphragm, and consequently it is deeply hollowed out. As the right cupola of the diaphragm ascends higher than the left, the basal concavity of the right lung is deeper than that of

the left lung. Laterally and behind, the base of each lung is limited by a salient thin margin which descends for some distance in the narrow pleural recess (sinus phrenico-costalis) between the diaphragm and the chest wall. This basal margin of the lung extends lower down on the outer side and behind than it does in front, but it falls considerably short of the bottom of the phrenico-costal sinus of pleura. Thus, after expiration, it reaches in the mammillary line the lower border of the sixth rib; in the axillary or mid-lateral line the eighth rib; whilst behind it proceeds inwards along a straight horizontal line so as to reach the vertebral column at the level of the extremity of the spine of the tenth dorsal vertebra. During respiration the thin basal margin rises and falls in the phrenico-costal sinus of the pleura, but even after the deepest breath it never reaches the lowest limit of this recess.

The bases of the lungs establish important relations with certain of the viscera which occupy the costal zone of the abdominal cavity, the diaphragm alone intervening. Thus

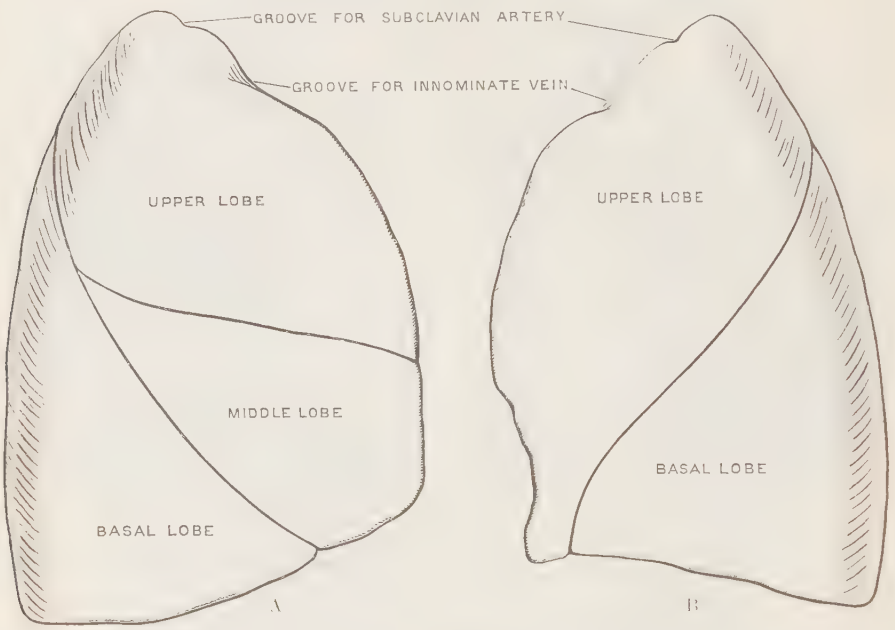

Fig. 702.—Outer or Costal Surfaces of the two Lungs.
A, Right lung. B, Left lung.

the base of the right lung rests upon the right lobe of the liver; whilst the base of the left lung is in relation to the left lobe of the liver, the fundus of the stomach, the spleen, and in some cases to the splenic flexure of the colon.

The **outer surface of the lung** (facies costalis pulmonis) is extensive and convex. It is accurately adapted to that part of the wall of the pleural cavity which is formed by the costal arches and the intervening intercostal muscles, and it presents markings corresponding to these. Thus the imprint of the ribs appear as shallow oblique grooves, while the intercostal spaces show as elongated intervening bulgings.

The **inner or mediastinal surface** of the lung (facies mediastinalis pulmonis) presents a smaller area than the outer surface. It is applied to the mediastinal septum, and presents markings in accordance with the inequalities upon this (Fig. 701, p. 985). Thus it is deeply hollowed out in adaptation to the pericardium upon which it fits. This pericardial concavity comprises the greater part of the mediastinal surface, and owing to the greater projection of the heart to the left side, it is much deeper and more extensive in the left lung than in the right lung. Above and behind the pericardial hollow is the **hilum** of the lung. This is a wedge-shaped depressed area, within which the vessels, nerves, and lymphatics, together with the

bronchus, enter and leave the organ. Amidst these structures also are some bronchial glands. The hilum is surrounded by the reflection of the pleura from the surface of the lung on to the pulmonary root. Behind the hilum and pericardial area there is on each lung a narrow strip of the inner surface of the lung which is in relation to the lateral wall of the posterior mediastinum. On the *right lung* this part of the surface is depressed, and corresponds to the œsophagus; on the *left lung* it presents a broad longitudinal groove, which is produced by the contact of the lung with descending thoracic aorta, and also, close to the base, a small flattened area in front of this which is applied to the œsophagus where it pierces the diaphragm.

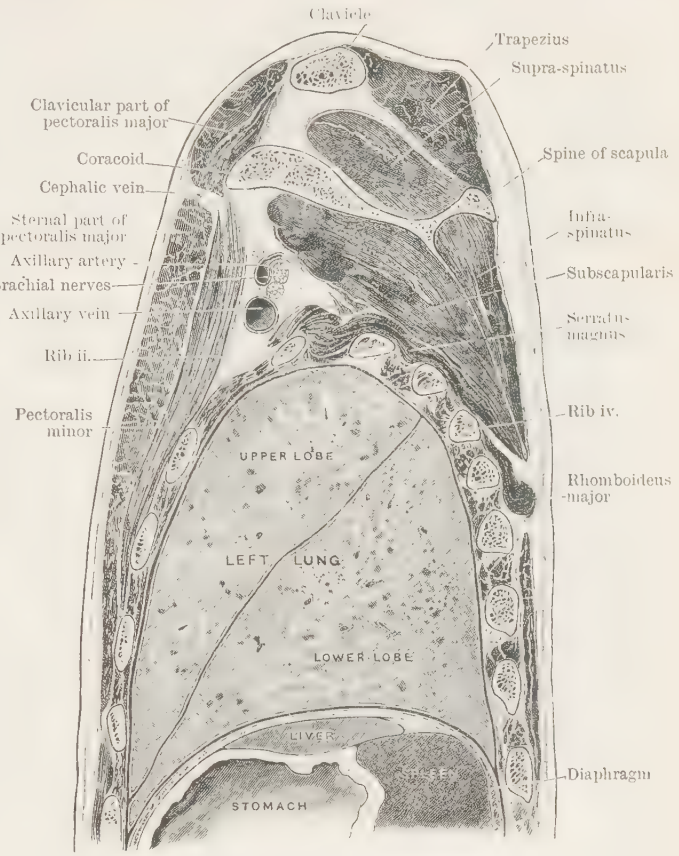

FIG. 703.—SAGITTAL SECTION THROUGH LEFT SHOULDER AND LEFT LUNG.

The portion of the inner surface of the lung which lies above the hilum and pericardiac hollow is applied to the lateral aspect of the superior mediastinum, and the markings are accordingly somewhat different on the two sides. On the *left lung* a broad deep groove, produced by the aortic arch, curves backwards over the hilum, and becomes continuous with the aortic groove on the posterior mediastinal surface. From this a narrower, deeper, and much more sharply-marked groove ascends, and turns outwards over the apex pulmonis a short distance from the summit. This is the sulcus subclavius, and it contains the left subclavian artery when the lung is in place. In front of this a shallow wide groove, also leading up to the front aspect of the apex, corresponds to the left innominate vein. In the *right lung* the hilum is also circumscribed above by a curved groove, but this is narrow and more distinctly curved than the aortic groove on the left side. It lodges the vena azygos major as it turns forwards to join the superior vena cava. From the anterior end of the azygos sulcus a wide shallow groove extends upwards to the lower part of the front of the apex pulmonis. This is produced by the apposition of the lung with the vena cava superior and the right innominate vein. Close to the summit of the apex there is also, on its inner aspect, a sulcus for the upper end of the innominate artery.

In addition to the hilum, it must now be evident that the inner surface of each lung presents three areas which correspond respectively with (1) the middle mediastinum (*i.e.* the pericardial hollow); (2) the posterior mediastinum; and (3) the superior mediastinum; and that in each of these districts impressions corresponding to structures contained within these portions of the interpleural space may be noticed.

The **posterior border of the lung** is thick, long, and rounded. It forms the most

bulky part of the organ, and occupies the deep hollow in the thoracic cavity which is placed on either side of the spine. Indeed the term "border" is somewhat inappropriate, as it forms in reality a somewhat extensive surface deeply impressed by the ribs, and not in any way marked off from the outer surface of the lung.

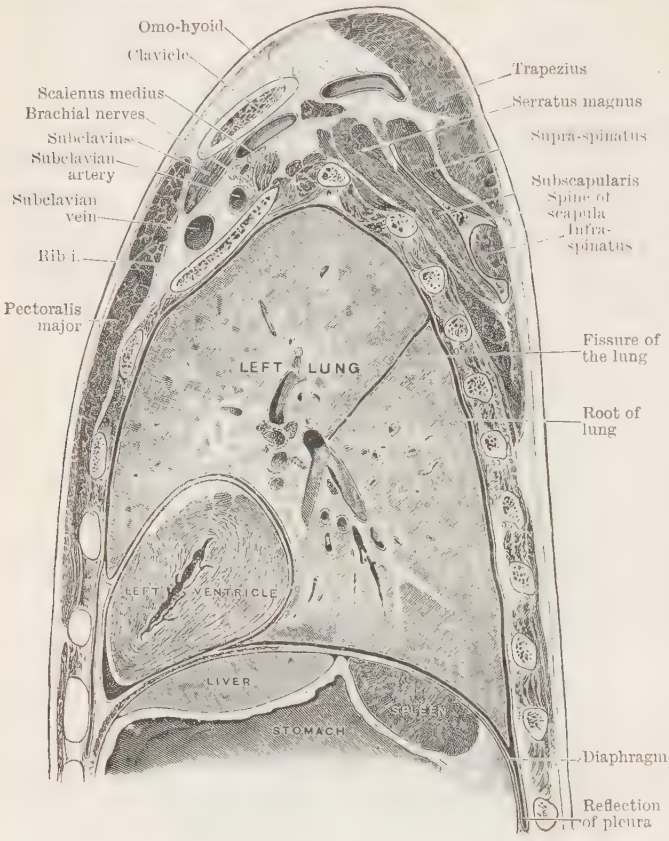

FIG. 704.—SAGITTAL SECTION THROUGH THE LEFT SHOULDER, LUNG, AND APEX OF THE HEART.

The **anterior border of the lung** is short and exceedingly thin and sharp. It begins abruptly above, immediately below the groove on the apex for the innominate vein, and extends down to the base, where it becomes continuous with the sharp basal border. The thin anterior part of the lung is carried forwards and inwards in front of the pericardium into the narrow pleural recess behind the sternum and costal cartilages (sinus costo-mediastinalis). The anterior border of the right lung fills up this recess completely, and in the upper part of the chest is only separated from the corresponding border of the left lung by the two layers of mediastinal pleura which are reflected backwards from the sternum to the pericardium. The anterior border of the left lung, in its lower part, shows a marked deficiency or notch (incisura cardiaca) corresponding to the apex of the heart, and where this exists the lung margin leaves a considerable portion of the pericardium uncovered, and fails to completely fill up the costo-mediastinal sinus of the pleural cavity. During respiration the anterior margin of the left lung at the incisura cardiaca advances and retreats to a small extent in this pleural sinus in front of the pericardium.

**Fissures and Lobes of the Lungs.**—The *left lung* is divided into two lobes by a long deep fissure which penetrates its substance to within a short distance of the hilum. Above and below the hilum this fissure cuts right through the lung and appears upon the mediastinal or inner surface. Viewed from the outer aspect of the organ, it begins at the posterior border about two and a half inches below the summit of the apex, about the level of the vertebral end of the third rib, and is continued downwards and forwards in a somewhat spiral direction to the base of the lung, which it reaches a short distance behind its anterior end. The **upper lobe** of the lung (lobus superior) lies above and in front of this cleft. It is conical in form, with an oblique base, and the apex and the whole of the anterior border of the lung belong to it. The **lower lobe** (lobus inferior) lies below and behind the fissure. It is the more bulky of the two, and includes almost the entire base and the greater part of the thick posterior border.

In the *right lung* there are two fissures subdividing it into three lobes. One of these fissures is very similar in its position and relations to the fissure in the left lung. It is, however, rather more vertical in its direction, and ends below somewhat

further outwards. It separates the lower lobe from the upper and middle lobes. The second cleft begins in the main fissure at the posterior border of the lung, and proceeds horizontally forwards, to end at the anterior border of the lung at the level of the fourth costal cartilage. The **middle** or **intermediate lobe** of the right lung is triangular or wedge-shaped in outline.

**Variations.**—Variations in the pulmonary fissures are fairly common. Thus it sometimes happens that the middle lobe of the right lung is imperfectly cut off from the upper lobe. Supernumerary fissures also are not infrequent, and in this way the left lung may be cut into three lobes, and the right lung into four or even more lobes. The occurrence of a **lobus azygos** in the right lung is a variation of some interest, seeing that such a lobe is constant in certain mammals. It is a small accessory lobe, pyramidal in form, which makes its appearance on the lower part of the inner aspect of the right lung. In certain cases the vena azygos major is enclosed within a fold of pleura, and is sunk so deeply in the pulmonary substance of the right lung that it marks off a small accessory lobe.

## ROOT OF THE LUNG.

The term **root of the lung** (radix pulmonis) is applied to a number of structures which enter and leave the lung at the hilum on its inner surface. They are held together by an investment of pleura, and constitute a pedicle which attaches the lung to the mediastinal wall of the pleural cavity. The phrenic nerve descends a short distance in front of the pulmonary root, whilst the vagus nerve breaks up into the posterior pulmonary plexus on its posterior aspect under cover of the investing pleura. The delicate anterior pulmonary plexus is placed in front of the root of the lung beneath the pleura, whilst from the lower border of the root of the lung the ligamentum latum pulmonis extends downwards. These are the relations which are common to the pulmonary root on both sides of the body, but there are others which are peculiar to each side. On the *right side* the superior vena cava lies in front of the pulmonary root, whilst the vena azygos major arches over its upper aspect. On the *left side* the aorta arches over the root of the lung, whilst the descending thoracic aorta passes down behind it.

**Constituent Parts of the Pulmonary Root.**—The most important structures which enter into the formation of the pulmonary root are (1) the two pulmonary veins; (2) the pulmonary artery; (3) the bronchus. But in addition to these there are one or more small bronchial arteries and veins, the pulmonary nerves and the pulmonary lymphatic vessels, and some bronchial glands.

The **pulmonary nerves** come from the vagus nerve and also from the sympathetic system. They enter the lung and follow the air-tubes through the organ. The **bronchial arteries** are small vessels which carry blood for the supply of the lung tissue. They arise from the aorta or from an intercostal artery, and vary in number from one to three for each lung. In the root of the lung they lie on the posterior aspect of the bronchus, and they follow the air-tubes through the organ. Part of the blood conveyed to the lung by the bronchial arteries is returned by the pulmonary veins; the remainder is returned by special **bronchial veins** which open on the right side into the vena azygos major, and on the left side into the vena azygos minor superior.

The **lymphatic vessels** of the lung, as they emerge from the hilum, unite into a small number of trunks, which, placed behind the large pulmonary vessels, open into the bronchial glands.

The **bronchus** in the root of the lung lies behind the great pulmonary vessels. The **pulmonary artery** occupies a different position on the two sides in relation to the main or undivided part of the bronchus. On the right side it is placed below it, whilst on the left side it crosses the bronchus and occupies a higher level in the pulmonary root. The two **pulmonary veins** on both sides lie at a lower level in the root of the lung than the pulmonary artery and bronchus, whilst the upper of the two veins occupies a plane in front of the pulmonary artery (Fig. 701, p. 985).

**Distribution of the Bronchial Tubes within the Lungs.**—The two lungs are not symmetrical; the right lung is subdivided into three lobes, and the left lung is cleft into two lobes. The bronchi exhibit a corresponding want of symmetry. The *right bronchus*, as it approaches the pulmonary hilum, gives off two branches for the upper and middle lobes of the right lung respectively, and then the main stem of the tube enters the lower lobe. The *left bronchus* sends off a large branch to the upper lobe of the left lung, and then sinks into the lower lobe. The first branch of the right bronchus for the upper right pulmonary lobe leaves the main stem about one

inch from the trachea. The first branch of the left bronchus, on the other hand, takes origin about twice that distance from the trachea.

The relation of the pulmonary artery to the bronchial subdivisions is different on the two sides. On the right side it turns backwards to reach the posterior aspect of the bronchus below the first and above the second bronchial branch. On the left side the pulmonary artery turns backwards above the level of the first bronchial branch. On the right side, therefore, the first bronchial branch is placed above the pulmonary artery, and in consequence it is termed the **eparterial bronchus**; all the others lie below the artery, and are termed **hyparterial bronchi**. On the left side there is no eparterial branch; they are all hyparterial.

When the main stem of the bronchus is followed into the inferior lobe of each lung, it is seen to travel downwards and backwards in the pulmonary substance until it reaches the thin back part of the base of the lung which lies between the diaphragm and the thoracic wall, and there it ends. As it proceeds through the inferior lobe it gives off a series of large **ventral** and a series of smaller **dorsal branches**. As a rule these are three in number in each case, and the dorsal and ventral branches do not arise opposite to each other, but alternately, one from the back, and then another, after a slight interval, from the front of the tube. The first hyparterial division on each side (*i.e.* the branch to the middle lobe of the right lung and the branch to the upper lobe of the left side) is generally regarded as the first member of the ventral group.

It was Aeby who first recognised the existence in each lung of a main or stem bronchus giving off a ventral and dorsal series of branches, and who drew the distinction between the eparterial and hyparterial bronchial branches. A consideration of these relations led this author to conclude that the eparterial bronchus and the upper lobe of the right lung have no morphological equivalents on the left side of the body. In other words, he was led to believe that the middle lobe of the right lung is the homologue of the upper lobe of the left lung. Hasse, who has also investigated the subject, endorsed this view, with certain modifications and additions, and the hypothesis, either in its original state as presented by Aeby, or as subsequently modified by Hasse, has been, until lately, very generally accepted by anatomists. More recent research, however, has seriously affected the stability of this conclusion. Narath contends that the distinction between the eparterial bronchus of the right side and the hyparterial bronchi of both sides is not one of fundamental importance, and further, that a branch which arises from the first hyparterial bronchus on the left side and turns upwards into the apex of the left lung is the direct equivalent of the eparterial bronchus of the right side. This he terms the **apical bronchus**, and he believes that it represents the first dorsal branch of the left stem-bronchus. Huntington, in a very convincing paper, strongly supports the contention of Narath, and holds that, except "for purposes of topography, we should abandon the distinction between eparterial and hyparterial bronchi." With Narath he regards the eparterial bronchus as a secondary branch which has migrated in an upward direction on the main stem. According to Huntington, therefore, Aeby's proposition should be amended as follows:—

| Right side. | | | | Left side. |
|---|---|---|---|---|
| Upper | + | middle lobe | = | Upper lobe. |
| Lower | + | cardiac lobe | = | Lower lobe. |

The cardiac lobe mentioned in this table is the occasional azygos lobe to which reference has already been made, and it is interesting to note that, whilst the lobe in question as a separate entity is rarely seen in the human lung, the bronchus which corresponds to it is always present in the pulmonary substance as an accessory branch, which proceeds from the main stem as it traverses the lower lobe of the right side. It receives the name of the **cardiac bronchus**.

## Structure of the Lung.

The lung is constructed so that the blood which reaches it through the pulmonary artery is brought into the most intimate relation with the air which enters it through the trachea and bronchi. An interchange of materials between the blood and the air is thus rendered possible, and the object of respiration is attained. As a result of this interchange the dark impure blood which flows into the lung through the pulmonary artery is rendered bright red and arterial.

**Lobules of the Lung.**—A thin layer of subpleural connective tissues lies subjacent to the continuous coating which the lung receives from the visceral pleura. From the deep surface of this subpleural layer fine septal processes penetrate into the substance of the lung, and these, with the connective tissue which enters at the hilum upon the vessels and bronchi, constitute a supporting framework for the organ. The lung is lobular, and on the surface the small polygonal areas which represent the lobules are indicated by the

pigment present in the connective tissue septa which intervene between them. Although no pigment is present, the lobular character of the lung is particularly well marked in the fœtus, and with a little care the surface lobules in the fœtal lung can be separated from each other by gently tearing through the intervening connective tissue. The lobules thus isolated are pyriform or pyramidal in form. The broad bases of these lobules abut against the subpleural layer, whilst each of the deep narrow ends receives a minute division from the bronchial system of tubes. The lobules which lie more deeply in the substance of the organ are not so large, and are irregularly polygonal in form.

**Alveolar Ducts, Infundibula, and Air-cells.**—The larger branches of the bronchi, as they traverse the lung, give off numerous divisions which, by repeated branching, ultimately form a system of tubes which pervade the entire organ. At first the bronchial divisions come off at very acute angles, but as the finer ramifications are reached this character becomes much less apparent. There is no anastomosis between the bronchial branches.

Within the various lobules the finer bronchioles send off further branches, which proceed at right angles from them. Soon the ultimate tubes are reached. These are not cylindrical, but have their walls pouched out by numerous hemispherical diverticula. Such a bronchiole is called an **alveolar duct**, and the diverticula are the **air-cells** or **alveoli**. Finally the alveolar duct divides into two, three, or more terminal parts, which become expanded and form the club-shaped, blind terminations of the bronchial system of tubes. These cæcal endings are the **infundibula**, and the walls of each are thickly covered by alveoli or air-cells, all of which open into the infundibulum as into a corridor.

**Structure of the Bronchi.**—When the large bronchi enter the lung they become cylindrical, and lose the flattening on the posterior aspect which is characteristic of the primary bronchi outside the lung. They possess the same coats as are present in the case of the trachea and primary bronchi, but as the tubes become smaller by repeated division, these coats become correspondingly thinner and finer. Certain marked differences also in the manner in which the constituents of these coats are arranged become apparent.

In the **external fibro-cartilaginous coat** the cartilage is no longer present in the form of incomplete rings, but in irregular plates or flakes deposited at various points around the wall. As the tubes diminish these cartilaginous deposits show a corresponding reduction in size, until at last, in bronchi of 1 mm. in diameter, they disappear altogether. The **glands** in relation to the tubes for the most part cease to exist about the same point. The **muscular** or **middle coat**, which in the trachea and primary bronchi is confined to the back wall of the tube, forms a continuous layer of circularly-arranged bundles in the bronchi as they ramify within the lung. Spasmodic contraction of the muscular coat gives rise to the serious symptoms which accompany asthmatic affections. The muscular fibres of the middle coat may be traced as far as the infundibula, on the walls of which they are present in considerable numbers. The **mucous lining** of the tubes becomes greatly thinned as it is followed into the smaller bronchioles. It contains a large number of longitudinally-arranged elastic fibres, and is disposed in longitudinal folds, so that when the tube is cut across the lumen presents a stellate appearance. The mucous membrane is lined by ciliated columnar epithelium.

**Structure of the Infundibula and Alveoli.**—The walls of the infundibula and alveoli are exceedingly fine and delicate, but nevertheless constituents continuous with those observed in the three coats of a bronchus are found entering into their construction. The epithelium is reduced to a single layer. Further, it is no longer columnar and ciliated, but it has become flat and pavement-like. Two kinds of epithelial cells may be recognised—(1) a few small granular polygonal cells, arranged singly or in groups of two or three; (2) more numerous thin cells of large size, and somewhat irregular in outline. Outside the epithelium is a delicate layer of faintly-fibrillated connective tissue. This is strengthened by a network of elastic fibres which is specially well marked around the mouths of the alveoli, and is also to some extent carried over the walls of the air-cells. Muscular fibres are likewise present on the walls of the infundibula, but it is questionable if any are prolonged over the air-cells.

**Pulmonary Vessels.**—The pulmonary artery, as it traverses the lung, divides with the bronchi, and closely accompanies these tubes. The resultant branches do not anastomose, and for the most part they lie above and behind the corresponding bronchi. The fine terminal divisions of the artery join a dense capillary plexus which is spread over the alveoli or air-cells. This vascular network is so close that the meshes are barely wider than the capillaries which form them. In the partitions between adjacent alveoli there is only one layer of the capillary network, and thus the blood flowing through these vessels is exposed on both aspects to the action of the air in the air-cells. The radicles

of the pulmonary vein arise in, and carry the blood from, the pulmonary capillary plexus. Each afferent arteriole supplies the blood which flows through the capillaries spread over a number of neighbouring alveoli, and in like manner each efferent venous radicle drains an area corresponding to several adjoining air-cells. At first the veins run apart from the arteries, but after they have attained a certain size they join them and the bronchi. As a rule the pulmonary veins are placed on the lower and front aspect of the corresponding bronchi.

### Development of the Respiratory Apparatus.

The larynx, the trachea, the bronchi, and the lungs arise as an outgrowth from the ventral aspect of the foregut. The first indication of a respiratory tract occurs in the human embryo when it has attained a length of 3·2 mm., on or about the fifteenth day of development. A median longitudinal groove makes its appearance within the foregut on its ventral wall. This extends from the pharynx in front to the region of the stomach behind, and it gradually deepens as it passes backwards. The hinder or gastric end of the pulmonary groove ends in a blind diverticulum or pocket, which freely communicates with the cavity of the foregut, and forms a hollow median protrusion on the ventral aspect of this portion of the primitive alimentary canal. The opposite end of the groove is bounded by the furcula (see p. 35). Further, it is lined with endoderm or hypoblast continuous with the endodermal lining of the foregut.

**Trachea and Larynx.**—The pulmonary groove on the ventral aspect of the foregut becomes first partially and then completely separated from the part of the foregut which lies on its dorsal aspect by two lateral ridges which grow inwards and finally meet. Two tubes are thus formed—viz. one behind, the œsophagus, and the other in front, the trachea and larynx. At their cephalic ends a communication between the two tubes is preserved as the permanent communication between the larynx and pharynx.

The cephalic end of the air-tube which is thus separated off from the foregut becomes enlarged to form the larynx, whilst the remainder is developed into the trachea. The cartilages of the larynx do not make their appearance until the eighth or ninth week. The thyroid cartilage is believed to be formed out of the ventral portions of the cartilages which support the 4th and 5th visceral arches of the two sides united in the median plane. The epiglottis takes form in the upper or front part of the furcula (see chapter on Embryology, p. 35), whilst the aryteno-epiglottidean folds and the arytenoid cartilages are developed in its lateral portions. The cricoid cartilage and the tracheal rings are formed in the mesoderm of the air-tube.

**Lungs and Bronchi.**—The endodermic diverticulum, or pocket in which the gastric end of the primitive respiratory groove terminates, very early bifurcates into two vesicular portions, which represent the primitive right and left bronchi and lungs. From the first the right pulmonary vesicle is slightly the larger of the two. Both elongate, and almost immediately each part undergoes a subdivision—the right into three vesicles, and the left into two vesicles—thus early indicating the three lobes of the right lung and the two lobes of the left lung. The endodermal cells form the epithelial lining of the air-passages, whilst from the mesoderm are derived the blood-vessels and the other tissues which build up the lung. The hypoblastic or endodermal subdivisions thus formed are embedded within the surrounding mesoderm. The main endodermal subdivisions continue to branch and rebranch, pushing their way into the pulmonary mesoblast, until the complete bronchial tree is formed. The method of subdivision is very characteristic, and from the first the various branches are bulbous or flask-shaped at their extremities. These bifurcate, and although at first the two subdivisions in each case appear of equal importance, one grows out as the continuation of the main bronchial stem, whilst the other remains as a lateral branch. When the ramification of the endodermal tubes into the lung mesoderm is complete, the small terminal flask-shaped extremities of the various branches represent the infundibula. At first these are devoid of air-cells, but between the sixth month and the termination of gestation the alveolar diverticula make their appearance on the alveolar ducts and on the infundibula. It is thus seen that the epithelial lining of the entire system of bronchial tubes, infundibula and alveoli, is originally derived from the endodermal lining of the foregut. The other constituents which enter into the constitution of the lungs and bronchi are derived from the mesoblast.

The rudiments of the lungs grow backwards on either side of the œsophagus into the fissure-like portion of the cœlom which occupies the thoracic region. They push before them the epithelial lining of the latter, and thus acquire their covering of visceral pleura. By the development of the diaphragm and the pericardium the pleural portions of the cœlom become cut off from the peritoneal cavity and from each other.

# THE DIGESTIVE SYSTEM.

By Ambrose Birmingham.

Under this head will be described the parts which are connected with the reception and mastication of the food, and its digestion and passage through the body. As the greater part of the digestive system is placed within the abdomen, the description of this cavity as a whole, with that of its lining membrane the peritoneum, will be included.

The different parts of the digestive system may be grouped under the following heads, viz:—

1. The Alimentary Canal or Digestive Tube.
2. The Digestive Glands.
3. Accessory Parts.

**Alimentary Canal.**—The alimentary canal, taken as a whole, measures about 30 feet in length (Fig. 705), and consists of the following parts in order:—mouth, pharynx, œsophagus, stomach, small and large intestines. The **mouth** is the first division of the tube. It is separated from the nasal cavities above by the **palate**, and opens behind into the **pharynx**. This latter is an expanded portion of the canal lying behind both the mouth and the nasal cavity, the former opening into it through the **isthmus of the fauces**, the latter through the **posterior nares**; whilst lower down, immediately below the base of the tongue, the aperture of the larynx is found on its anterior wall. Opposite the lower border of the larynx, the pharynx is succeeded by the **œsophagus**, a long and comparatively straight portion of the digestive tube, leading through the neck and thorax to the abdomen, which it reaches by piercing the diaphragm. Immediately after entering the abdomen the tube expands into a pear-shaped dilatation, the **stomach**. This is followed by over 20 feet of **small intestine**, the junction of the two being marked by a constriction, the **pylorus**. The small intestine presents three more or less arbitrary divisions—namely, (*a*) the **duodenum**, a part about 10 inches in length, curved somewhat like a horse-shoe, and closely united to the posterior abdominal wall; (*b*) the **jejunum**, which includes the upper two-fifths, and (*c*) the **ileum**, the lower three-fifths of the small intestine beyond the duodenum. The jejunum and ileum are movably suspended from the posterior abdominal wall by the **mesentery**, a fan-shaped fold of the **peritoneum** or lining membrane of the abdominal cavity. The terminal part of the ileum opens into the side of the **large intestine**, a few inches ($2\frac{1}{2}$) from the blind commencement of the latter. There is thus formed at the beginning of the great intestine a cul-de-sac, the **cæcum**, in connexion with which is found a small worm-shaped diverticulum, the **vermiform appendix**.

The orifice through which the ileum opens into the large intestine is guarded by the **ileo-cæcal valve**, which prevents any return of its contents from the large into the small bowel. After the cæcum comes the **ascending colon**, which runs up in the right side of the abdomen. This is succeeded in order by the **transverse colon** crossing from right to left, the **descending colon** running down on the left side, the **sigmoid flexure** of the colon (which includes the iliac and greater part of the pelvic colons of the text), and finally the **rectum**, which opens on the surface at the **anus**.

**Digestive Glands.**—Whilst the greater part of the alimentary canal is furnished with numerous minute glands contained entirely within its walls,

there are in addition certain special accumulations of glandular tissue, namely, the **liver**, the **pancreas**, and the **salivary glands**, which, although developed in the

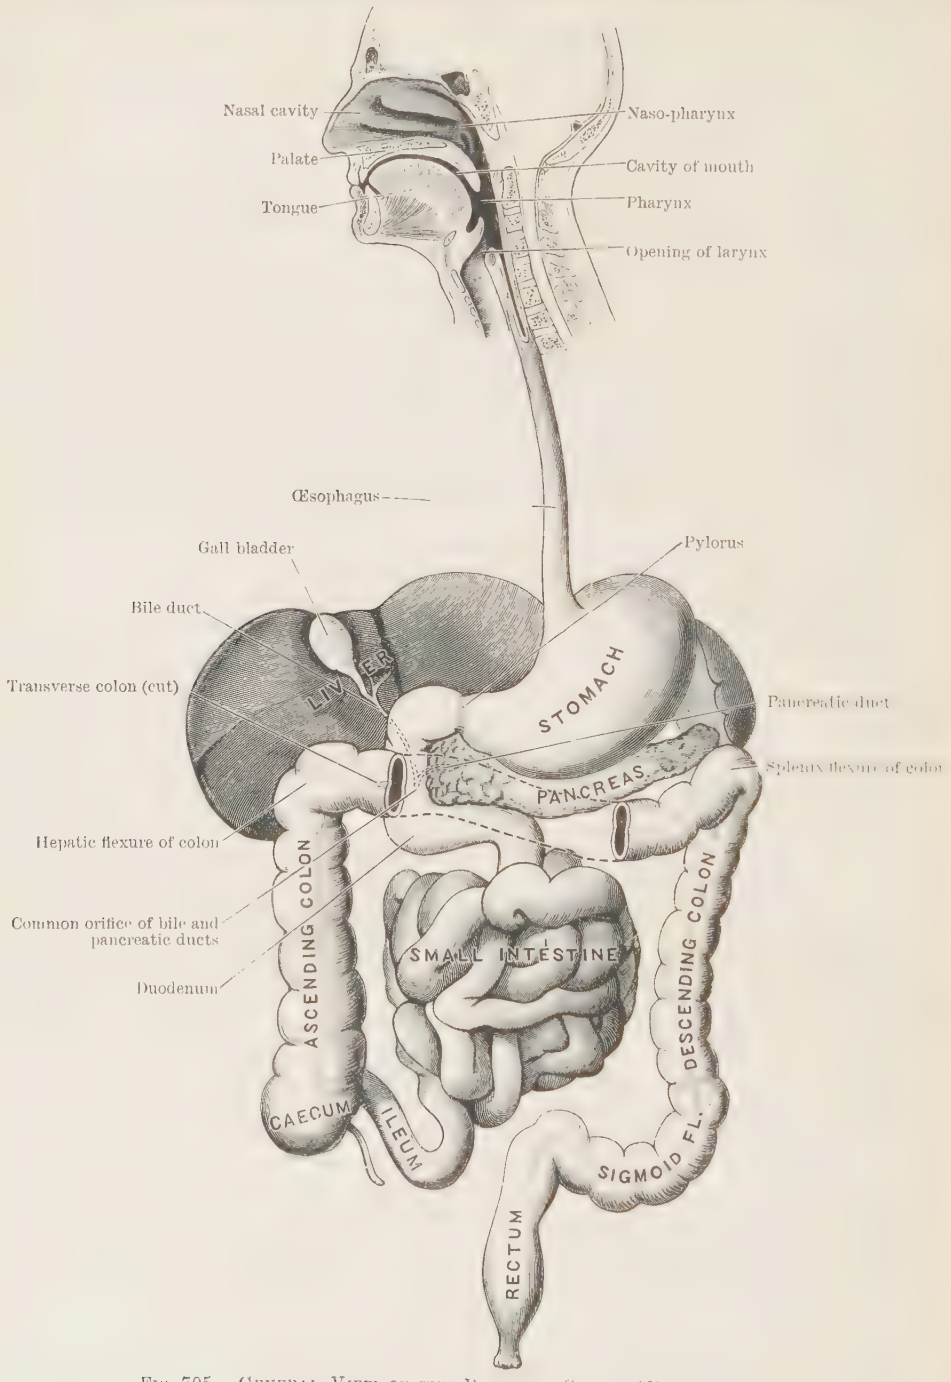

FIG. 705.—GENERAL VIEW OF THE DIGESTIVE SYSTEM (diagrammatic).

The transverse colon has been cut to show the duodenum, but its course is indicated by dotted lines. The vermiform appendix is seen hanging down from the cæcum. The loop of large intestine which precedes the rectum is marked "sigmoid flexure," and includes the iliac colon and the greater part of the pelvic colon.

embryo as outgrowths of its wall, lie entirely outside the tube in the adult, and are connected with it by special ducts through which the gland-secretions pass. The largest of these, the **liver**, is placed in the upper and right portion of

the abdominal cavity, immediately beneath the diaphragm, and its secretion—the bile—is conveyed into the duodenum by the **bile duct**. The **pancreas**, next in size, lies across the front of the vertebral column, with its right end or head resting in the concavity of the duodenum, into which its secretion flows through the **pancreatic duct**. The **salivary glands**, of which there are three chief pairs—**parotid**, **submaxillary**, and **sublingual**—are placed about the face, and their ducts, which convey the saliva, open into the mouth. Whilst the secretion of these latter undoubtedly possesses some digestive action, and they must consequently be classed as digestive glands, nevertheless the saliva is to be looked upon as a mechanical lubricant, which facilitates swallowing and the movements of the tongue in speaking and masticating, rather than as an aid to the digestive process.

**Accessory Parts.**—Under this heading we group the teeth, tongue, gums, palate, and tonsils. The **teeth**, 32 in number in the adult, are embedded in the jaws and surrounded by the **gums**. The **tongue** is a muscular organ, useful alike in masticating, swallowing, speaking, and in the exercise of the sense of taste, which specially resides in its modified epithelium; it occupies the greater portion of the floor of the mouth, whilst the roof of that cavity is formed by the **hard palate** anteriorly, and by the **soft palate** behind. Finally, the **tonsils** (Fig. 707) are two large masses of lymphoid tissue, found on the side-walls of the oral portion of the pharynx, just behind the mouth.

## THE MOUTH.

The mouth is the expanded upper portion of the digestive tube, specially modified for the reception and mastication of the food. In it we distinguish: the **aperture of the mouth** placed between the lips; the **vestibule**, the slit-like space which intervenes between the teeth and gums internally, and the lips and cheeks externally (Fig. 706); and the **cavity of the mouth**, which lies within the round of the dental arches, and opens behind into the pharynx through the **isthmus of the fauces** (Fig. 707).

The **aperture of the mouth** (rima oris) is the upper or anterior opening of the alimentary canal, and is bounded above and below by the corresponding lips, which, by their junction at the sides, form the angles of the mouth (commissuræ labiorum). In a state of rest, with the lips in apposition, the rima appears as a slightly curved line, corresponding in length to the interval between the first premolar teeth, and in level to a line drawn across just below the middle of the upper incisor crowns. The shape of the rima varies with every movement of the lips, from the resting linear form, curved like the conventional bow, to a circular or oval shape when the mouth is widely open, or the "pursed up" condition produced by the contraction of the orbicularis oris.

The **vestibule** (vestibulum oris, Fig. 706) lies immediately within the aperture of the mouth. In the normal resting condition its cavity is practically obliterated by the meeting of its walls, which reduces it to a slit-like space. It is limited on the one hand by the deep surface of the lips and cheeks, and on the other by the dental arches and gums. Its narrow roof and floor are formed respectively by the reflection of the mucous membrane, from the deep surface of the lips and cheeks to the corresponding gum. This reflection is interrupted in the middle line by a small but prominent fold of the mucous membrane, the **frenulum**, which connects the back of each lip to the front of the gum. The upper frenulum is the better developed, and is readily brought into view by everting the lip.

On the outer wall of the vestibule, opposite the crown of the middle upper molar, is seen, upon a variably developed eminence (Fig. 716), the small opening of Stenson's duct, which conveys the saliva from the parotid gland to the mouth.

When the teeth are in contact the vestibule communicates with the cavity of the mouth, only through the small and irregular spaces left between the opposing teeth, and posteriorly by a wider but variable aperture behind the last molars.

Advantage is sometimes taken of the presence of this aperture, which lies between the wisdom teeth and the ramus of the jaw, for the introduction of liquid food in certain cases—trismus, anchylosis, etc.—in which the mouth is rigidly closed.

The anterior border of the masseter can be distinctly felt with the finger, on the outer wall of the vestibule, when the muscle is thrown into a state of contraction. Still further back, the front of the coronoid process, bearing the lower part of the insertion of the temporal muscle, can be easily made out. Whilst the pterygo-maxillary ligament, which corresponds to, and is felt along with, the anterior border of the internal pterygoid, is distinguishable as a pliant ridge when the finger is carried from the front of the coronoid process inwards behind the wisdom teeth to the cavity of the mouth.

In addition to Stenson's duct, the ducts of numerous small glands which are embedded in the lips and cheeks open into the vestibule.

Under normal conditions, as pointed out above, the lips and cheeks lie against the teeth and gums, obliterating the cavity of the vestibule, and helping, with the aid of the tongue, to keep the food between the grinding surfaces of the molar teeth during mastication. In facial palsy, however, owing to the paralysis of their muscles, the lips and cheeks fall away from the dental arches, and allow the food to pass out from between the teeth and to accumulate in the vestibule.

**Lips** (labia oris, Fig. 708).—These are the two movable folds, covered superficially by skin, and on their deep surface by mucous membrane, which surround the rima oris. Laterally the two meet at the angles of the mouth, and beyond this are

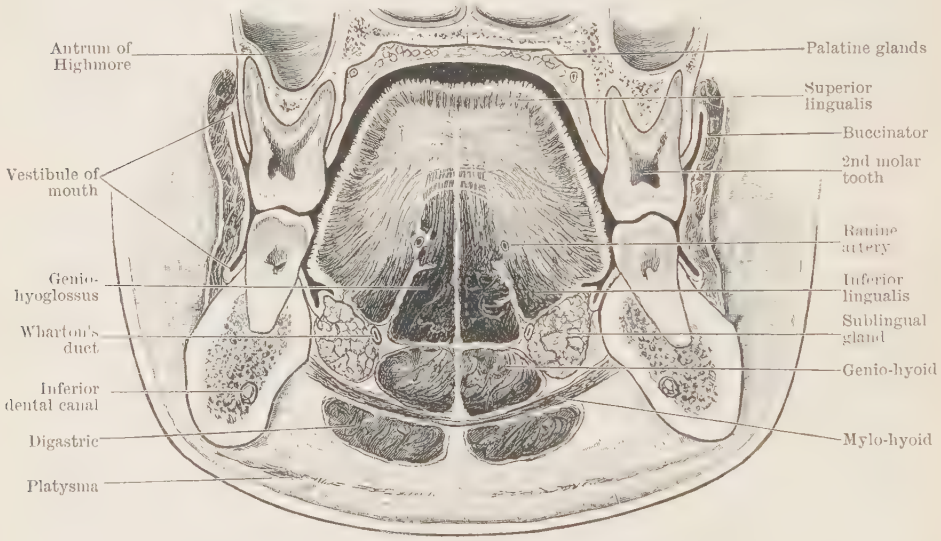

FIG. 706.—CORONAL SECTION THROUGH THE CLOSED MOUTH.

The slit-like character of the vestibule, the manner in which the tongue fills up the mouth cavity, the close apposition of the teeth, the relations of the roots of the upper molars to the antrum of Highmore, the plica sublingualis over the sublingual gland, and the position of the ranine artery should be noted.

prolonged into the cheeks, with which they are continuous. The upper lip presents on its superficial surface a well-marked vertical groove, the **philtrum**, bounded by two distinct ridges descending from the columella nasi (Fig. 712); inferiorly the groove widens out, and terminates opposite a slight projection—the *labial tubercle*—on the free edge of the upper lip. This tubercle is particularly well developed in children, and is chiefly responsible for the characteristic curve of the rima oris. The lower is usually longer and more movable than the upper lip.

In passing from before backwards the following structures are found in the lips:—(1) The **skin**, which is closely beset with hairs, small and fine in the child and female, long and stout in the adult male. (2) A layer of fatty **superficial fascia** continuous with the fascia of the face generally. (3) The **orbicularis oris muscle**, continuous at its periphery with the various muscles converging towards the mouth. A number of its fibres, or those of the muscles joining it, pass through the superficial fascia and are attached to the skin, thus establishing a close connexion between the latter and the muscle. (4) The **submucous tissue**, which is occupied by an almost continuous layer of racemose glands—the **labial glands** (glandulæ labiales). These open into the vestibule, and their secretion is said to be mucous. (5) The **mucous membrane** of the mouth, covered by stratified squamous epithelium. Between the orbicularis and mucous membrane, but nearer to the

former, that is, in the deeper part of the submucosa, the coronary artery is found a short distance from the free margin of the lip, running to meet its fellow of the opposite side.

The free margin of the lip is covered by a dry and otherwise modified mucous membrane. It begins where the integument changes colour at the outer edge of the lip, and ends posteriorly just behind the line along which the two lips meet when closed, where it passes into the ordinary moist mucous membrane of the vestibule. It presents numerous simple vascular papillæ, and its nerves (which are derived from the infra-orbital in the upper lip, from the long buccal at the angles, and from the mental branch of the inferior dental in the lower lip) terminate in special end organs, hence the acute sensitiveness of this part. In the child, at birth, the margin of the lip is divided by a very pronounced groove or fissure into an outer and an inner zone, differing considerably in their appearance.

When the tongue is pressed firmly against the back of the lips and moved about, the labial glands can be distinctly felt through the mucous membrane, giving the impression of a knobby or irregular surface. The glands, which are about the size of hemp-seeds and can be readily displayed by removing the mucous membrane, are more numerous in the lower than in the upper lip. Stoppage of their ducts, with the resulting distension of the glands, gives rise to "mucous cysts," a well-known pathological condition.

It should be remembered, in connexion with epithelioma of this part, that the lymphatics of both lips pass down to join the submaxillary lymphatic glands.

**Cheeks** (buccæ).—The cheeks resemble the lips in structure, being formed of corresponding layers. Superficially is the skin. Under this lies the fatty superficial fascia of the face, through which Stenson's duct runs inwards to pierce the buccinator; in it also, near the end of the duct, are found four or five mucous glands, as large as hemp-seeds. These are known as the **molar glands** (glandulæ molares); their ducts pierce the cheek and open into the vestibule. Beneath this superficial fascia lies the buccinator muscle, covered by the thin buccopharyngeal aponeurosis. Deeper still is the submucosa, which, like that of the lips, contains numerous racemose **buccal glands** (glandulæ buccales). And finally the mucous membrane is reached (Fig. 709).

An important constituent of the cheek of the infant is the **sucking pad** (corpus adiposum buccæ), an encapsuled mass of fat, distinct from the surrounding superficial fascia, which lies on the outer side of the buccinator, and passes backwards into the large recess between that muscle and the overlying anterior part of the masseter. This fatty mass, which is relatively more developed in the child than in the adult, strengthens the cheek, and helps it to resist the effects of atmospheric pressure during the act of sucking. In the adult the remains of the pad can be distinctly made out under the anterior border of the masseter.

**Cavity of the Mouth Proper** (cavum oris proprium).—This is the space situated within the dental arches. The latter, with the gums, separate it from the vestibule (Fig. 706), so that the two communicate, when the teeth are in contact, only by the irregular interdental spaces, and through the passages behind the wisdom teeth already referred to.

*Posteriorly* the cavity of the mouth opens, through the isthmus of the fauces, into the pharynx (Fig. 707).

Its **roof** is formed by the hard and the greater part of the soft palate; whilst its **floor**, in the ordinary resting condition, is entirely occupied by the tongue (Fig. 709). If, however, the tip and marginal parts of the tongue be raised, there is exposed a limited surface to which the term "floor of the mouth" or sublingual region is more usually applied (Fig. 712).

The **sublingual region** (Fig. 712) is covered by the oral mucous membrane which is carried across from the deep surface of the gum to the inferior aspect of the tongue, with the mucous membrane of which it becomes continuous. When the tip of the tongue is raised the membrane forms in the middle line a prominent fold, the **frenum linguæ**, stretching from the floor of the mouth to the under surface of the tongue. On each side of the frenum, near its junction with the floor, there can be readily made out a prominent soft papilla (caruncula sublingualis), on which the opening of **Wharton's duct** (of the submaxillary gland) may be seen (Fig. 712). Running outwards and backwards on each side from this, and occupying the greater part of the floor of the mouth, there is a well-marked ridge (plica sublingualis) due to the projection of the underlying sublingual gland, most of the ducts of which open near the crest of the ridge.

When the mouth is closed, and respiration is carried on through the nose, the cavum oris is reduced to a slit-like space, and practically obliterated by the tongue coming in contact with the palate above, and with the gums and teeth laterally and in front (Fig. 706). When the mouth is slightly open and the teeth nearly in contact, the tongue becomes somewhat concave or grooved along the middle line, and leaves a channel-like space between it and the palate, while it remains in contact with the roof and gums laterally. By depressing the hyoid bone with the root of the tongue, the cavum oris can be increased to a considerable size even when the teeth are in contact. Finally, by the simultaneous descent of the lower jaw and hyoid bone with the tongue, and the ascent of the soft palate, the cavity is increased to its greatest dimensions (Fig. 707).

**Gums** (gingivæ).—This term is applied to the red firm tissue, continuous with the mucous membrane of the vestibule on the one hand, and with that of the palate or floor of the mouth on the other (Fig. 706), which covers the alveolar borders of the maxilla and mandible, and surrounds the necks of the teeth. The gums are composed of dense fibrous tissue, inseparably united to the periosteum and covered by mucous membrane. They are richly supplied with blood-vessels, but sparsely with nerves, and are covered by stratified squamous epithelium. Around the neck—or more correctly the base of the crown—of each tooth, the gum forms a free overlapping collar, and at this part particularly it is closely beset with small papillæ, visible to the naked eye. In thickness it usually measures from 1 to 2 mm.

## THE PALATE AND ISTHMUS FAUCIUM.

The **palate** (palatum) is the term applied to the strongly-arched structure which forms the roof of the mouth, and projects posteriorly into the pharynx as a pliant fold, imperfectly dividing that cavity into two (Figs. 708 and 710). Its anterior half or more has a foundation of bone, and separates the nasal fossæ from the mouth. This part is known as the **hard palate**. The posterior portion, which is free from bone, separates the naso-pharynx above, from the mouth and oral pharynx below, and is known as the **soft palate**.

The **hard palate** (palatum durum, Fig. 708) occupies the space within the upper dental arch, and is continuous with the gums in front and laterally, whilst behind it passes into the soft palate. It is formed by the palatal processes of the superior maxillary and palate bones (Fig. 721), covered by periosteum, and by a layer of firm mucous membrane. Beneath this mucous membrane, particularly at the sides and in front, is found a considerable quantity of dense fibrous tissue, firmly united to the periosteum on the one hand and to the mucous membrane on the other. This dense tissue forms an effective protection for the palate, and, in addition to the palatine vessels and nerves, it contains in its posterior half a large number of racemose (palatine) glands.

Traversing the middle of the palate is seen a faint central ridge or **raphe** (Fig. 707), indicating its original development from two lateral halves. Behind, this raphe is continued along the soft palate to the base of the uvula, and in front it ends in a slight elevation, the **incisive pad** or papilla palatina. From the anterior end of the raphe a series of transverse ridges of mucous membrane, about six in number, run outwards, just behind the incisor teeth; they are known as the **palatine rugæ**, and are composed of dense fibrous tissue. Sometimes a small pit, which will admit the point of a pin, is seen on each side immediately behind the central incisor teeth, and about 2 mm. from the middle line. These pits correspond to the lower openings of Stenson's canals, with which they are occasionally continuous.

The **soft palate** (palatum molle, or velum pendulum palati, Fig. 708) is a movable valve-like fold which runs obliquely downwards and backwards, like the "tongue" of a whistle, across the cavity of the pharynx almost as far as its posterior wall. Whilst it is attached to the hard palate in front, and blends with the pharyngeal walls laterally, its posterior border is free, and between it and the posterior wall of the pharynx is left a valvular passage—the isthmus of the pharynx—through which the naso-pharynx and the oral pharynx communicate with one another.

The soft palate is composed of two layers of mucous membrane between which are contained the palatine muscles, vessels, nerves, and connective tissue, the aponeurosis of the palate, and, in addition, a very large number of racemose glands. These glands are arranged in a thick continuous layer on the inferior surface beneath the mucous membrane, and form quite one-half of the mass of the soft palate

generally, whilst in its anterior part, where muscular fibres are wanting, they constitute almost its entire thickness.

Its *upper surface*, which is convex, forms a continuation backwards and downwards of the floor of the nasal fossæ (Fig. 708), and is covered by a prolongation of the nasal mucous membrane—ciliated in its upper half or more. The *under surface* is arched, and prolongs backwards the roof of the mouth, towards the cavity of which it looks. *In front* the soft palate is attached to the posterior edge of the hard palate. *Laterally* it blends with the side wall of the pharynx along a very oblique line as it slopes downwards and backwards (Fig. 708). Its *posterior margin* is thin and free: it presents in the middle line an elongated conical projection, the **uvula** (Fig. 707), and at each side of this a sharp concave edge arches outwards, and passing downwards and slightly backwards becomes continuous with a ridge on the side wall of the pharynx termed the **posterior palatine arch** (posterior pillar of fauces). From the under surface of the soft palate, 7 or 8 mm. further forwards, and near the base of the uvula, spring another pair of ridges, the **anterior palatine arches** (anterior pillars of fauces), which pass downwards and slightly forward to the sides of the tongue (Fig. 707).

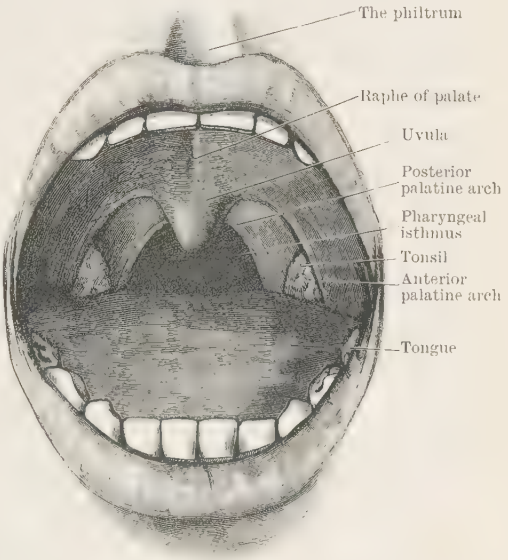

Fig. 707.—Open Mouth showing Palate and Tonsils.

It also shows the two palatine arches, and the pharyngeal isthmus through which the naso-pharynx above communicates with the oral portion of the pharynx below.

The anterior part of the soft palate for 8 or 10 mm. ($\frac{1}{3}$ inch) contains practically no muscular fibres; it is composed of the palatine aponeurosis, covered by an extremely thick layer of glands on the under surface and by mucous membrane on both surfaces. This anterior portion is much less movable than the rest of the soft palate, and forms a relatively horizontal continuation backwards of the hard palate, stretching across between the two internal pterygoid plates. It is upon this portion chiefly that the tensor palati acts. The posterior and larger part contains muscular fibres in abundance, slopes strongly downwards, and is freely movable, being the portion upon which the remaining palatine muscles act.

The palatine aponeurosis, which is confined to the anterior part of the soft palate, is in the form of a thin flat sheet, constituting, as it were, a kind of common tendon for the palatine muscles which are attached to (or blended with) its posterior margin; whilst its anterior margin is united to the posterior edge of the palatal processes of the palate bone. With the exception of the aponeurosis of the tensor palati which passes into its lateral part, the muscles do not, as a rule, reach further forwards than to within 8 or 10 mm. of the posterior edge of the hard palate.

The **uvula**, already referred to, is a conical projection, very variable in length, which is continued downwards and backwards from the middle of the soft palate. It is composed chiefly of a mass of racemose glands and connective tissue covered by mucous membrane, and containing a slender prolongation of the azygos uvulæ muscle in its upper part.

The **mucous membrane** of the palate, which is covered by stratified squamous epithelium, is firmer and more closely adherent in front, near the rugæ, than behind, near the soft palate.

Mucous glands, the orifices of which can be seen as dots with the naked eye, are extremely abundant in the soft palate, and in the posterior half of the hard palate, except near the raphe. They are wanting in the anterior part of the palate, where the mucous membrane is particularly dense.

The **palatine rugæ** (which correspond to more strongly developed ridges in carnivora, etc.) are very well marked in the child at birth, although, perhaps, relatively less distinct in the fœtus of five or six months; in old age they become more or less obliterated and irregular. At birth,

also, and in the fœtus, the incisive pad at the anterior end of the raphe is continued over the edge of the gum into the frenulum of the upper lip.

The **vessels** of the palate are derived from the **posterior palatine artery**, which runs forwards on the hard palate close to the alveolar border, and from the **ascending palatine branch** of the facial, which accompanies the levator palati to the soft palate.

The **nerves**—all branches of Meckel's ganglion—are: the **large posterior palatine**, which descends through the posterior palatine canal and runs forward on the hard palate with the posterior palatine artery; the **naso-palatine**, which passes down through the foramen of Scarpa and reaches the front of the hard palate; and the **small posterior** and **accessory posterior palatine nerves**, which run through the accessory palatine canals and supply the soft palate.

**Fauces** or **Isthmus of the Fauces** (isthmus faucium).—This is the aperture through which the mouth communicates with the pharynx (Fig. 707). It is bounded at the sides by the anterior palatine arches, above by the under surface of the soft palate, and below by the dorsum of the tongue; in width it corresponds pretty closely to the cavum oris.

The **anterior palatine arches** (arcus glosso-palatinus), often known as the anterior pillars of the fauces, are two prominent folds of mucous membrane, containing the palato-glossus muscles in their interior, which bound the isthmus of the fauces laterally (Fig. 707). Springing above from the under surface of the soft palate, a little way (about 8 mm.) in front of its free edge, and near the base of the uvula, they pass downwards and slightly forwards to join the tongue a little behind the middle of its lateral border.

The **posterior palatine arch** is described with the pharynx (p. 1034).

## THE TONGUE.

The tongue (lingua) is a large mobile mass composed chiefly of muscular tissue, and covered by mucous membrane, which occupies the floor of the mouth and forms the anterior wall of the oral pharynx (Fig. 708).

Whilst the sense of taste resides chiefly in its modified epithelium, the tongue is also an important organ of speech, and, in addition, it assists in the mastication and deglutition of the food—functions which it is well fitted to perform, owing to its muscular structure and great mobility. In length it measures, when at rest, about three and a half inches, but both its length and width are constantly varying with every change in the condition of the organ, an increase in length being always accompanied by a diminution in width, and *vice versa*.

In describing the tongue we distinguish the following parts: the **body** (corpus linguæ), made up chiefly of striped muscle, and forming the mass of the organ; the **dorsum** (Fig. 709), which looks towards the palate and pharynx, and is free in its whole extent; the **base**, the posterior wide end which is attached to the hyoid bone; the **apex** or tip, the pointed and free anterior extremity; the **margin**, which is free in its anterior half or more, *i.e.* in front of the attachment of the anterior palatine arch (Fig. 709). Finally, the unattached portion on the inferior aspect, seen when the apex is turned strongly upwards (Fig. 712), constitutes the **inferior surface**; whilst the attached portion, fixed by muscles and mucous membrane to the hyoid bone and mandible, is known as the **root.**

The **dorsum of the tongue** (dorsum linguæ), when the organ is at rest, is strongly arched from before backwards in its whole length (Fig. 708), the greatest convexity corresponding to the attachment of the anterior palatine folds. When removed from the body the tongue, unless previously hardened *in situ*, loses its natural shape, and appears as a flat, elongated oval structure, which gives a very erroneous idea of its true form and connexions.

The dorsum is naturally divided into two areas—an anterior or *oral part*, which lies nearly horizontally on the floor of the mouth, and constitutes about two-thirds of the length of the whole tongue (Fig. 709); and a posterior or *pharyngeal part*, the remaining third of the organ, which is placed nearly vertically, and forms the anterior wall of the oral pharynx (Fig. 710). The separation between these two parts, which differ in appearance as well as in direction, is indicated by a distinct V-shaped groove, called the **sulcus terminalis** (Fig. 710), the apex of which is directed backwards, and corresponds to a blind depression on the surface of the tongue, the **foramen cæcum**, whilst its diverging limbs pass outwards and forwards

towards the attachments of the anterior palatine arches. The foramen cæcum is the remains of a tubular down-growth formed early in embryonic life, in the region of the dorsum of the tongue, from which the isthmus of the thyroid gland is developed (see page 38).

The **posterior or pharyngeal portion of the dorsum linguæ** (Fig. 708), nearly vertical in direction, forms the greater portion of the anterior wall of the oral pharynx (Fig. 710). Its surface is free from evident papillæ, but is thickly studded

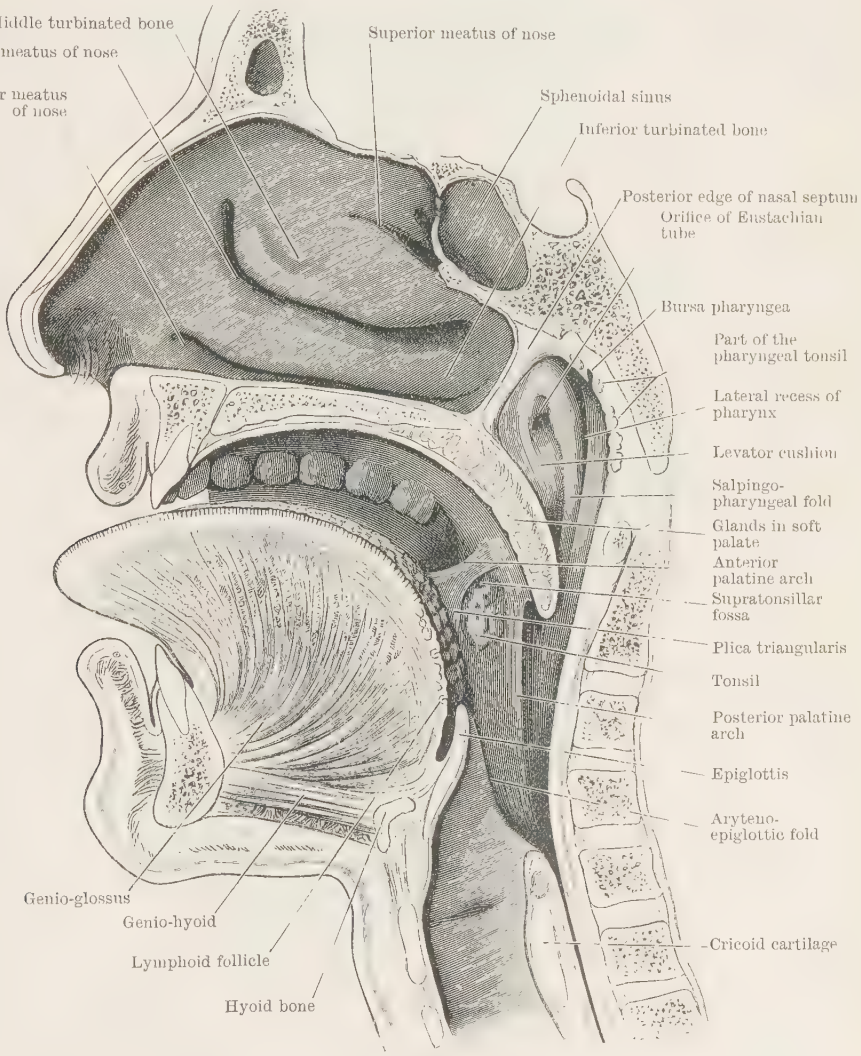

Fig. 708.—Sagittal Section through Mouth, Tongue, Larynx, Pharynx, and Nasal Cavity.

The section was slightly oblique, and the posterior edge of the nasal septum has been preserved. The specimen is viewed slightly from below, hence the apparently low position of the inferior turbinated bone.

with rounded projections, each presenting, as a rule, a little pit, visible to the naked eye, at its centre; the great majority of these are lymphoid follicles (folliculi tonsillares linguales, Fig. 713, C) similar to those found in the tonsils; some few are said to be mucous glands; all are covered by a smooth mucous membrane, and they combine to give to this region a characteristic nodular appearance.

The *mucous membrane* of this portion of the tongue is separated from the muscular substance by a submucous layer in which the lymphoid follicles and the mucous glands lie embedded (Fig. 708). At the sides it is continuous with that covering the tonsils and the side wall of the pharynx; whilst behind

it is reflected on to the front of the epiglottis, forming in the middle line a prominent fold, the **frenulum epiglottidis** or **middle glosso-epiglottic fold** (plica glosso-epiglottica media, Fig. 709), at each side of which is a wide depression, the **vallecula**.

Two lateral glosso-epiglottic folds have been described, but these pass from the side of the epiglottis, not to the tongue, but upwards along the wall of the pharynx, upon which they are soon lost; consequently the term pharyngo-epiglottic is more applicable to them.

The **anterior or oral portion of the dorsum linguæ**, namely, the part in front of the sulcus terminalis (Fig. 709), is convex, both from before backwards and

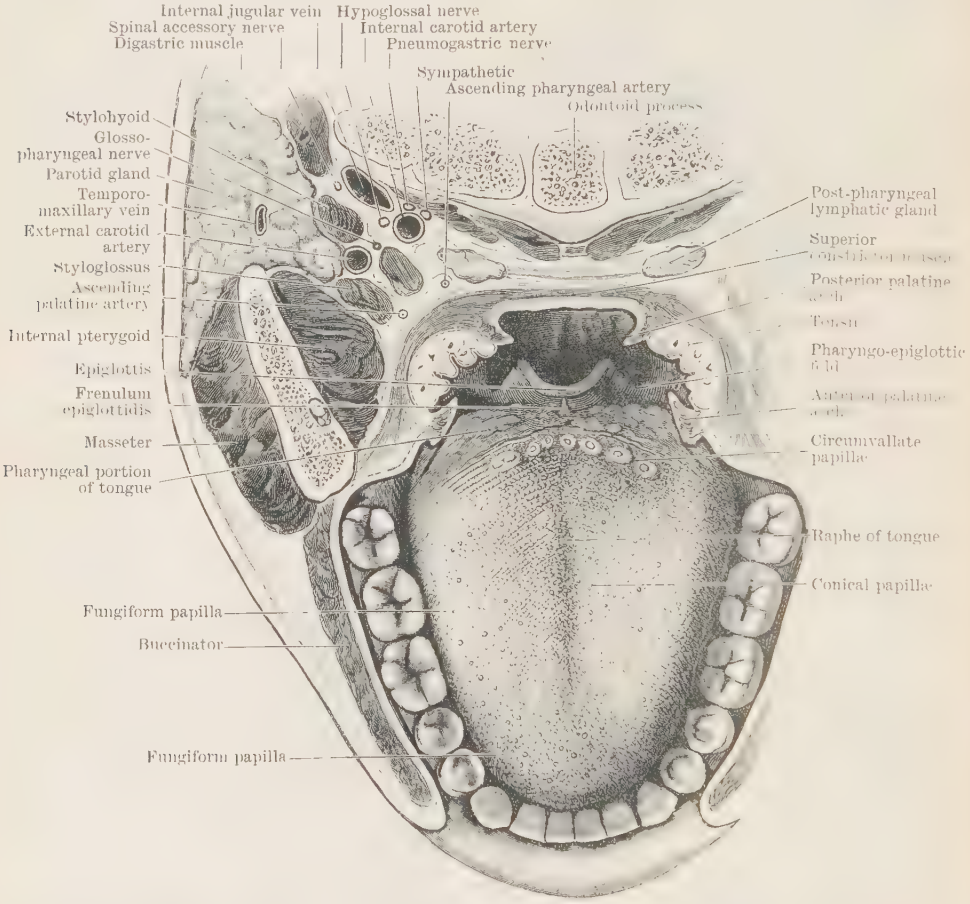

FIG. 709.—HORIZONTAL SECTION THROUGH MOUTH AND PHARYNX AT THE LEVEL OF THE TONSILS.

The stylopharyngeus, which is shown immediately to the inner side of the external carotid artery, and the prevertebral muscles, are not indicated by reference lines.

from side to side in the resting condition of the organ (Fig. 706). It usually presents also a slight median depression, along the centre of which may be seen some indication of a median **raphe** in the form of an irregular crease, which ends posteriorly near the foramen cæcum. The mucous membrane of this portion of the dorsum is thickly covered with the prominent and numerous **papillæ** (papillæ linguales) which give the tongue its most characteristic appearance.

On the pharyngeal part of the tongue there are also small papillary projections of the corium, but the epithelium fills up all the intervals between the papillæ, and, as it were, levels off the surface, so that none are visible to the eye as projections above the general level. Over the anterior part of the tongue, on the contrary, the projections of the corium are large and prominent, and the intervals between them, while they are covered, yet are not filled up, by the epithelium, so that the projections stand out distinctly and independently, and in places attain a height of nearly 2 mm. above the general surface.

**Papillæ of the Tongue** (Fig. 709).—These are formed by variously-shaped projections of the corium of the mucous membrane, covered by thick caps of epithelium. They are of three different varieties:—1, Conical or filiform (papillæ conicæ, p. filiformes); 2, Fungiform (papillæ fungiformes et p. lenticulares); and 3, Circumvallate (papillæ vallatæ).

The **conical or filiform papillæ** (Fig. 711) are the smallest and most numerous, forming as they do a dense crop of minute projections all over the anterior two-thirds of the dorsum, and also upon the upper part of the margin and tip, of the tongue. Posteriorly they are arranged in divergent rows running outwards and forwards from the raphe, parallel to the limbs of the sulcus terminalis. More anteriorly, the rows become nearly transverse, and near the tip irregular. Each papilla is composed of a conical projection of the corium, beset with microscopic papillæ like those of the skin, and covered by a thick long cap of stratified squamous epithelium.

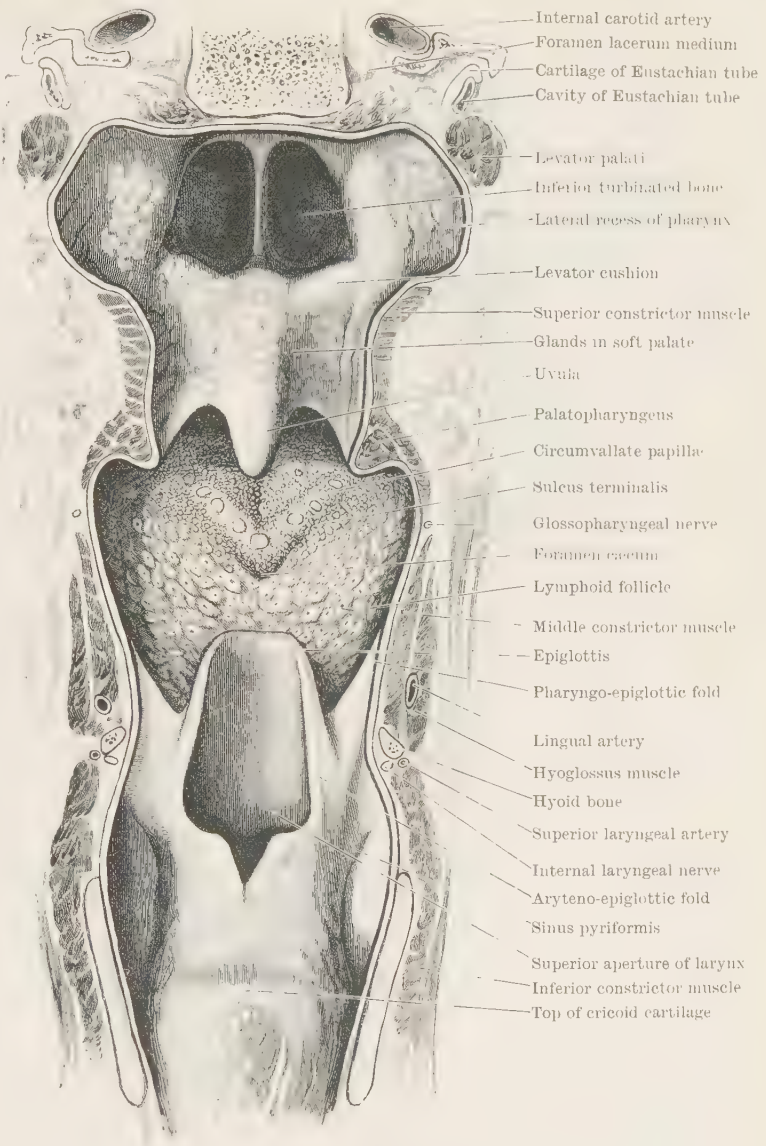

FIG. 710.—THE ANTERIOR WALL OF THE PHARYNX WITH ITS ORIFICES, SEEN FROM BEHIND.

The specimen from which the drawing was made was obtained from a formalin-hardened body, by removing the posterior wall of the pharynx while leaving the anterior wall undisturbed. The following points should be noted: the greatest width of the pharynx, above, at the lateral recesses; the posterior nares, with the inferior turbinated bones seen through them; the levator cushion; and the pharyngeal portion of the tongue.

Often, however, the cap of epithelium is broken up into several long slender hair-like processes, giving rise to the variety known as *filiform papillæ*. The cap of epithelium is being constantly shed and renewed, and an excessive or diminished rate of shedding or renewal, coupled with the presence of various fungi, gives rise to the several varieties of "tongue" found in different diseases.

The conical and filiform papillæ are probably of a prehensible or tactile nature, and are highly developed, and horny, in carnivora.

The **fungiform papillæ** (Fig. 711) are larger and redder, but less numerous than the last variety, and they are found chiefly near the tip and margins of the tongue, comparatively few being present over the dorsum generally. Each is in shape like a "puff-ball" fungus (Halliburton), consisting of an enlarged rounded head, attached by a somewhat narrower base. As in the case of the conical papillæ, the corium is studded over with microscopic papillæ, which are buried in the covering of squamous epithelium and do not appear on the surface. Most of the fungiform papillæ, if not all, appear to be furnished with taste-buds, and they are probably intimately connected with the sense of taste.

A circumvallate papilla. ×12.

FIG. 711.—THE PAPILLÆ OF TONGUE.

The upper illustration shows conical and fungiform papillæ, the lower a circumvallate papilla. C, Corium, and E, Epithelium of the mucous membrane. The wavy dark lines represent arteries.

The **circumvallate papillæ** (Fig. 711), much the largest of all the papillæ of the tongue, are confined to the region immediately in front of the sulcus terminalis and foramen cæcum. Usually about ten in number, they are arranged in the form of the letter V, with the apex backwards, just in front of and parallel to the sulcus terminalis. One or two of the papillæ are usually placed at the apex of the V, immediately anterior to the foramen cæcum. In appearance a circumvallate papilla resembles very closely the impression left by pressing the barrel of a small pen on soft wax (Fig. 710). Each is composed of a cylindrical central part (1 to 2·5 mm. wide), slightly tapering towards its base, and flattened on its crown, which projects a little above the general surface of the tongue. This is surrounded by a deep, narrow, circular trench or **fossa**, the outer wall of which is known as the **vallum**. The vallum appears in the form of an encircling collar very slightly raised above the adjacent surface (Fig. 709).

As in the case of the other forms, the circumvallate papillæ are made up of a central mass of corium, beset with numerous microscopic papillæ on the crowns, but not on the sides, and covered over, as are the surfaces of the fossa and vallum, by stratified squamous epithelium. Into the fossæ open the ducts of some small serous glands (Fig. 711).

On the sides of the circumvallate papillæ, as well as upon the opposed surface of the vallum, are found, in considerable numbers, the structures known as **taste-buds**, the special end-organs of the nerves of taste.

The **apex** (apex linguæ), and the **margin** (margo lateralis) of the tongue in front of the attachment of the anterior palatine arch, are free, and lie in contact with the teeth when the tongue is at rest.

On the upper half or more of the margin and apex, papillæ are present as on the dorsum; but on the lower part they are absent, and the surface is covered by smooth mucous membrane.

Just in front of the anterior palatine arch, on the margin, are usually seen about five or six distinct vertical folds, forming the **folia linguæ**, which are beset with taste-buds, and correspond to a well-defined area (the papillæ foliatæ) on the side of the tongue in certain animals (rabbit, hare, etc.), in which it forms an important part of the organ of taste.

The **inferior surface** (facies inferior) of the tongue, which is exposed by turning the apex of the organ upwards, is limited in extent (Fig. 712), and is free from visible papillæ, the surface being covered by a smooth mucous membrane. Running

along its middle, except near the tip, is a depression, from which a fold of mucous membrane, the **frenulum linguæ**, passes down to the floor of the mouth, and on towards the back of the mandible. At each side of the frenulum, and a short distance from it, the large ranine vein is distinctly seen through the mucous membrane. Further out still are situated two indistinct, fringed folds of mucous membrane, the **plicæ fimbriatæ**, which converge somewhat as they are followed forward towards the tip, near which they are lost.

From the inferior surface of the tongue the mucous membrane passes across the floor of the mouth to the inner surface of the gum, with the mucous covering of which it becomes continuous.

The **plicæ fimbriatæ** correspond pretty closely to the course of the ranine arteries as they run towards the tip; the arteries, however, are deeply placed in the substance of the tongue, at a distance of 3 to 6 mm. from the inferior surface. The plicæ, which are more distinct at birth and in the fœtus, are said to correspond to the under tongue found in the lemurs.

The **root of the tongue** (radix linguæ) is the portion of the inferior aspect which is connected by muscles and mucous membrane to the mandible and hyoid bone. It is of very considerable extent, and is, with the base, the most fixed part of the organ. It is also the situation at which the vessels and nerves as well as the extrinsic muscles enter.

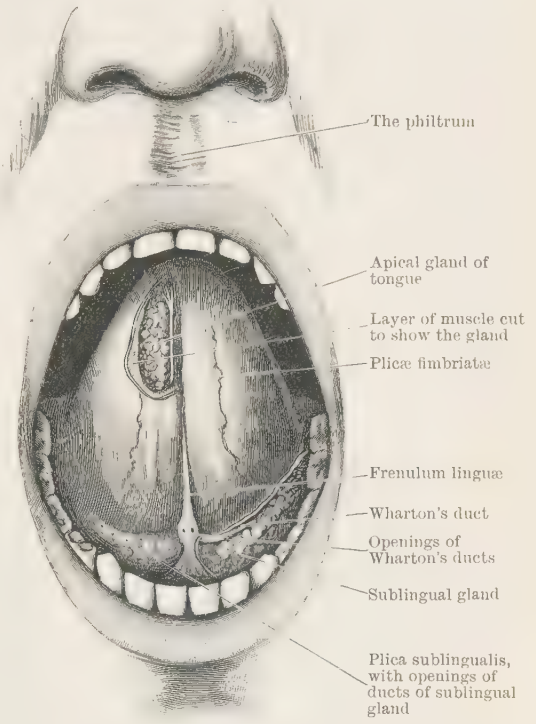

FIG. 712.—OPEN MOUTH WITH TONGUE RAISED, AND THE SUBLINGUAL AND APICAL GLANDS EXPOSED.

The sublingual gland of the left side has been laid bare by removing the mucous membrane; to expose the apical gland of the right side a thin layer of muscle, in addition to the mucous membrane, has been removed. A branch of the lingual nerve is seen running on the inner aspect of the gland. The ranine vein is faintly indicated on this side also.

**Structure of the Tongue.**—The tongue is chiefly composed of striped muscular tissue, in connexion with which are found a considerable admixture of fine fat and a median septum of connective tissue occupying the central part of the organ. In addition, there are vessels, nerves, glands, and lymphoid tissue, the whole being covered over by mucous membrane, except at the root (Fig. 713).

The muscular tissue is derived partly from the terminations of the extrinsic muscles namely, the hyoglossus, styloglossus, genioglossus, palatoglossus, and chondroglossus; but also largely from the intrinsic muscles—namely, the superior lingualis, inferior lingualis, the transverse, and the vertical lingual muscles. These are so arranged that they form a **cortical portion**, made up chiefly of longitudinal fibres—derived above from the superior lingualis and the hyoglossus, at the sides from the styloglossus, and below from the inferior lingualis. This cortex surrounds a central or **medullary portion**, divided into two lateral halves by the **septum**, and formed in great part by the transverse and vertical fibres, and also by the fibres of the genioglossi ascending to the dorsum. The muscular fibres derived from these various sources end by being inserted into the deep surface of the mucous membrane.

The detailed description of the extrinsic and intrinsic muscles will be found on page 414.

The **septum** is a median fibrous partition found in the medullary portion only, and easily exposed by separating the two genioglossi on the under surface of the tongue. Anteriorly it usually extends to the apex; whilst posteriorly it grows gradually narrower, and expanding transversely at the same time, it passes into a broad sheet (the hyoglossal

membrane) which is united to the upper border of the hyoid bone, and gives attachment to the posterior fibres of the genioglossus. From the sides of the septum the transverse fibres of the tongue arise.

The **mucous membrane** on the anterior two-thirds of the dorsum, and on the free margins, is firm and closely adherent to the underlying muscular substance, the fibres of which are inserted into it. On the posterior third of the dorsum, and on the inferior surface, it is neither so firm nor so closely united to the muscular substance, from which it is separated in both of these situations by a layer of submucous tissue.

The mucous membrane of the tongue, like that of the rest of the mouth, is covered by stratified squamous epithelium.

**Glands of the Tongue.**—Numerous small racemose glands are found scattered beneath the mucous membrane of the posterior third of the tongue; and a small collection of similar glands is present at the margin, opposite the circumvallate papillæ. Small serous glands are also found embedded in the dorsum near the circumvallate papillæ, into the fossæ of which their ducts open (Fig. 711).

The chief collections of glandular tissue in the tongue, however, are found embedded in the muscle of the under surface, a little way behind the apex, on each side of the middle line (Fig. 712). They are known as the **apical glands** (glandulæ linguales anteriores of Nuhn or Blandin).

These apical glands are displayed by removing the mucous membrane and also a layer of

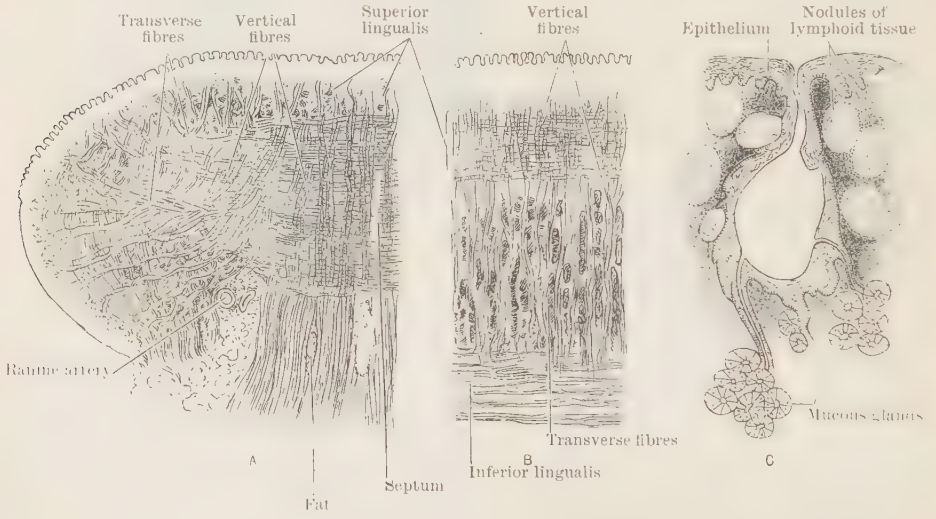

FIG. 713.—A, TRANSVERSE, AND B, LONGITUDINAL VERTICAL SECTION THROUGH THE TONGUE (Krause); C, A LYMPHOID FOLLICLE FROM BACK PART OF TONGUE (Macalister, slightly modified).

muscular fibres (derived from the united inferior lingualis and styloglossus) about 2 mm. in thickness from the under surface of the tongue a little distance behind the apex. They are oval in shape, often partly broken up by muscular fibres, and they measure from $\frac{1}{2}$ to $\frac{3}{4}$ in. (12 to 19 mm.) in length. They are mixed serous and mucous glands, and they open by three or four very small ducts on the inferior surface of the tongue.

**Vessels.**—The chief *artery* is the **lingual**. This vessel passes forwards on each side beneath the hyoglossus muscle, and then is continued on to the apex—between the genioglossus on the inner side and the inferior lingualis externally—under the name of the ranine artery. Anteriorly it is covered by the fibres of the inferior lingualis, and lies $\frac{1}{8}$ to $\frac{1}{4}$ inch from the surface. Near the apex the arteries of opposite sides are connected by a branch which pierces the septum, but otherwise, with the exception of capillary anastomosis, they do not communicate. The **dorsalis linguæ branch** of the lingual is distributed to the pharyngeal part of the tongue, whilst some twigs of the **tonsillar branch** of the facial are also distributed in the same region.

The *veins* are: the **ranine**, the chief vein, which lies beneath the mucous membrane at the side of the frenum, and runs backwards over the hyoglossus muscle with the hypoglossal nerve; two **venæ comites**, which accompany the lingual artery; and a **dorsalis linguæ vein** from the back of the tongue. These either unite and form a common trunk, or open separately into the internal jugular vein.

**Nerves.**—The nerves which supply the tongue are: (1) The **hypoglossal**, the motor nerve of the tongue, which enters the genioglossus and passes up in its substance to the intrinsic muscles, in which it ends. (2) The **lingual**, a branch of the inferior maxillary nerve, which is accompanied by the **chorda tympani branch** of the facial. The lingual, after crossing the hyoglossus muscle, breaks up and enters the inferior lingualis and genioglossus, and thus makes its way upwards to the mucous membrane of the anterior two-thirds of the tongue—the lingual itself conferring common sensation on this part, the chorda tympani probably carrying to it taste

fibres. (3) The **glossopharyngeal nerve** passes forwards beneath the upper part of the hyoglossus, and sends its terminal branches to the mucous membrane of the posterior third of the tongue, supplying the circumvallate papillæ, and the part of the tongue behind these, with both gustatory and common sensory fibres. (4) The **internal laryngeal nerve** also distributes a few fibres to the posterior part of the base of the tongue, near the epiglottis.

The **lymphatics** of the anterior half of the tongue pass down through the floor of the mouth and join the **submaxillary lymphatic glands**. Those from the posterior half run with the ranine vein across the hyoglossus muscle (where they are connected with some small lingual glands) and join the **deep cervical glands**.

## GLANDS.

Various organs, differing widely both in structure and function, are commonly included under the general term glands. It is made to embrace: (*a*) the *glands with ducts*, such as the digestive glands (liver, pancreas, salivary glands, etc.), the sweat and sebaceous glands of the skin, the testes, etc., and the small glands embedded in the walls of the digestive and respiratory tracts; (*b*) the so-called *ductless glands* (spleen, thyroid, suprarenals, etc.), which possess no ducts, but throw their secretions into the blood or lymph passing through them. We shall here consider only the true glands—namely, those included in the first group mentioned above, which are all characterised by the possession of ducts; and what follows refers to them alone.

A **gland** may be defined as an epithelial organ which separates or elaborates from the blood some substance which is either to be discharged from the body or used further in the economy. The product of the activity of the gland is known as its secretion, and the secretion is conveyed to its destination in all true glands, as explained above, by the gland duct.

Every gland is primarily an outgrowth of the epithelium from the surface to which the secretion of the gland is to be subsequently conveyed. This outgrowth may remain undivided, constituting a **simple gland**. On the other hand, it may break up into two or more branches, giving rise to a **compound gland**. We thus arrive at the two great classes of glands—simple and compound.

A **simple gland** may remain tubular, when it is known as a *simple tubular gland*, of which Lieberkühn's follicles in the wall of the small intestine and the sweat glands are examples. Or it may be dilated at its extremity, the enlargement being known as an acinus (ἄκινος, a grape or grape-stone) or alveolus, thus constituting a simple *acinous* or *alveolar gland*, of which there are few examples in man (viz. some sebaceous glands), though they are numerous in the skin of the frog, etc. This gives us two varieties of simple glands—tubular and acinous or alveolar.

Similarly a **compound gland** may remain tubular, constituting a *compound tubular gland*, such as the kidney, testicle, and the majority of the gastric glands. Or, on the other hand, the terminal branches of its ducts may be beset with dilatations (*i.e.* acini or alveoli), giving rise to a *compound acinous* or *alveolar gland*, which latter, owing to a remote resemblance presented by its clustering lobules to a miniature bunch of grapes, is often known as a *racemose gland* (*racemus*, a cluster). Most of the glands of the body are examples of this variety—*e.g.* the salivary glands, the small glands of the mouth, tongue, pharynx, œsophagus, respiratory passages, eyelids, etc. Thus we arrive at two varieties of compound glands also—tubular and acinous or alveolar.

A compound acinous (racemose) gland is composed of a main duct which branches and re-branches more or less freely according to the size of the gland, and the terminal divisions of which end finally in specialised secreting parts, the acini or alveoli, quite distinguishable from the ducts or conducting parts. In true acinous glands the acini or alveoli are distinctly saccular; in other glands, such as the pancreas, this is not the case, the acini being long and narrow. Accordingly, the term *acino-tubular* has been introduced and applied to glands of this latter type, which is usually made to include the pancreas, the prostate, and Brunner's glands.[1]

It should be added that the term acino-tubular is by some authors used exclusively instead of acinous for all racemose glands.

There is one gland, however, which cannot be included in any of the above varieties, and which must be placed in a class by itself. This is the liver. It is composed of an enormous number of small secreting lobules, between which run the branches of the bile-duct. These lobules in the mammalian liver cannot in any way be compared to acini, or to collections of acini, as their cells are not arranged around a central lumen, but form a practically solid mass, with minute bile capillaries running everywhere between them. It might in mammals, for want of a better term, be classed as a *solid gland*.

The foregoing may be summarised in tabular form thus:—

I. **Simple glands.**—Duct undivided.
- (*a*) **Simple tubular.**—Undilated at end—*e.g.* Lieberkühn's follicles, sweat, and many gastric glands.
- (*b*) **Simple acinous** (alveolar or saccular).—Dilated at end—*e.g.* some sebaceous glands (rare)

[1] Some authorities consider the glands of Brunner to belong to the class of compound tubular glands (Heidenhain, Watney, Jonnesco, etc.).

II. **Compound glands.**—Duct divided.
(*a*) **Compound tubular.**—Branched elongated tubes, no acini—*e.g.* testes, kidney, most gastric glands.
(*b*) **Compound acinous or alveolar** (racemose glands), branched duct with saccular acini on terminal branches—*e.g.* salivary, sebaceous, and Meibomian glands; the mucous glands of the mouth, tongue, palate, pharynx, nose, œsophagus, and respiratory tube.
(*c*) **Acino-tubular.**—Branched duct, with elongated narrow acini on terminal branches—*e.g.* pancreas, Brunner's glands, prostate.
III. **Solid gland.**—The liver.

To save confusion it may be pointed out that instead of acinus the term alveolus (and also saccule and follicle) is often used, and also that the term "racemose gland" is often conveniently used instead of compound acinous gland.

**General Structure of Glands.**—Whilst the small glands, such as those of the mouth and pharynx, are placed in the mucosa or submucosa immediately beneath the point at which their ducts open on the surface, the large glands form distinct masses, generally surrounded by special capsules, and often lie at a considerable distance from the points at which their ducts open.

One of these large glands of the acinous type, such as the parotid or submaxillary, presents the following general arrangement. The gland is made up, as can be seen with the unaided eye, of a number of masses, often as large as peas, which are surrounded and held together by connective tissue. These are known as lobes, and to each a branch of the duct passes. The lobes are in turn made up of a number of smaller masses—lobules—each having a special branch of the lobar duct. These again are composed of smaller lobules, and so on to a varying degree. Finally, the smallest are made up of a terminal branch of the duct, with a cluster of acini or alveoli developed upon it.

The **acini** or **alveoli**, the special secreting portions of the gland, are composed of a basement membrane, often fenestrated or basket-like, formed of flattened cells, on the outer side of which the blood and lymph vessels lie. The inner surface of this membrane is lined by the secreting epithelial cells, usually polygonal in shape, which almost completely fill the alveolus. A small lumen, however, is left, into which the secretion of the cells is shed, whence it passes into the duct of the lobule, and thus to the main duct.

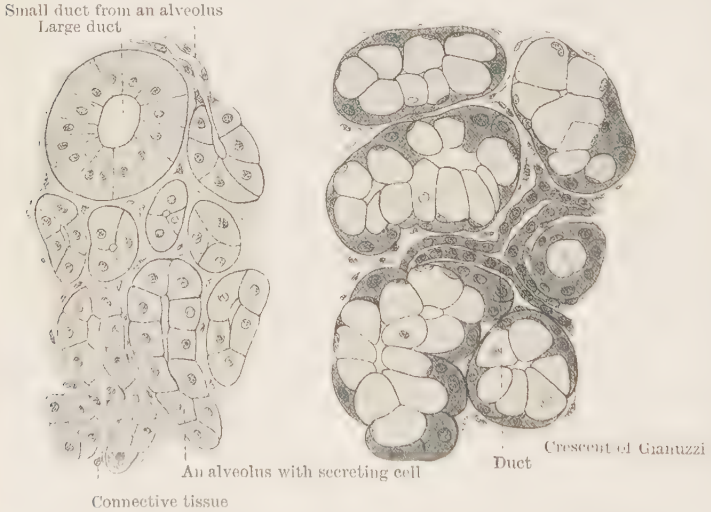

Fig. 714.—Section of a Serous Gland on the left, a Mucous Gland on the right side (Böhm and v. Davidoff).

In the serous gland the granular secreting cells and the centrally-placed nucleus should be noted. The relatively clear cells, with the dark crescents of Gianuzzi, are distinctive in the mucous gland.

The blood-vessels and lymphatics, on entering the gland, break up and run, branching as they go, in the connective tissue which conveys them to all parts of the gland.

**Mucous and Serous Glands.**—Two distinct varieties of salivary glands are found, the serous and the mucous, differing not only in the nature of their secretion, but also in the character of the epithelium lining their alveoli. In those of the mucous type (Fig. 714) the epithelial cells are large, clear, or faintly granular, and the nucleus lies as a rule near the base of the cell. In addition, many mucous glands, but not all, have small flattened or crescentic cells, distinctly granular, which stain strongly with ordinary stains, lying between the basement membrane and the bases of the chief cells. These are the *crescents* or *demilunes of Gianuzzi.*

In the acini or alveoli of serous glands, on the other hand (Fig. 714), the epithelial cells are distinctly granular, the granules staining well with ordinary stains; the nuclei are rounded and lie near the centre of the cells, and no demilunes are present.

In man the parotid and the small glands which open into the fossæ of the circum-

vallate papillæ alone are *serous*. The submaxillary and the apical gland of the tongue are *mixed*, the serous alveoli being the more numerous; whilst the sublingual, labial, buccal, and all other glands of the mouth, tongue, and palate are said to be *mucous*.

## Salivary Glands.

This term is generally understood to include only the three large masses of glandular tissue found on each side of the face—namely, the parotid, submaxillary, and sublingual glands. But, as previously pointed out, numerous other small glands

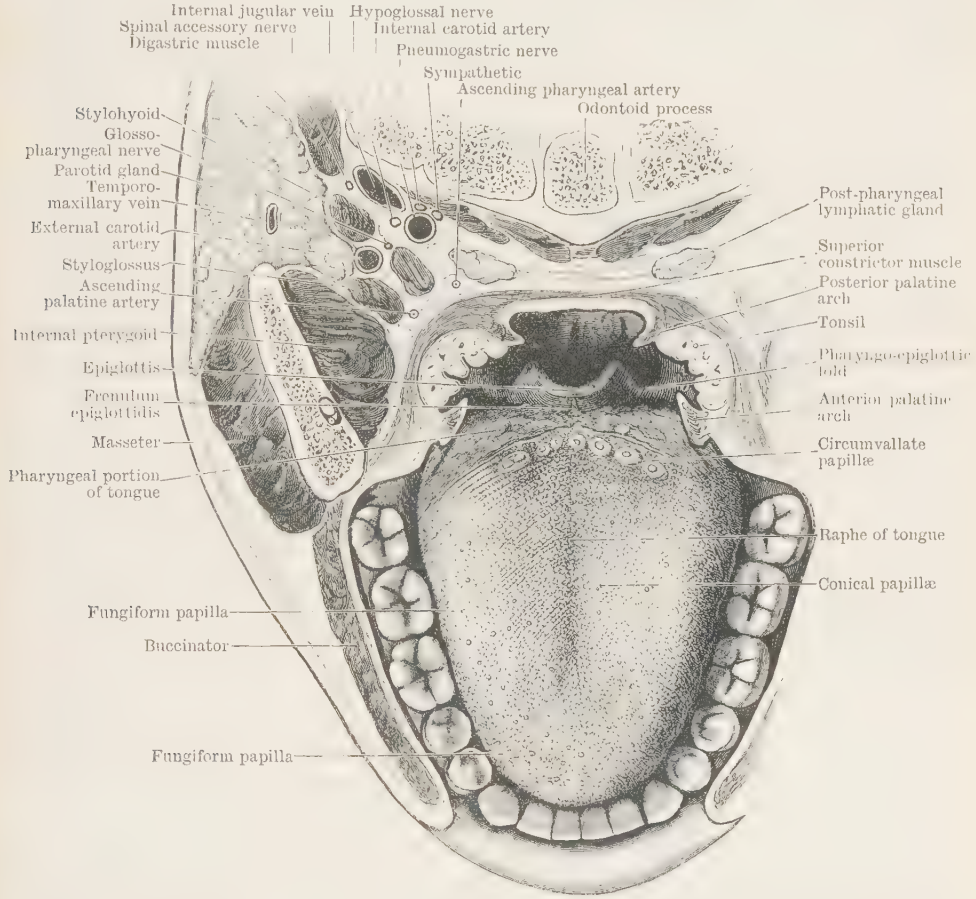

Fig. 715.—Horizontal Section through Mouth and Pharynx at the Level of the Tonsils.

The stylopharyngeus, which is shown immediately to the inner side of the external carotid artery, and the prevertebral muscles, are not indicated by reference lines.

of a similar nature are found in the lips, cheeks, palate, tongue, etc. These have already been sufficiently described, and require no further mention.

**Parotid Gland** (glandula parotis).—This, the largest of the salivary glands, is a distinctly lobulated mass of a yellowish or light reddish-brown colour, which is placed in a deep recess (the parotid recess) at the side of the head, below and in front of the ear (Fig. 716). It extends up to the zygoma, down to the angle of the jaw or even to a lower level, and backwards to the sterno-mastoid muscle. Internally it lies on the styloid process, and anteriorly its facial process is continued for a variable distance over the surface of the masseter.

When the gland is carefully removed without disturbing the surrounding parts, the recess which it occupies is seen to be a considerable space, between the ramus of the jaw in front and the sterno-mastoid muscle behind, with a floor formed of two sloping walls, an anterior and a posterior, which meet at an angle corresponding pretty

closely to the styloid process. Thus the recess is three-sided (Fig. 715), the third side corresponding to the parotid fascia covering the gland. Into this *parotid recess* the greater part of the parotid gland fits closely. From its anterior part, however, the variably-developed **facial process** is continued forward over the masseter muscle.

**Parotid Fascia.**—The parotid recess is covered over on the one hand, and lined on the other, by fascia. The covering layer is specially known as the parotid fascia, and both it and the lining layer are derived from the deep cervical fascia, which divides below to enclose the gland. The parotid fascia proper is connected above to the zygoma; behind, to the auditory meatus and anterior border of the sterno-mastoid; below, it is continuous with the deep cervical fascia, and in front it passes forwards over the masseter, and blends with the fascia of that muscle. The layer of fascia beneath the gland forms a lining for the recess, and is united above to the periosteum over the auditory meatus and back part of the glenoid fossa; internally it is connected to the styloid process; whilst below it joins the deep cervical fascia. Taken together, the two layers form a definite capsule which completely encloses the gland. In connexion with the lower and anterior part of this capsule is developed a special flat band, the **stylo-mandibular ligament**, which passes downwards and outwards from the styloid process to the angle of the jaw. It separates the anterior part of the parotid gland from the back of the internal pterygoid muscle; perhaps occasionally, also, from the upper and posterior part of the submaxillary gland.

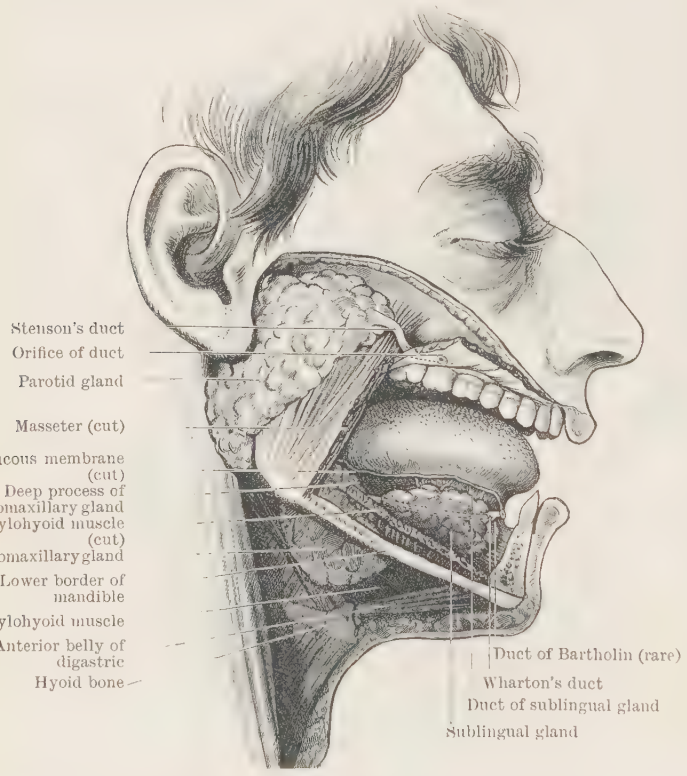

FIG. 716.—THE SALIVARY GLANDS AND THEIR DUCTS.

The greater portion of the body of the mandible has been removed to expose the sublingual and the deeper parts of the submaxillary glands. Four ducts of the sublingual gland are shown opening on the floor of the mouth over the gland, a fifth is shown opening into the anterior end of Wharton's duct. The course of Wharton's duct is shown by a dotted line.

**Shape and Relations of the Parotid Gland.**—Like the recess in which it lies, the main mass of the parotid gland is three-sided (Fig. 715), the three surfaces being superficial, anterior, and posterior.

The *superficial surface* is closely covered by the parotid fascia, and its lower part is also crossed by the highest fibres of the platysma. The *anterior surface*, approximately flat, lies in contact with the wide posterior surface of the internal pterygoid muscle; it is also related to the posterior border of the mandible and the masseter muscle, whilst from its superficial part the **facial process** is continued forwards over that muscle. The *posterior surface* lies from without inwards against (1) the anterior border of the sterno-mastoid and the auditory meatus, (2) the posterior belly of the digastric and the occipital artery, and (3) the spinal accessory nerve and carotid sheath—the internal jugular vein within the sheath being in very close relation. The *inner angle* formed by the meeting of the anterior and posterior surfaces corresponds to the styloid process and the styloid muscles (Fig. 715). *Above*, the gland is limited superficially by the zygoma; more deeply a thin process runs up into the posterior part of the glenoid

fossa. *Inferiorly* it usually reaches a little distance below a line prolonged horizontally backwards from the angle of the jaw, but its limit in this direction is variable.

Occasionally the parotid gland passes down a considerable distance below the angle of the mandible, lying here superficial to the posterior part of the submaxillary gland, from which it is separated by a thickened band of the deep cervical fascia, passing from the angle of the jaw to the fascia of the sterno-mastoid. At other times it does not quite reach the angle.

The **facial process** of the gland—often of considerable size—is a flat and somewhat triangular portion which runs forwards from the upper part of the gland, and overlaps the masseter muscle to a varying extent; from its most anterior part the parotid duct emerges, and a separated portion of this process, often found lying immediately above the duct, is known as the **socia parotidis** (glandula parotis accessoria).

Traversing the substance of the gland (Fig. 715) are found:—(1) the temporo-maxillary vein; (2) on a deeper plane, the branches of the facial nerve passing forwards; and (3) more deeply still, the external carotid artery which lies beneath the lower part of the gland, but is embedded in its deep surface above. Just before it emerges, the artery divides into its two terminal branches in the gland substance.

The **parotid** or **Stenson's duct** (ductus parotideus) leaves the anterior border of the gland at its most prominent part (Fig. 716). It first runs forwards across the masseter, usually accompanied by the socia parotidis which lies above it, and also by branches of the facial nerve; whilst the transverse facial artery is commonly some distance above, though its relation is variable. Having crossed the masseter, it turns abruptly round the anterior border of this muscle and runs inwards through the fat of the cheek, practically at right angles to the first part of its course, to reach the buccinator, which it pierces. Then passing for some distance (5 to 10 mm.) between the buccinator and mucous membrane, it opens into the vestibule of the mouth by a very small orifice, on a variably-developed papilla, opposite the crown of the second upper molar tooth.

The course of the duct, which is fairly constant, can be marked on the side of the face by drawing a line from the lower edge of the auditory meatus to a point midway between the ala of the nose and the red of the lip; the middle third of this line corresponds fairly accurately on the surface, to the course pursued by the duct.

The gland varies in weight from half an ounce to an ounce or more. Several small lobes or processes are found in connexion with it—viz. one running backwards between the sterno-mastoid and the digastric; a glenoid lobe of very small size, which lies in the posterior part of the glenoid cavity; a pharyngeal process (Fig. 715), which runs forwards and inwards between the styloid process and the external carotid artery towards the pharynx. A pterygoid extension running forwards between the two pterygoid muscles, although described, cannot properly be said to exist.

Stenson's duct measures from $1\frac{1}{2}$ to $2\frac{1}{2}$ inches (38 to 62 mm.) in length, and $\frac{1}{8}$ inch (3 to 4 mm.) in diameter. The calibre of the duct is very much greater than that of its orifice, which only admits a fine bristle, and for this reason the duct may, to some extent, be looked upon as a reservoir for the saliva, as well as a duct for its conveyance. In the child it pierces the "sucking pad" on its way to the mouth.

**Vessels and Nerves.**—The **arteries** which supply the gland arise from the external carotid, and from the branches of this artery in relation to the gland.

The **veins** join the temporo-maxillary and its tributaries. The **lymphatics** pass to both the superficial and the deep cervical glands; there are also a few small parotid lymphatic glands, which lie on the surface of the upper and lower part of the parotid beneath the capsule. Some are said to be embedded in the substance of the parotid itself.

The **nerves** are derived (*a*) from the auriculo-temporal, and (*b*) from the sympathetic on the external carotid. The fibres of the sympathetic are mainly vaso-constrictor. Those of the auriculo-temporal convey to the gland secretory fibres from the glosso-pharyngeal.

**Submaxillary Gland.**—The submaxillary gland is next in size to the parotid, and resembles it in its lobulation and colour. It is placed partly in the submaxillary triangle and partly under cover of the posterior part of the mandible near its angle (Fig. 716).

In size and shape it may be compared to a small walnut with three flattened

sides. It is enclosed in a complete capsule derived from the deep cervical fascia: embedded in this capsule, and superficial to the gland, are found a few submaxillary lymphatic glands, which are of importance owing to their connexion with the lymphatics of the lips and of the anterior half of the tongue.

In considering the relations of the gland, it is well to remark that there is in this region a three-sided space bounded externally by the inner surface of the mandible below the mylohyoid ridge, internally and above by the mylohyoid muscle running inwards and downwards, and below by the skin and fascia passing from the margin of the jaw obliquely inwards and downwards to join the side of the neck. In this space the gland lies with external, internal, and inferior surfaces corresponding to the walls of the space.

The *superficial* or *inferior surface* looks downwards and outwards; it is covered by the deep cervical fascia and the platysma, and is crossed by the facial vein, which lies superficial to the gland, whilst the artery passes in part beneath it. The *external surface* rests against the inner aspect of the lower jaw (submaxillary fossa) for an inch and a half forward from the angle, to which latter it usually reaches behind. The *deep* or *internal surface* lies on the posterior part of the mylohyoid muscle, and behind this, on the hyoglossus and the posterior belly of the digastric with the stylohyoid; for the gland is not contained within the limits of the submaxillary triangle inferiorly, but passes down some little distance over the digastric muscle. From the deep surface, anterior to its middle, a narrow tongue-like **deep process** (Fig. 716) is continued forwards beneath the mylohyoid muscle along with the duct.

The *posterior end* of the gland, which is its most bulky portion, either abuts against, or lies very close to, the sterno-mastoid, and is often overlapped by the lower end of the parotid gland. The facial artery, on its way to the border of the mandible, lies in a groove in the upper and back part of the gland.

The **submaxillary** or **Wharton's duct** leaves the deep surface of the gland about its middle, and runs forwards beneath the mylohyoid muscle with the deep process, along the upper and inner aspect of which it is placed (Figs. 716 and 712). Pursuing its course forwards beneath the floor of the mouth, on the inner side of the sublingual gland, the duct crosses the hyoglossus and the genioglossus muscles, and finally opens on the floor of the mouth at the side of the frenulum linguæ, where its small orifice is placed on the summit of a soft papilla (caruncula sublingualis) close to its fellow of the opposite side.

While running forward beneath the floor of the mouth the duct, which is about two inches long (50 mm.), is crossed on its inferior aspect by the lingual nerve near the anterior border of the hyoglossus, that is opposite the 2nd molar tooth. The nerve at the time is arching from the posterior end of the mylohyoid ridge (against which it lies) inwards and forwards in order to reach the under surface of the tongue, and in this course it passes beneath the duct at the point indicated. As in the case of Stenson's duct, the calibre of Wharton's duct is much greater than that of the orifice by which it opens; for this reason it may likewise be looked upon as forming, to some extent, a reservoir for the saliva secreted by the gland.

**Vessels and Nerves.**—The **arteries** come chiefly from the facial and its submental branch: the **veins** are similarly disposed. The **nerves** are derived from the submaxillary ganglion (which lies above the deep process of the gland), and are composed of fibres from the chorda tympani, from the lingual, and from the sympathetic on the facial artery. The lymphatics pass to the submaxillary lymphatic glands.

**Sublingual Gland.**—This is an elongated almond-shaped mass, flattened from side to side, and much wider (from above downwards) in front than behind, which lies on the floor of the mouth beneath the plica sublingualis—a ridge of the mucous membrane produced by the prominent upper border of the gland. It is usually from $1\frac{1}{2}$ to $1\frac{3}{4}$ inches (37 to 45 mm.) in length, whilst its bulk is about equal to that of two or three almonds.

It is placed between the mandible externally, the genioglossus internally, the mylohyoid muscle below, and the mucous membrane of the mouth above (Fig. 706).

Its detailed relations are as follows:—Its *outer surface* rests against the inner aspect of the body of the mandible above the mylohyoid ridge. Its *inner surface* is in contact with the genioglossus and the hyoglossus muscles, as well as with Wharton's duct, which runs forwards between the gland and the muscles. *Below*, it rests on the mylohyoid, and at its posterior part on the deep process of the submaxillary gland; whilst its *upper*

*prominent border* is covered only by the mucous membrane of the mouth, here raised up by the gland to form the plica sublingualis (Fig. 712). The anterior portion of the gland is much deeper and more bulky than the posterior half, and it meets its fellow in the middle line beneath the frenulum linguæ. The posterior extremity grows gradually more slender, and ends near the posterior part of the mylohyoid ridge, where it lies above the deep process of the submaxillary gland.

Its **ducts**, generally known as the **ducts of Rivinus** (ductus sublinguales minores), are numerous and of small size; they leave the upper part of the gland, and, after a short course, open on a series of papillæ, visible to the naked eye, which are placed along the summit of the plica sublingualis.

The gland is not enclosed in a distinct capsule, thus differing from the parotid and submaxillary glands; but its numerous lobules, which are smaller than those of the glands just mentioned, are held together by fine connective tissue, loosely, but still in such a manner as to make one more or less consolidated mass out of what was, in the embryo, a number of separate glands.

As a rule all the ducts open separately on the summit of the plica sublingualis, and apparently none of them join Wharton's duct. Frequently some of those from the anterior and more bulky part of the gland are larger than the others, but the presence of a large duct running alongside of Wharton's duct, and opening with or beside it (ductus major Rivini, duct of Bartholin), is very rare, and must be considered as an exceptional condition in man, although normal in the ox, sheep, and goat. The same may also be said of ducts from the sublingual, which are described as opening into the duct of Wharton.

**Vessels and Nerves.**—The **arteries** are derived from the sublingual branch of the lingual and from the submental branch of the facial. The **nerves** come from the lingual, the chorda tympani, and the sympathetic, through a branch of the submaxillary ganglion which joins the lingual, and is conveyed by it to the gland.

The **apical gland** of the tongue (Nuhn's) is described with the tongue, p. 1006.

## Development of the Salivary Glands, Palate, and Tongue.

The general development of the lips, mouth, palate, and tongue is described on pages 37 to 42, and reference wil' be made here only to a few special points bearing upon this matter.

Several explanations of the formation of the **philtrum** or groove on the front of the upper lip have been put forward; most probably it is produced by the union of the median fronto-nasal process with the two maxillary processes (see p. 39), the floor of the groove being formed by the fronto-nasal process, and the ridges bounding the groove at the sides corresponding to the line of meeting of the fronto-nasal with the maxillary processes.

The **salivary glands** are developed as *solid* outgrowths of the buccal epithelium, one each for the submaxillary (the first developed) and the parotid, several for the sublingual gland. The outgrowths are at first simple; they subsequently divide, and finally develop alveolar enlargements on their extremities. By a separation of the lining cells, the ducts, and later on (about the 22nd week) the alveoli, become hollowed out, and present a lumen as in the adult.

The development of the **palate** is given at page 40; but it should be mentioned that, in order to account for the position which the fissure in cleft palate usually occupies, viz. between the central and lateral incisors, the theory has been advanced by Albrecht, that each premaxilla is made up of two separate segments, an inner (or endo-gnathion), containing the central incisor, and an outer (or meso-gnathion), containing the lateral incisor (the rest of the maxilla constituting the exo-gnathion). Between these two segments of the premaxilla (endo- and meso-gnathion) the cleft is said to run, and not between the premaxilla and maxilla as usually held.

**Tongue.**—The tongue is developed in the embryo, not on the floor of the primitive mouth, but upon the anterior wall of the pharynx, and in two parts, which are at first distinct but soon unite. The anterior two-thirds of the organ is formed from the **tuberculum impar**, a single median elevation, developed on the ventral wall of the pharynx, immediately behind the first, or mandibular, visceral arch. Behind the tuberculum impar, at first, lies a prominent elevation—the **furcula**, from the anterior part of which the epiglottis is formed—the two being separated by a distinct sulcus, the **sinus arcuatus** (see p. 37). Soon, however, the ventral extremities of the second and third visceral arches, growing downwards, unite across the middle line. The tuberculum is thus separated from the furcula, and the middle portion of the sinus arcuatus is divided into an anterior and a posterior part. The ventral ends of the two arches having fused, develop, after a little time, into a prominent semilunar ridge, the rudiment of the posterior

third of the tongue. This ridge embraces the back of the tuberculum impar, but it is separated from it in part by the anterior division of the sinus arcuatus, which persists even in the adult as the foramen cæcum, with the sulcus terminalis running forwards and outwards on each side from it. Finally, the two rudiments of the tongue—the tuberculum impar and the semilunar ridge—become blended, the only indication of the original separation being the foramen cæcum, the sulcus terminalis, and the different characters which the mucous membrane presents on the two divisions of the organ. At the foramen cæcum the downgrowth which gives rise to the isthmus of the thyroid gland takes place, and a part of the thyro-glossal duct which in the early condition connects the two may in rare cases persist in the adult in connexion with the foramen.

## THE TEETH.

The teeth are highly modified portions of the mucous membrane of the mouth, specially developed to perform the important function of mastication, that is, the division and trituration of the food which takes place in the mouth before the *bolus*, as the resulting mass is called, can be swallowed. Each tooth is a calcified papilla of the mucous membrane of the mouth, and consists like that membrane of two chief portions—namely, the dentine derived from the connective tissue, and the enamel from the epithelial layer of the mucous membrane. The **dentine** constitutes the chief mass of the tooth, whilst the **enamel** forms a cap for the portion which projects above the gum. There is also found in the teeth another special tissue—the **cementum** or **crusta petrosa**, a form of modified bone—which encases the roots, these latter being formed chiefly of dentine.

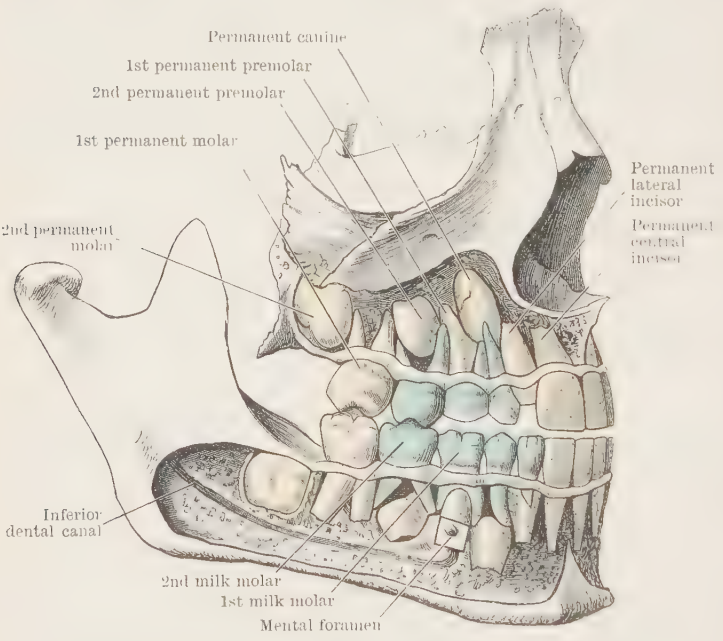

Fig. 717.—Teeth of a Child over Seven Years old (modified from Testut).

By removing the bony outer wall of the alveoli, the roots of the teeth which have been erupted, and the permanent teeth which are still embedded in the mandible and maxilla, have been exposed. The milk teeth are coloured blue, the permanent teeth yellow. It will be seen that the first permanent molars have appeared, the central and lateral milk incisors have been replaced by the corresponding permanent teeth in the upper jaw, but the milk canine and molars have not yet been shed. In the lower jaw the central milk incisor has been replaced by the permanent central; the lateral has not yet been shed, but its permanent successor is making its way up to the surface on its lingual side. In addition, the canine and two molars of the milk set persist. The position of the crowns of the permanent teeth between the roots of the milk molars, and the deep situation occupied by the permanent canines, should be noted. Observe also the absorption of the root of the lower lateral incisor.

Dentine and enamel, but particularly the latter, are the hardest and most resistant structures in the body, and are thus specially fitted for the functions which they have to perform.

**Temporary and Permanent Teeth.**—The mouth of the infant at birth contains no teeth, although a number, partly developed, lie embedded in the jaws beneath the gum. Some six months later teeth begin to appear, and by the end of the second year a set, known as the **milk teeth**, twenty in number, has been "cut." Then follows a pause of about four years, during which no visible change takes place in the mouth, although in reality an active preparation for further development is going on beneath the gum.

At the end of this period, namely, about the sixth year, the next stage in the production of the adult condition begins. It consists in the eruption of four new teeth—the first permanent molars—one on each side, above and below, behind those of the milk set. This is followed by the gradual falling out of the twenty teeth which have occupied the mouth since the second year (Fig. 717), and the substitution for them of twenty new teeth, which take up, one by one, the vacancies created by the dropping out of each of the milk set. Finally, the adult condition is attained by the eruption of eight additional teeth—the 2nd and 3rd molars—two on each side, above and below, behind those which have already appeared. All of these—the **permanent set**—have appeared by the end of the twelfth or thirteenth year, except the four wisdom teeth, which are usually cut between the seventeenth and twenty-fifth year, but are often delayed until a very much later period, and occasionally never appear.

The set of teeth which, as indicated above, begin to appear in the infant about the sixth month, are known as the **deciduous, temporary**, or **milk teeth** (dentes decidui), whilst those which succeed them and form the adult equipment are the **permanent teeth** (dentes permanentes).

The **milk teeth** are twenty in number, and are named as follows in each jaw, beginning at the middle line:—central incisor, lateral incisor, canine, first molar and second molar; or more briefly, two incisors, one canine, two molars. This is conveniently expressed by the "dental formula" for the deciduous teeth in man, which shows the number of each class of teeth above and below on one side of the mouth, viz.:—

$$i.\ \tfrac{2}{2},\ c.\ \tfrac{1}{1},\ m.\ \tfrac{2}{2}.$$

The **permanent teeth**, thirty-two in number, are named in each jaw, beginning at the middle line:—central incisor, lateral incisor, canine, 1st premolar (or bicuspid), 2nd premolar (or bicuspid), 1st molar, 2nd molar, and 3rd molar or wisdom tooth (dens serotinus). The dental formula for the permanent set in man is thus:—

$$i.\ \tfrac{2}{2},\ c.\ \tfrac{1}{1},\ pm.\ \tfrac{2}{2},\ m.\ \tfrac{3}{3}.$$

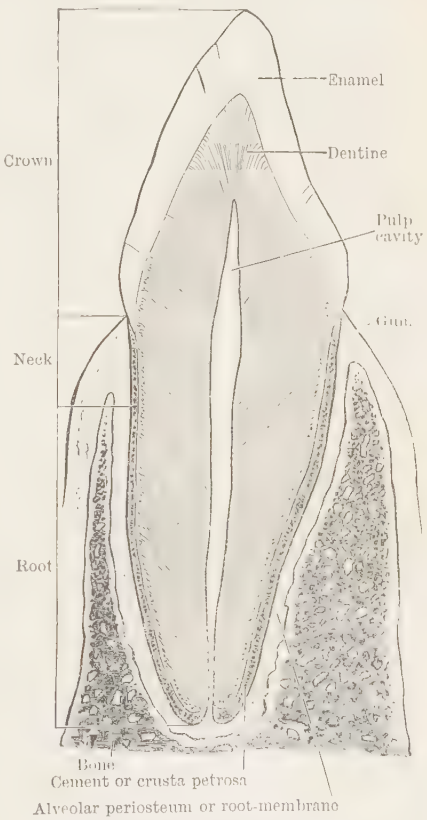

Fig. 718.—Vertical Section of Canine Tooth to illustrate its various parts, and its structure.

**General Form and Structure.**—A tooth consists (Fig. 718) of (1) the **crown** (corona dentis), the portion projecting above the gum, which varies in shape in the different teeth, and in all, except the incisors and canines, bears on its grinding surface a number of tubercles or **cusps** (tubercula coronæ), varying in number from two to five in the different teeth; (2) the **neck** (collum dentis), the faintly constricted part which is surrounded collar-wise by the gum, and which connects the crown with (3) the **root** (radix dentis), the portion of the tooth which is embedded in the alveolus of the maxilla or the mandible. In the majority of teeth, namely, in all except the molars, the root, as a rule, is single, or nearly so, and consists of a long, tapering, conical, or flattened piece, perfectly adapted to the alveolus in which it lies. In the molar teeth (and in some of the others occasionally) the root is divided into two or three tapering or flattened **roots** or fangs. At the apex of each root there can be made out, even with the naked eye, a minute opening (foramen apicis) through which the vessels and nerves enter the tooth.

On making a section of a tooth (Fig. 718), it will be seen that the interior of

the body is occupied by a cavity of some size, generally called the **pulp cavity** (cavum dentis), owing to the fact that it is filled in the natural state by the soft and sensitive tissue known as the **pulp**. This pulp cavity gradually narrows below, and is prolonged into each root of the tooth as a slender tapering passage, the **root canal** (canalis radicis), which opens at the apical foramen already referred to. Through these root-canals, which also contain some pulp, the vessels and nerves, which enter at the apex, pass to the interior of the tooth.

Short diverticula of the pulp cavity are prolonged into the bases of the cusps in the molar and premolar teeth, and in the incisors also there are similar slight prolongations of the cavity towards the angles of the crown.

The **roots** of the teeth are embedded in the sockets or **alveoli** of the jaws, to which they are accurately adapted, and firmly united (Fig. 718) by a highly vascular layer of connective tissue—the **alveolar periosteum** (alveolo-dental periosteum or root-membrane). This is attached to the wall of the alveolus on the one hand and to the root of the tooth on the other, whilst above it is continuous with the connective tissues of the gum.

So accurately are the root and the alveolus adapted to each other over their whole extent, and so firmly does the periosteum bind them together, that, under normal conditions, the tooth is quite firmly fixed in the bone, and no movement of the root within the alveolus can take place; the vessels and nerves entering at the apex are thus secured against pressure or strain.

When, however, the alveolar periosteum is inflamed it becomes swollen and exquisitely sensitive; the tooth, as a result of the swelling, is pushed partly out of its socket, its crown projects above those of its neighbours, and strikes against the opposing tooth when the mouth is closed, giving rise to much pain and discomfort.

The **neck**, although a useful term, can scarcely be recognised as a distinct constriction in the permanent teeth; it corresponds to the line along which the gum and alveolar periosteum meet, or along which the gum is united to the tooth; but, as already pointed out, the gum does not stop at the neck, but forms a free fold which surrounds the base of the crown collar-wise for a short distance. The outline of the margin of the gum opposite the labial and lingual surfaces of the crown is usually concave, but opposite the proximal and distal sides of the tooth it is convex, and reaches much nearer to the edge of the crown than on the other surfaces.

In the incisors and canines the **pulp cavity**, which is about $\frac{1}{8}$ to $\frac{1}{4}$ the diameter of the tooth, passes very gradually into the root canal (Fig. 718), so that it is difficult to say where one ends and the other begins. The reverse is the case in the molars, whilst the premolars are somewhat variable in this respect.

**Tartar** is a hard calcareous deposit from the saliva (salivary calculus), often found on the teeth near their necks. It is composed of lime salts, and its deposit is largely determined by the presence of organisms (leptothrix, etc.) in the mouth.

## THE PERMANENT TEETH.

The permanent teeth (Figs. 719 and 724) are thirty-two in number, sixteen above and sixteen below, or eight in each half of either jaw; and, although we can group them under four heads—incisors, canines, premolars, and molars—the individual teeth differ so much in their characters that each tooth will require a separate description.

**Descriptive Terms.**—Before describing the permanent teeth, it is requisite that certain terms which are employed to denote the surfaces of the teeth should be defined. This is a matter of some importance, seeing that the terms inner and outer, anterior and posterior, cannot, owing to the curvature of the dental arches, be properly applied to all the teeth in the same sense. The terms given below have been adopted seeing that they are free from the danger of misconception.

The part of a tooth which comes in contact with the teeth of the opposite jaw is known as the **grinding** or **masticating surface** (facies masticatoria, Fig. 721). The surface in contact with or looking towards its predecessor in the row is known as the **proximal surface** (*facies medialis* in incisors and canines, *facies anterior* in premolars and molars); the opposite surface, namely, that which looks towards its successor in the row, is known as the **distal surface** (*facies lateralis* in incisors and canines, *facies posterior* in molars and premolars). The surface which looks towards the tongue is the **lingual surface** (facies lingualis), and that looking in the opposite direction, *i.e.* towards the lips and cheek, the **labial surface** (facies labialis). The portion of a tooth which touches its neighbour in the same row is known as the **contact surface** (facies contactus).

**Incisor Teeth** (dentes incisivi, Figs. 719 and 720).—These teeth, four in number in each jaw, are used specially for cutting the food, hence their name. The **crown** of each is chisel-shaped, and presents an anterior or labial surface which is convex in all directions, a posterior concave surface, and a chisel-like edge, which, when first cut, is surmounted by three small tubercles separated by two grooves. These tubercles, however, are soon worn down, and the edge becomes straight or nearly so. Owing to the fact that the upper incisors overlap those in the lower jaw, the cutting edge is worn away, or becomes bevelled, on the posterior aspect in the former, but on the anterior aspect or summit in the latter. The upper, but particularly the upper central incisors, are of large size, and slope somewhat forwards;

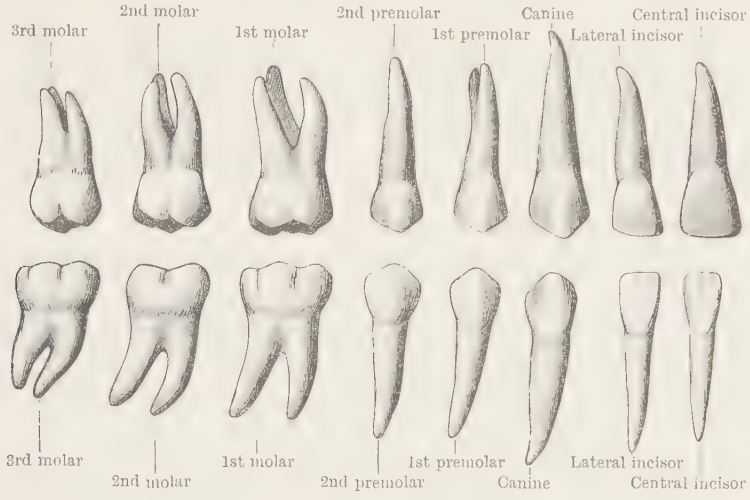

FIG. 719.—THE PERMANENT TEETH OF THE RIGHT SIDE. OUTER OR LABIAL ASPECT.

The upper row shows the upper teeth, the lower row, the lower teeth. The wide vertical "labial ridge" is distinct on the upper canine and premolar teeth.

whilst the lower incisors, which are all nearly equal in size, are much smaller—being the smallest of all the teeth—and are placed vertically. The roots of the incisors are single, though a groove is occasionally seen on each side, suggesting a division.

The central upper incisors are very much larger than the upper lateral incisors (Fig. 719), but in the lower jaw the opposite is the case, the lateral incisors being slightly the larger. In all incisors the outer (distal) angle of the crown is more rounded than the proximal. The posterior concave surface of the crown in the upper incisors is usually limited towards the gum by a ∧-shaped ridge (Fig. 720), known as the **basal ridge** or **cingulum**. The two limbs of the ∧ are continued up along the sides of the posterior surface, whilst the apex is turned towards the gum; and here, particularly in the lateral incisor, there is often developed a small **lingual cusp** (Fig. 720). The cingulum is rarely found on the lower incisors.

The roots of the upper incisors and canines are conical and rounded (the laterals and canines not so distinctly as the centrals, Fig. 723), whilst those of the lower jaw are flattened from side to side (proximo-distally).

**Canine Teeth.**—In the four canine teeth (dentes canini), which succeed the incisors in each row (Figs. 719 and 720), the **crown** is large and conical, corresponding closely in general form to a very large central incisor with its angles cut away, so that the crown assumes a pointed or conical shape. The labial surface is convex, the lingual usually somewhat concave. The root is single and long, particularly in the upper canine, the root of which is longer than that of any other tooth, and produces the canine eminence on the anterior surface of the upper jaw. The upper canines are larger than the corresponding lower teeth, behind which they bite; and they are sometimes known as the "eye teeth."

The upper canine presents on its lingual surface a well-marked cingulum, and often a distinct lingual cusp; in addition, there is usually a median ridge running from the point of the crown to the apex of the cingulum, which is separated from the lateral part of the cingulum on each side by a slight depression. These points are neither so well marked, nor so constant, in the lower as in the upper canine.

Of the two margins sloping away from the apex of the crown, the lateral is the longer in both teeth. After it has been a little worn the lower canine is less distinctly pointed than the upper;

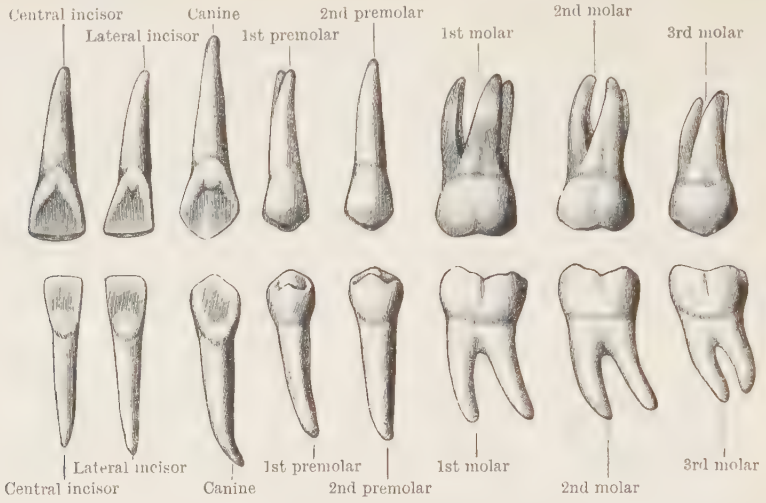

FIG. 720.—THE PERMANENT TEETH OF THE RIGHT SIDE, INNER OR LINGUAL ASPECT.

The upper row shows the upper teeth, the lower row the lower teeth. The cingulum is distinct on the upper incisors and both canines, the lingual cusp on the upper lateral incisor and the upper canine.

its root is also more flattened. On the labial surface of the crown, of both canines and premolars, a wide low vertical ridge (labial ridge) can generally be made out (Fig. 719); it is most distinct on the canine and first upper premolar.

**Premolar or Bicuspid Teeth** (dentes premolares, Figs. 719 and 720).—Eight in number, two in each jaw above and below, the premolar teeth are placed behind the canines, and in front of the molars as indicated by the term "premolar." The **crown** which, unlike that of the incisors and canines, is flattened from before backwards (proximo-distally), is characterised by the presence of two cusps (Fig. 721), hence the term bicuspid often applied to these teeth. One of the cusps, the larger, is placed on the outer or labial, the other on the inner or lingual side. The labial and lingual surfaces are both convex. The **root** is single, but it is, as a rule, flattened from before backwards (proximo-distally) and grooved, showing in this a tendency to division, which often actually takes place in the first upper premolar. The upper premolars are easily distinguished by the fact that their two cusps are large and are separated from one another by a distinct antero-posterior fissure (Fig. 721); whilst in the lower premolars, on the other hand, the separation between the two cusps is not effected by a continuous fissure as in the upper teeth, but by two dimple-like depressions separated by a ridge, which joins the two cusps (Fig. 722). In the upper premolars, therefore, the two cusps are separated by a fissure, in the lower they are united by a ridge.

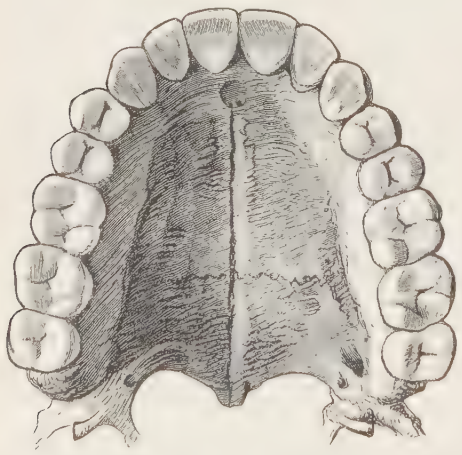

FIG. 721.—THE UPPER PERMANENT TEETH, viewed from below.

The cusps of the premolars and molars of the right side (left of picture) are particularly well shown. The ridge from the inner anterior (proximo-lingual) to the outer posterior (labio-distal) cusp is also distinct in the first and second molars. The second molars show four cusps, one of them small, although three only are frequently found.

The first upper premolar is often slightly larger than the second; the reverse is the case in the lower jaw. The outer or labial surface of the crown is usually somewhat larger than the

inner or lingual surface in all premolars. The upper are distinguished from the lower bicuspids, as pointed out above, by the fact that in the upper the two cusps are separated by a groove, in the lower they are united by a ridge; in the latter also the crowns are more circular (Figs. 715 and 722). It will further usually be found that the outer or labial surface of the crown is strongly sloped (bevelled) inwards, near the grinding surface, in the lower premolars. The first can usually be distinguished from the second by the fact, that, while the lingual cusp and surface are smaller than the labial in the first premolar, they are nearly of the same size in the second. In addition, the root of the first upper premolar is bifid or nearly so, and its labial ridge is fairly distinct, but is indistinct in the second. In the first lower premolar the lingual cusp and surface are very small, in fact the cusp is quite rudimentary. It should, however, be added that it is often extremely difficult to identify the various bicuspids. The differences may be expressed in tabular form thus:—

**Premolars.**

| | | Root. | Cusp and Surface. |
|---|---|---|---|
| **Upper** (have two cusps separated by a groove) | 1st premolar | bifid, or nearly so | Lingual smaller than labial. |
| | 2nd ,, | single | Lingual nearly as large as labial. |
| **Lower** (have two cusps united by a ridge) | 1st premolar | single | Lingual much smaller than labial. |
| | 2nd ,, | ,, | Lingual nearly as large as labial. |

**Molar Teeth** (dentes molares).—The molar teeth, also known as the **grinders** or **multicuspidati**, are twelve in number—three on each side above and below—and are distinguished as first, second, and third molars. The latter is also known as the wisdom tooth, owing to its late eruption. All the molars are characterised by the large size of the crown and the possession of three or more trihedral cusps on the masticating surface (Figs. 721 and 722). They are the largest of all the teeth, but they diminish in size from the first to the third, the last being, as a rule, the smallest of the three. In shape the crown is more or less quadrangular, with convex labial and lingual surfaces. The roots are either two or three in number, but frequently in the wisdom teeth they are united to a varying degree.

The molars of the upper and lower jaws differ so considerably in their further details that they must be considered separately. They may be most readily distinguished from one another by the fact that normally the **upper molars** possess three roots (Figs. 719 and 720), whilst the **lower molars** have two at most. The number of cusps, though not so reliable a guide as the form of the root, is also generally sufficient to distinguish them. In the upper molars there are either three or four cusps, whilst in the lower the number is most commonly five (see, however, page 1021).

In the **upper molars**, the **crown**, viewed from the grinding surface (Fig. 721), is rhomboidal in shape (*i.e.* quadrangular with the angles not right angles). The outer (labial) and the inner (lingual) surfaces are convex. The number of **cusps** is either four or three. On the *first* there are invariably four—two on the labial and two on the lingual side—the antero-internal (proximo-lingual) of these being connected with the postero-external (labio-distal) by an oblique ridge (Fig. 721), which is also found on the *second* and *third* molars when these bear four distinct cusps. The *second* upper molar has either four or three cusps in about an equal proportion of European skulls, whilst in the third the number is much more frequently three than four. The **roots** in the upper molars are three in number (except, occasionally, when the three roots of the wisdom tooth are confluent), two being external or labial, and the third internal or palatal (Figs. 719, 720, and 723).

In the **lower molars**, the **crown**, viewed from above (Fig. 722), is somewhat cubical. The outer and inner surfaces are convex, as in the upper molars. The *first*, as a rule, bears five cusps, two being on the outer side, two on the inner, and the fifth behind and external, that is, between the two posterior cusps and somewhat to the outer side. The *second* has usually only four cusps; a fifth, however, is sometimes present. The *third* has either four or five, the former number more frequently than the latter.

The **roots** of the lower molars are two in number, each wide, grooved, and

flattened from before backwards. One is placed anteriorly, the other posteriorly, and both are usually recurved in their lower portions (Fig. 719). As in the corre-

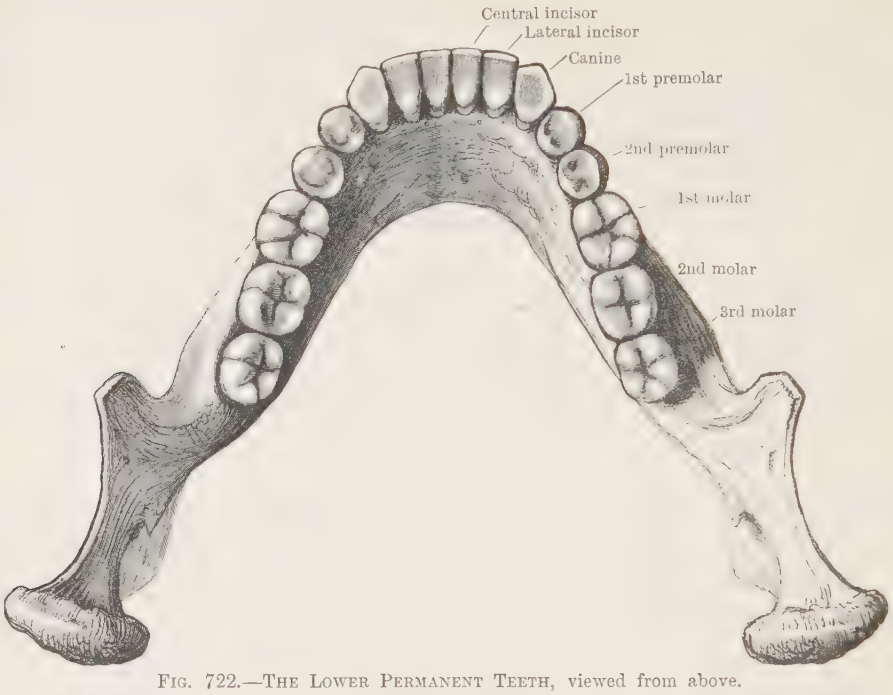

FIG. 722.—THE LOWER PERMANENT TEETH, viewed from above.

sponding teeth of the upper jaw, the roots of the lower wisdom teeth are often more or less united into a single mass.

The chief characters of the upper and lower molars may be summarised thus :—

**Molars.**

| | | 1st Upper. | 2nd Upper. | 3rd Upper. |
|---|---|---|---|---|
| Upper | Cusps . . | 4 | 3 or 4 | 3 or 4 |
| | Roots . . | 3 | 3 | 3 (or 1) |
| | | **1st Lower.** | **2nd Lower.** | **3rd Lower.** |
| Lower | Cusps . . | 5 | 4 or 5 | 4 or 5 |
| | Roots . . | 2 | 2 | 2 (or 1) |

The molars diminish in size from before backwards. This remark applies particularly to the wisdom teeth, which are extremely variable in form and position among civilised races. The long axis of the upper molars has a general direction downwards and outwards; whilst that of the lower molars, which the former partly overlap, slopes upwards and inwards, with the result that the outer cusps of the lower molars lie in the groove separating the inner from the outer cusps of the upper teeth (Fig. 706, p. 996). As a further result of this overlapping, the outer edge of the crown is sharp and the inner edge rounded in the upper molars; whilst the inner edge is sharp and the outer edge rounded in the lower set. The cause of this is obvious. The outer margins of the upper molars overlap their fellows on the buccal side, whilst the inner margins of the lower molars overlap their fellows on the lingual side; these margins, therefore, are subject to comparatively little attrition, and consequently remain sharp. The other margin of each tooth, on the other hand, strikes against the groove on the crown of the opposing tooth, and consequently becomes worn and round.

The fissures which separate the cusps on the grinding surfaces of the molar teeth are generally continued as faint grooves on the labial and lingual surfaces.

**Upper Molars.**—The crowns, as already stated, are rhomboidal in shape, and when viewing their grinding surfaces, as in Fig. 721, if the planes of separation between them be prolonged, they would strike the middle line near the back part of the hard palate; in other words, their

proximal and distal surfaces are not in transverse but in oblique planes, sloping strongly backwards and inwards, and converging somewhat internally. A knowledge of this is useful in determining the side to which an upper molar belongs, as is the fact that the anterior labial root is broader than the posterior (Fig. 723).

As regards the *number of cusps* (Fig. 721):—The first upper molar has four cusps in practically all skulls (99 per cent); occasionally, indeed, another, but very rudimentary, cusp is present on the lingual side of the antero-internal (proximo-lingual) cusp. The second molar has either three or four in an almost equal proportion of Europeans, but more frequently four taking the teeth of all nations together. (According to Topinard, four cusps are present in 66 per cent of all races, and in 58 per cent of European, Semitic, and Egyptian skulls; according to Zuckerkandl, in 73·5 per cent of the lower races and 45·6 per cent of Europeans.) The third upper molar has three cusps much more frequently than four amongst Europeans (four cusps only in 36 per cent, although it has four cusps more frequently in certain lower races). It should be remarked that, while there are practically always four cusps in the first molar, still there is a tendency to the disappearance of the postero-internal (disto-lingual) cusp, which tendency grows more pronounced as we pass backwards to the second and third molars. The other cusps are practically constant.

The three **roots** of the upper molars (Figs. 719, 720, and 723) are a large inner or palatal, sub-cylindrical in shape, and two external or labial roots, smaller and flattened from before backwards. The palatal fang, which is placed opposite the posterior labial root, is often united to one of the others. The lower part of the antrum of Highmore generally extends down between the palatal and the two labial fangs (Fig. 706, p. 996), but the latter project on its floor more frequently than the palatal root. In the wisdom tooth the three roots are frequently more or less united into a single conical process (Fig. 723).

**Lower Molars.**—The **crowns** are more massive than those of the upper molars, and are elongated antero-posteriorly (Fig. 722). A crucial groove separates the four chief cusps from one another; this bifurcates behind to enclose the fifth cusp, which lies slightly to the outer side of the middle of the tooth. The *number of cusps* present in the lower molars is as follows:—The first has usually five cusps (62 per cent of all races, 61 per cent of Europeans); the second has four cusps, as a rule (five cusps in only 24 per cent of all skulls); the lower wisdom tooth has four cusps a little more frequently than five (five in 46 per cent of all skulls), but like the upper wisdom tooth it is extremely variable.

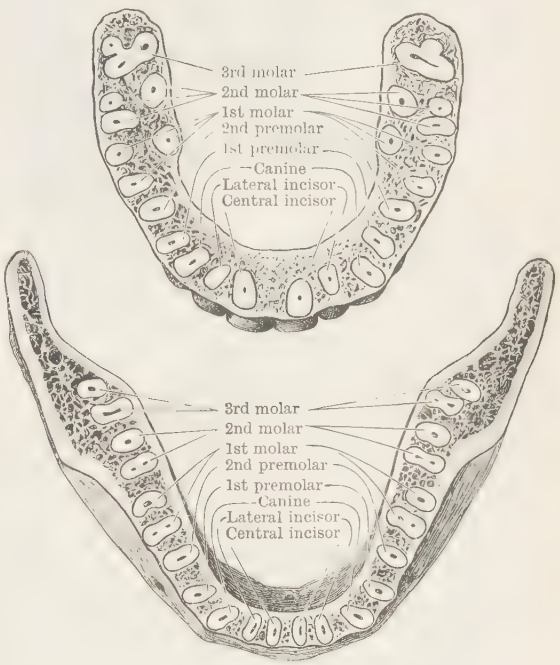

Fig. 723.—Horizontal Sections through both the Upper and Lower Jaws to show the roots of the teeth. The sections were carried through the bones a short distance from the edge of their alveolar borders. The upper figure shows the upper teeth, the lower figure the lower teeth. Note the flattened roots of the lower incisors, the two root canals in the anterior root of each lower molar, and the confluence of the three roots of the upper wisdom teeth.

The **roots** of the lower molars (Fig. 719), two in number, are flattened from before backwards, and very wide. The anterior of these has two root canals; the posterior but one (Fig. 723). The wisdom tooth has commonly two roots like its fellows; occasionally the two are united. In determining the side to which a lower molar belongs, it should be remembered that the lower part of the root is generally curved backwards, and also that the blunter margin of the crown (see above) and the fifth cusp, if present, are on the outer side.

**Arrangement of the Teeth in the Jaws.**—The teeth are arranged in each jaw in a curved row—the **dental arch** (arcus dentalis)—of approximately a semi-oval form (Figs. 721 and 722). The curve formed by the upper teeth, however, is wider than that formed by the lower set, so that when the two are brought in contact the upper incisors and canines overlap their fellows in front, and the outer cusps of the upper premolars and molars overlap the corresponding cusps of the lower teeth (Fig. 706, p. 996). It will also be seen that, as a rule, the teeth in one jaw are not placed exactly opposite their fellows, but rather opposite the interval between two teeth, in the other jaw (Fig. 724). This arrangement is brought about largely by the great width of the upper central incisors as compared with

their fellows of the lower jaw, which throws the upper canines and the succeeding teeth into a position behind (distal to) that of the same named teeth of the lower set. But as the lower molars are larger in their antero-posterior diameter than those of the upper row—and this remark applies particularly to the wisdom teeth—the two dental arches terminate behind at approximately the same point.

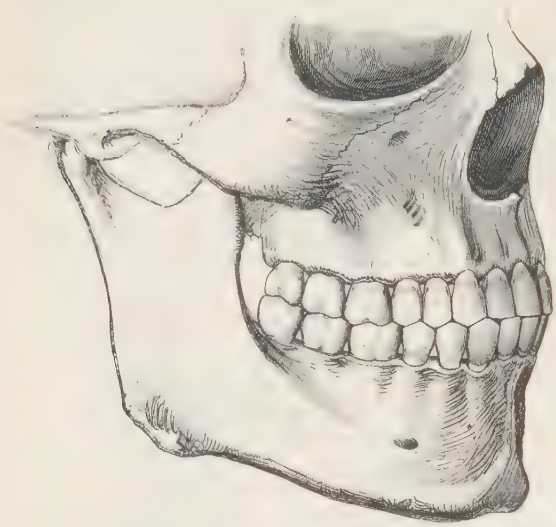

Fig. 724.—To show the relation of the upper to the lower teeth when the mouth is closed. The manner in which a tooth of one row usually strikes against two teeth of the opposite row, and the resulting interlocking of the teeth, is to be noted.

The upper dental arch is said to form an **elliptical**, the lower a **parabolic curve** (Figs. 721 and 722). The line formed by the grinding surfaces of the upper teeth, as seen on profile view (Fig. 724), is usually somewhat convex, owing largely to the failure of the wisdom tooth to descend into line with the others. Similarly the line of the lower teeth is as a rule concave.

In both jaws the crowns of the front teeth are higher (longer) than those of the molars.

**Period of Eruption of the Permanent Teeth.**—Although there is considerable variety in the *dates* at which the various permanent teeth appear above the gums, the *order* of eruption is practically constant in different individuals, and is as follows:—Before any of the temporary teeth are lost the first permanent molars appear behind the 2nd milk molars. Next the central milk incisors fall out, and their places are taken by the permanent teeth of the same name; then follow the remaining teeth in the following order: Lateral incisors, 1st premolars, 2nd premolars, canines, 2nd molars, and 3rd molars. It will be observed that the eruption of the canine is delayed until the two premolars, which succeed it in the row, are cut, so that it breaks the otherwise regular order of eruption. The 1st molar is sometimes popularly known, owing to the date of its eruption, as the "six-year-old tooth," and the 2nd molar as "the twelve-year-old tooth."

The dates at which the eruption usually takes place may be simply stated as follows for the lower teeth; those of the upper jaw appear a little later:—

| | | | | |
|---|---|---|---|---|
| 1st molars appear | soon after the | | 6th | year. |
| Central incisors appear | soon after the | | 7th | year. |
| Lateral ,, | ,, | ,, | 8th | ,, |
| 1st premolar | ,, | ,, | 9th | ,, |
| 2nd ,, | ,, | ,, | 10th | ,, |
| Canine ,, | ,, | ,, | 11th | ,, |
| 2nd molar | ,, | ,, | 12th | ,, |
| 3rd ,, | ,, | from the | 17th | ,, to |

**Variations in the Number of the Teeth.**—The presence of an additional tooth is by no means uncommon. It may appear in connexion with the incisor, premolar, or the molar groups. Windle very properly draws a distinction between "supernumerary" or imperfect additions to the dentition and "supplemental" teeth which correspond in size with those with which they are associated. When a supplemental incisor appears it has an interesting bearing upon the solution of the much-debated point as to which incisor has disappeared from the primate dentition. The addition of a third premolar may be looked upon as a reversion to the condition present in the New World Apes and the Lemurs. The presence of a fourth molar has not infrequently been observed, and recently it has formed the subject of an instructive and suggestive paper by J. T. Wilson (*Journ. Anat. and Phys.*, vol. xxxix. part ii.).

## The Milk Teeth.

The **deciduous, temporary**, or **milk teeth** (dentes decidui) are twenty in number, ten above and ten below, or five in each half of each jaw—namely, two incisors, one

canine, and two molars. They may be distinguished from the permanent teeth by their smaller size, their well-marked and constricted necks, and, in the case of the molars, by the wide divergence of their roots (Fig. 725). Otherwise they correspond so closely to the same named teeth of the permanent set, that they require no separate description, except in the case of the molars. The first upper molar has but three cusps on its crown—two external and one internal; the first lower molar has four—two external and two internal, and the crowns of both are flattened from side to side. The second molars of the upper jaw have four, those of the lower jaw five cusps each. In every case the second are much larger than the first molars. The cusps are sharper and are separated by deeper fissures or fossæ than those of the permanent teeth, whilst the roots of the milk molars, except for their greater divergence, agree with those of the permanent set.

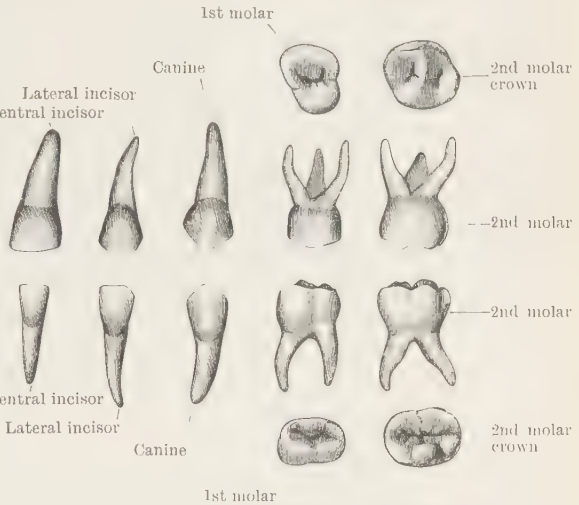

FIG. 725.—THE MILK TEETH OF THE LEFT SIDE.

The masticating surfaces of the two upper molars are shown above. In the second row the upper teeth are viewed from the outer or labial side. In the third row the lower teeth are shown in a similar manner; and below are the masticating surfaces of the two lower molars. In the specimen from which the first upper molar was drawn the two outer or buccal cusps were not distinctly separated, as is often the case.

The marked constriction at the neck of the milk teeth (Fig. 725) is due to a great thickening of the cap of enamel on the crown, and its abrupt termination as the neck is reached. The enamel, too, is much whiter as a rule than in the permanent teeth. It should be added that the labial surface of the canines and molars departs very markedly from the vertical; it slopes strongly inwards towards the mouth cavity as it approaches the grinding surface of the crown, which latter is, as a result, much reduced in width.

The divergence of the fangs in the milk molars allows the crowns of the permanent premolars to fit in between them before the milk molars are shed.

## STRUCTURE OF THE TEETH.

As mentioned above, the teeth are composed of three special tissues, enamel, dentine, and crusta petrosa, in addition to the pulp which occupies the tooth cavity. The chief mass of the tooth is formed of dentine, which surrounds the pulp cavity and extends from crown to root; outside this is a covering of enamel on the crown, and a layer of crusta petrosa or cement on the root.

The **enamel** (substantia adamantina) is the dense, white, glistening layer which forms a cap, thickest over the cusps, for the portion of each tooth projecting above the gum (Fig. 718). At the neck it ceases gradually, being here slightly overlapped by the crusta petrosa.

It is composed chiefly of phosphate and carbonate of lime (phosphate of calcium 89·82 per cent, carbonate of calcium 4·37 per cent, magnesium phosphate 1·34 per cent, a trace of calcium fluoride, other salts ·88 per cent), and has generally been considered to contain about 3·6 per cent of organic substance; but this Tomes has recently shown to be inaccurate: "That which has heretofore been set down as organic matter is simply water combined with the lime salts. Enamel is to be regarded as an inorganic substance composed of lime salts, which have been deposited in particular patterns and formed under the influence of organic tissues, which have themselves disappeared during its formation."

Enamel consists of calcified microscopic prisms (prismata adamantina), radiating from the surface of the dentine, on which their inner ends lie, to the surface of the crown, on which they terminate by free ends. These prisms are hexagonal in shape, solid, and of considerable length, for most of them reach from the dentine to the surface of the crown without interruption. The prisms, which are calcified themselves, are held together by the smallest possible amount of calcified matrix (Tomes). In old teeth the cap of enamel is

often worn away over the cusps, the dentine is then exposed, and is easily recognised by its yellowish colour, which contrasts strongly with the whiteness of the enamel.

Whilst adjacent enamel prisms are in general parallel to one another, they do not usually take a straight, but rather a wavy course, and in alternate layers they are often inclined in opposite directions, thus giving rise to certain radial striations seen by reflected light (Schreger's lines). Certain other pigmented lines, more or less parallel to the surface, are also seen in the enamel (brown striæ of Retzius). They are due to true pigmentation (Williams), and mark the lines of deposit of the enamel during its development. The enamel prisms are more or less tubular in certain animals—viz. in all marsupials except the wombat, in the hyrax, certain insectivora, and certain rodents.

**Nasmyth's membrane** (enamel cuticle) is an extremely thin ($\frac{1}{20000}$ of an inch) cuticular layer which covers the enamel of recently-cut teeth, and is very indestructible, resisting almost all reagents. Two chief views are held as to its origin. One that it is the last formed layer of enamel, which has not yet been calcified, and therefore the final product of the enamel cells. The other that it is produced by the outer layer of cells of the enamel organ. This latter seems to be the more probable view.

**Dentine** (substantia eburnea) is the hard and highly elastic substance, yellowish white in colour, which forms the greater part of the mass of every tooth (Fig. 726). Like the enamel it is highly calcified, but it differs from enamel in containing a very considerable amount of organic matter and water incorporated with its salts, which are chiefly phosphate and carbonate of lime.

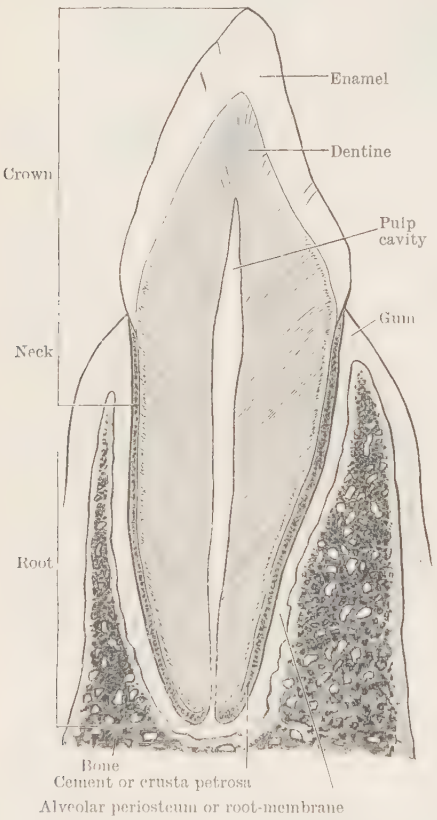

Fig. 726.—Vertical Section of Canine Tooth, to illustrate its various parts, and its structure.

Fresh human dentine contains 10 per cent of water, 28 per cent of organic and 62 per cent of inorganic material. The organic matter is composed chiefly of collagen, and to a less extent of elastin. The organic matter consists of (1) calcium phosphate (with a trace of fluoride), (2) calcium carbonate, and (3) magnesium phosphate, the percentages present in dried dentine being 66·72, 3·36, 1·08 respectively.

Dentine consists of a highly calcified organic matrix, which is itself practically structureless, although everywhere traversed by tubes—the **dentinal tubes**—which give to this tissue a finely striated appearance, the striæ usually running in wavy lines. The dentinal tubes begin by open mouths on the wall of the pulp cavity, whence they run an undulating, and at the same time a somewhat spiral course, towards the periphery of the dentine. They give off fine anastomosing branches, and occasionally divide into two. Somewhat reduced in size, they usually end in the outer part of the dentine.

The tubules are generally described as being lined by special sheaths (dentinal sheaths of Neumann) which are composed of a most resistant material, and possibly are calcified. It should be mentioned that the presence of these sheaths as separate structures is doubted by some authorities, who hold that the part described as the sheath is only a modified portion of the dentinal matrix surrounding the tubules.

The dentinal tubules are occupied by processes, prolonged from the outermost cells of the pulp—the odontoblasts. These processes are called after their discoverer, **Tomes' fibrils** (dentinal fibrils), and they are probably sensory in function.

The concentric **lines of Schreger**, frequently seen in the dentine, are due to bends in successive dentinal tubes taking place along regular lines parallel to the periphery of the dentine. Other lines (the incremental lines of Salter), due to imperfect calcification, are found arching across the substance of the dentine, chiefly in the crown. There must also be mentioned the **interglobular spaces**, intervals left in the dentine, as a result of imperfect calcification, bounded by the fully calcified surrounding dentine, the contour of which is in the form of a number of small projecting

globules of dentine. These interglobular spaces are very numerous in the outer or "granular layer" of the dentine, particularly beneath the cementum (see Fig. 726).

The **crusta petrosa** or **cementum** (substantia ossea) is a layer of modified bone which encases the whole of the tooth except its crown. It begins as a very thin stratum, slightly overlapping the enamel at the neck. From this it is continued, increasing in amount, towards the apex, which latter is formed entirely of this substance. It is relatively less in amount in the child, and increases during life. In places the dentine seems to pass imperceptibly into the crusta petrosa (the "granular layer" of dentine marking the junction of the two, see Fig. 726), and some of the dentinal tubes are continuous with the lacunæ of the cementum. Like true bone, it is laminated, it possesses lacunæ, canaliculi, and, when in large masses, it may even contain a few Haversian canals.

The **tooth pulp** occupies the pulp cavity and the root canals of the teeth. It is composed of a number of branched connective tissue cells, the anastomosing processes of which form a fine connective tissue network, containing in its meshes a jelly-like material, in addition to numerous vessels and nerves, but no lymphatics. The most superficial of these cells form in the young tooth a continuous layer of columnar, epithelium-like cells, lying on the surface of the pulp against the dentine; they are known as **odontoblasts**, for they are the active agents in the formation of dentine. From the outer ends of the odontoblasts processes are continued into the dentinal tubes, where they have been already referred to as Tomes' fibrils. The vessels of the pulp are numerous, and form a capillary plexus immediately within the odontoblasts. The nerves form rich plexuses throughout the pulp, but their exact mode of ending is unknown.

The **alveolar periosteum** (alveolo-dental periosteum or root-membrane) is a layer of connective tissue free from elastic fibres, but well supplied both with blood-vessels and nerves, which fixes the root of the tooth in the alveolus, being firmly united by perforating fibres of Sharpey, to the crusta petrosa on the one hand, and to the bone of the alveolus on the other. It establishes a communication between the bone of the jaw and the cementum, and above it is continuous with the tissue of the gum. Its blood comes chiefly from the arteries, which subsequently enter the apical canals for the supply of the pulp, but in part also from the vessels of the bone and those of the gum (hence the relief obtained in dental periostitis by lancing the gum).

## Development of the Teeth.

At the beginning of this chapter a tooth was described as a calcified papilla of the mucous membrane, composed of two chief parts—namely, the enamel formed by the epithelial layer, and the dentine by the connective tissue layer of the mucous membrane. The details of the process by which such a tooth is developed from the two layers of the mucous membrane are both numerous and intricate, and can be but briefly described here.

In lower vertebrates (sharks, rays, etc.), teeth which correspond essentially, both in structure and development, to those of mammals, are found on the surface of the body, and are known as **dermal teeth**. The following outline of the development of the dermal tooth of a shark may assist in rendering the development of the human teeth more intelligible:—

First, a **papilla** is formed from the corium or connective tissue layer of the skin (Fig. 727, B), which papilla is covered over by the epithelial layer.

Next the superficial (connective tissue) cells of the papilla begin to form a layer of **dentine** on the surface of the papilla (Fig. 727, C), which it soon encases, the remains of the papilla persisting in the interior as the future **pulp**. At the same time the deepest cells of the epithelium deposit a layer of **enamel**, outside the dentine, over the summit of the papilla (Fig. 727, C), and subsequently the two—enamel and dentine—become inseparably united, thus giving rise to the substance of the tooth.

A, Section of skin showing epithelium *c*, basement membrane *b*, and connective tissue layer *c*.

B shows the papilla of the connective tissue layer growing up covered by the epithelial layer.

In C the superficial cells of the papilla *z* begin to deposit dentine *d* over the papilla, and at the same time the deepest cells of the epithelium deposit enamel *a*.

D shows the tooth breaking through the epithelium and reaching the surface.

Fig. 727.—Diagram to illustrate the Development of a Dermal Tooth in the Shark.

In all figures—*a*, enamel; *b*, basement membrane; *c*, connective tissue layer of skin; *d*, dentine; *e*, epithelium; and *z*, superficial cells of papilla.

At a later period the epithelium covering the summit disappears and the tooth comes to the surface; this constitutes its **eruption** (Fig. 727, D).

In the case of the mammalian tooth a similar process takes place, not, however, on the surface, but deep down in the substance of the gum, into which a downgrowth of epithelium has previously taken place. This epithelial downgrowth spreads out in the substance of the jaw, and into it the papilla grows up, and goes through the other changes described above, as if the whole process took place on the surface.

**Development of Human Teeth.** The following is a brief summary of the chief events in the development of a human tooth. For convenience in expression and terms, the description refers to the development of a lower tooth. The upper teeth are of course developed in a manner exactly similar.

I. Shows the downgrowth of the dental lamina D.L from the surface epithelium E and the beginning of the enamel germ E.G.

II. Shows the further growth of the enamel germ and its invagination.

III. The enamel germ is more invaginated, and its inner layer of cells becomes columnar. A, the dental lamina, grows thinner, but near its posterior or lingual edge there is an enlargement R.G which is the reserve germ for a permanent tooth. The superficial cells of the dentine papilla P are becoming columnar.

IV. The inner columnar cells of the enamel germ (called enamel cells) A have formed a cap of enamel En, inside which the superficial cells of the papilla, the odontoblasts O, have formed a layer of dentine D.

V. Shows a more advanced stage still. The deposit of dentine is extending downwards, and enclosing the papilla to form the future pulp, in which a vessel V is seen.

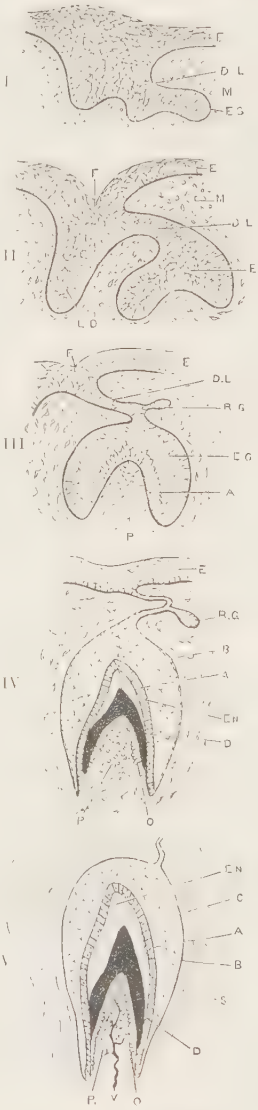

Fig. 728.—Diagram to illustrate Development of a Tooth.

A, Inner layer of enamel germ; B, Outer layer; C, Remains of intermediate cells; D, Dentine; D.L, Dental lamina; E, Epithelium; E.G, Enamel germ; En, Enamel; F, Dental furrow; L.D, Labio-dental furrow; M, Connective tissue cells; O, Odontoblasts; P, Dentine papilla; R.G, Reserve germ; V, Blood-vessel.

1. The first distinct evidence of the development of the teeth is to be found in a thickening of the mouth epithelium, at the site of the future gum, and a resulting downgrowth of its deeper portion into the substance of the primitive jaw (Fig. 728, I.). This epithelial downgrowth is continued along the whole length of the gum, and is known as the **dental lamina** or **tooth-band** (Zahnleiste). On the under surface of the dental lamina there soon appears a series of knob-like projections—one for each of the milk teeth (Fig. 728, II.)—which are known as **enamel germs** or **enamel organs**. These enamel organs are connected with the epithelium of the dental lamina by a constricted part, and although at first knob-like, they soon become bell-shaped owing to the invagination of the lower surface of the knobs, so that each may now be compared to an inverted egg-cup.

2. As soon as the enamel organs begin to assume a cup-like shape, the cellular connective tissue of the jaw beneath grows up and projects into the cavity of the cup (Fig. 728, III.) in the form of a papilla—the **dentine papilla** (papilla dentis). The arrangement, pursuing our simile, may now be compared to an egg fitting into its cup—the dentine papilla representing the egg, and the enamel organ the cup (Fig. 728, III.).

3. The two layers of cells which are thus brought in contact, namely, the epithelial cells lining the concavity of the enamel organ, and the superficial cells of the dentine papilla, become elongated or columnar, and undergo other changes, preliminary to the production of the enamel by the former—which are now called **enamel cells** or **ameloblasts**—and the dentine by the latter, which are known as **odontoblasts**.

4. The **odontoblasts**, that is the layer of columnar-shaped connective tissue cells lying on the surface of the dentine papilla, begin to form at their outer ends a layer of **dentine** (Fig. 728, IV.). Similarly, the enamel cells lining the cup begin to form at their inner surface a layer of **enamel** on the top of the layer of dentine (Fig. 728, IV.), to which it adheres: in each case the deposit taking place first at the summit of the tooth.

5. The formation of dentine and enamel proceeds apace, the dentine increasing at the expense of the papilla, the enamel similarly encroaching on the cup or enamel organ;

and in each case the two layers of cells—odontoblasts and enamel cells—which produced the deposits, retiring gradually from one another, as the space between them becomes occupied by the newly-formed dentine and enamel respectively (Fig. 728, V.).

The remains of the dentine papilla persist as the **pulp** of the tooth, which is covered even in the adult by the odontoblasts, and occupies the **pulp cavity**, *i.e.* the central part of the tooth to which the dentine formation has not extended.

6. Turning now to the jaw itself: The connective tissue of the gum surrounding the **tooth germ** (as the developing tooth with its enamel organ and dentine papilla are called) early becomes condensed and vascular (Fig. 728, V.), and later on forms a membranous bag—the **tooth-sac** or **follicle**—which completely shuts off the developing tooth from the surrounding structures. On the floor of this sac the tooth germ sits, the base of its dentine papilla being continuous with the tissue of the floor of the sac, and the young tooth being enclosed by the sac, as a kernel is enclosed by its shell.

7. Reverting to the tooth: When the crown is completed the deposit of dentine, but not of enamel, is continued downwards to form the **root**. This latter is composed chiefly of dentine continuous above with that of the crown, and like it formed by the odontoblasts of the dentine papilla. As the dentine is deposited, and the root is being built up, the connective tissue of the tooth-sac comes to surround the root more closely, and deposits on its surface, after the manner of a periosteum, a layer of bone, the **cementum** or **crusta petrosa**. The cementum having been formed, the connective tissue of the sac then persists as the **alveolar periosteum**. The development of the root takes place very slowly, and its lower end is not completed as a rule for some time after the eruption of the tooth has taken place.

8. During the development of the teeth the ossification of the jaw has been going on, and as it grows up on each side, the young teeth, enclosed in their tooth-sacs, come to lie in an open bony groove, which is subsequently divided by septa into compartments—the **alveoli**—for the individual tooth-sacs. The bone continuing to grow after birth, these compartments become more perfect, but are never entirely closed in over the crowns of the teeth. During the eruption of the teeth the upper and anterior part of these bony cells is absorbed; subsequently, however, it is reformed around each tooth when it has taken its final position.

9. **Eruption.**—Long before the root is completed, the crown, by some force which is not properly understood, but which does not seem to depend on additions to the root, is pushed through the top of the tooth sac, and—the upper and anterior wall of the roomy alveolus having been absorbed at the same time—onwards through the gum until the mouth is reached. Later on, when the tooth has assumed its final position, the alveolus, as already stated, is re-formed, and closely embraces the completed root.

10. After the enamel organs of the milk teeth have been formed on the inferior aspect of the dental lamina, as described above, the neck of epithelium by which the lamina is still connected with the surface becomes broken up into a cribriform sheet. Its free posterior border, on the other hand, continues to grow backwards in the tissue of the gum towards the cavity of the mouth (Fig. 728, III. and IV.), and at a later date there appear on its under surface, near the free edge, and behind the several developing milk teeth, the enamel organs—or so-called "reserve germs"—for the corresponding **permanent teeth**, which are developed from these in exactly the same manner as the milk teeth described above.

In connexion with the development of the **permanent molars**, which have no corresponding teeth in the milk set, there takes place a prolongation backwards of the posterior extremity of the dental lamina into the tissue of the jaw, behind the last milk molar. On the inferior aspect of this prolongation, which has no direct connexion with the surface epithelium, enamel organs are formed for the permanent molars, and their further development goes on in the manner described for the other teeth.

The *dates* at which some of the chief events in the development of the teeth occur may be briefly given:—The thickening of the epithelium, the first sign of the future teeth, begins about the sixth week of fœtal life, and the dental lamina is completed by the end of the seventh week.

The dentine papillæ for the eight front teeth appear and become surrounded by their enamel organs about the tenth week, and the papilla for the first permanent molar about the seventeenth week.

The first traces of calcification, and the formation of the tooth-sacs, take place about the fifth month of fœtal life.

**Eruption of Deciduous Teeth.**—The period at which the eruption of the milk teeth takes place is extremely variable, and no two observers seem to agree upon the question.

The following, according to Tomes, may be taken as representing the average. The lower central incisors appear first, usually between the sixth and ninth months; then follows a rest of a few months. Next come the four upper incisors, followed by a rest of a few months. Then the lower lateral incisors and the four first molars erupt, succeeded by a rest of a few months. Next appear the canines, and finally the four second molars, which are all cut by the end of the second year.

The following statement is simple, and perhaps is sufficient for all ordinary purposes. The temporary teeth usually appear in the following order:—Central incisors, lateral incisors, first molars, canines and second molars; the eruption commences between the sixth and the ninth month, and is usually completed by the twenty-fourth—the lower teeth, as a rule, preceding the upper.

**Formation of Enamel and Dentine.**—Different opinions are held as to the method in which the **enamel** is produced by the enamel cells. One view maintains that it is secreted and shed out by the enamel cells (Kölliker). According to the other view, part of the substance of the cells is actually converted or transformed into enamel (Tomes). In connexion with this latter view, which seems to receive more support at present, Tomes has discovered that there projects from the base of each enamel cell, towards or into the most recently formed enamel, a fibrillar process, which has received the name of **Tomes' process**, and he holds that the enamel is formed by calcification taking place in or around the process.

Similarly, two views are held as to the production of **dentine** by the odontoblasts; one, that the odontoblasts secrete the matrix of the dentine, and the other, that their substance is actually converted into the matrix. The odontoblasts, when active, are branched columnar-shaped cells, and from their outer ends one or more processes extend towards and into the dentine; between these processes a matrix appears—produced probably by the odontoblasts—and soon this matrix becomes calcified. In this way the dentine is formed, and the process is repeated until its full thickness is attained. The branches of the odontoblasts, encased in dentine, just mentioned, are the Tomes' fibrils already described; the canals in which they lie are the dentinal tubes; and the fibrils themselves are concerned in the production of the sheaths of Neumann which line the tubes.

The **tooth-sacs**, when fully developed, are large and distinct fibrous bags which lie in the alveoli of the maxilla and mandible, and are continuous above with the tissue of the gum. On the lingual side of the sacs of the milk teeth are found the germs of the permanent teeth, surrounded by their own sacs. These latter are at first very small, and are partly embedded in the posterior wall of the temporary tooth-sacs, but subsequently they come to lie in distinct but incomplete bony cavities of their own. The bone surrounding the tooth-sacs, temporary and permanent, is always wanting over the summit of the sac, and the band of connective tissue by which the sac is connected with the overlying gum tissue, through the deficiency, is known as the **gubernaculum dentis**.

These points are easily demonstrated on the lower jaw of a child at birth, particularly when the tissues have been allowed to soften a little. If, in such a specimen, the gum and periosteum be reflected upwards from the outer and inner surfaces of the mandible, and freed as far as the upper border of the jaw, the gum, with the tooth-sacs depending from it like small bags, can be pulled away out of the bony groove of the jaw; and if the operation has been successfully performed, the tooth-sacs of the three front permanent teeth may be seen, varying in size from a small pin's-head to a hemp-seed, hanging down behind the upper part of the corresponding temporary sacs. As already explained, the tooth-sacs are produced simply by a condensation of the connective tissue around the developing tooth, the condensation going on to the formation of a distinct membranous bag.

**Formation of Alveoli and Eruption.** At first the developing teeth lie in an open bony groove or channel between the outer and inner plates of the young jaw. This groove is subsequently divided up into separate compartments for the sacs of each of the temporary teeth. As development proceeds these compartments or alveoli surround the sacs more completely, but never actually close over the summit. When the eruption of the temporary teeth is about to take place, the anterior wall and roof of the alveolus are absorbed; the tooth passes through the sac and appears above the gum, and then the alveolus, which up to this was much too large to give actual support, is re-formed more closely around the tooth. Meanwhile the root, which was only partly formed at the time of the eruption, continues to be added to, possibly for a few years more, and, as it grows, the alveolus is completed around it. When the permanent tooth, or as much of it as is then formed, is about to be erupted, it makes its way from its own bony cell through the posterior wall of the alveolus of its temporary predecessor; the root of the temporary tooth undergoes absorption at the same time, but quite independently of pressure from the permanent tooth. The alveolus, now occupied by both teeth, is again much enlarged by absorption, particularly in front; what remains of the temporary tooth is shed; the

permanent tooth passes onwards through the enlarged alveolus, and, making its way to the surface, appears above the gum. After some time, when the tooth has taken its final position, the alveolus is again re-formed, first around its neck, and later on, as the root is built up, around it also, and thus the tooth is permanently fixed.

What the force is which causes the eruption, is a question that has not been answered satisfactorily. That the growth of the root pushes up the crown was formerly the favourite explanation. For several reasons, unnecessary to detail, this view is now discarded, and a theory which attributes the impelling force to the blood pressure is looked upon with more favour, although even this is not altogether satisfactory. (See Tomes' *Dental Anatomy*, 5th Edition, page 211.)

### Morphology of the Teeth.

In most vertebrates below mammals all the teeth are alike in form ; such a dentition is said to be **homodont**. In the majority of mammals, on the other hand, the teeth are arranged in groups of different size and form ; such a dentition is **heterodont**.

Again, mammals have, neglecting exceptional cases, but two functional sets of teeth ; they are consequently said to be **diphyodont**. Most vertebrates below mammals, on the other hand, have a continuous succession of teeth throughout life, and hence are said to be **polyphyodont**.

Seeing that practically all lower vertebrates are provided with simple conical teeth, the evolution of the many-cusped mammalian molar has given rise to much speculation. The jaws of the earliest fossil mammals found are furnished with tri-tubercular teeth, the three tubercles being placed in an antero-posterior line ; by a rotation of two of the cusps out or in, as the case may be (a condition found in certain other fossil skulls), we arrive at a tri-tubercular form, from which the transition to an ordinary mammalian molar is not difficult. As to how the tri-tubercular tooth arose from the simple cone, two different views are advanced : one, that it was formed by the union of several conical teeth as a result of the shortening of the jaw and the crowding of the teeth together ; the other, that the single conical tooth developed on its crown two subsidiary cusps, one in front and the other behind, and that these cusps growing larger, the tooth assumed the tri-tubercular form.

The complete or **typical mammalian dentition**, in its highest development, as in the horse, is represented by the following formula : $\frac{3}{3}$, $\frac{3}{3}$, c. $\frac{1}{1}$, pm. $\frac{4}{4}$, m. $\frac{3}{3}=44$. In the dentition of man, therefore, one incisor and two premolars are wanting. Different views are held as to which teeth have been suppressed—most probably they are the second incisors, and the first and second or first and last premolars.

In general it may be said that the **dentition of the lower races** differs from that of the higher, in that the dental arches are squarer in front, the teeth larger and more regular, the canines stronger, the wisdom teeth better developed, and the cusps on the molars more perfect, in the lower than in the more civilised races. It may be mentioned, however, that the teeth of a savage man, if seen in the mouth of a European, would be looked upon as an "exceedingly perfectly-formed set of teeth" (Tomes).

To express the proportionate size of the crowns of the premolars and molars to that of the skull in different races, Flower compared the distance from the front of the first premolar to the back of the last molar, *in situ*, with the distance from the front of the foramen magnum to the naso-frontal suture (basi-nasal length), in the form of a "dental index"—

$$\text{Thus : } \frac{\text{Length of teeth} \times 100}{\text{Basi-nasal length}} = \text{Dental index,}$$

and by this means he has divided the various races into **microdont** (index 42 to 43, Europeans, Egyptians, etc.), **mesodont** (index 43 to 44, Chinese, American Indians, Negroes, etc.), and **macrodont** (index 44 and upwards, Australians, Melanesians, etc.).

## THE PHARYNX.

The **pharynx** is the expanded upper portion of the digestive tube which lies behind, and communicates with, the mouth, the larynx, and the nasal cavities (Fig. 729). It serves for the passage of both air and food, conveying the former to the larynx and the latter to the œsophagus.

It extends from the base of the skull above to the level of the sixth cervical vertebra below (Fig. 730), where, opposite the lower border of the cricoid cartilage, it passes into the œsophagus; its total length varies from 5 to $5\frac{1}{2}$ inches (12·5 to 14·0 cm.).

When in its natural state within the body, the pharynx is expanded laterally and compressed in the opposite direction, so that its anterior and posterior walls approach one another, and its sides are reduced to little more than mere borders. Although its cavity is much reduced by this approximation of the anterior and posterior walls, there is always left, above the orifice of the larynx, a sufficient

space for the entrance of air to the lungs. Below the laryngeal orifice, on the other hand, the anterior and posterior walls are in contact, and the cavity, except during the passage of food, is reduced to a transverse slit (Fig. 730).

As usually seen in the dissecting-room, when distended for dissection, the pharynx is of an elongated oval form, tapering rapidly below. This form, however, is due entirely to the artificial conditions under which it is placed.

Taken as a whole, the pharynx is a tube, the anterior wall of which is wanting. The place of this wall is occupied by the nasal, oral, and laryngeal cavities, as well as by the base of the tongue; and to the lateral boundaries of all these parts the sides of the tube are connected. In this way it comes to be attached from above downwards to the following more or less fixed points:—(1) The Eustachian tube and internal pterygoid plate; (2) the pterygo-maxillary ligament, the posterior end of the mylohyoid ridge on the inner aspect of the lower jaw, and the mucous membrane of the mouth; (3) the base of the tongue and the hyoid bone; and (4) the thyroid and cricoid cartilages of the larynx. Above, it is firmly fixed by its aponeurosis to the periosteum of the basi-occipital and petrous portion of the temporal bones; and in addition the raphe of the constrictors is attached to the pharyngeal tubercle of the occipital bone. Below it becomes continuous with the œsophagus. Behind and at the sides, the pharynx is connected merely by loose areolar tissue to the surrounding parts.

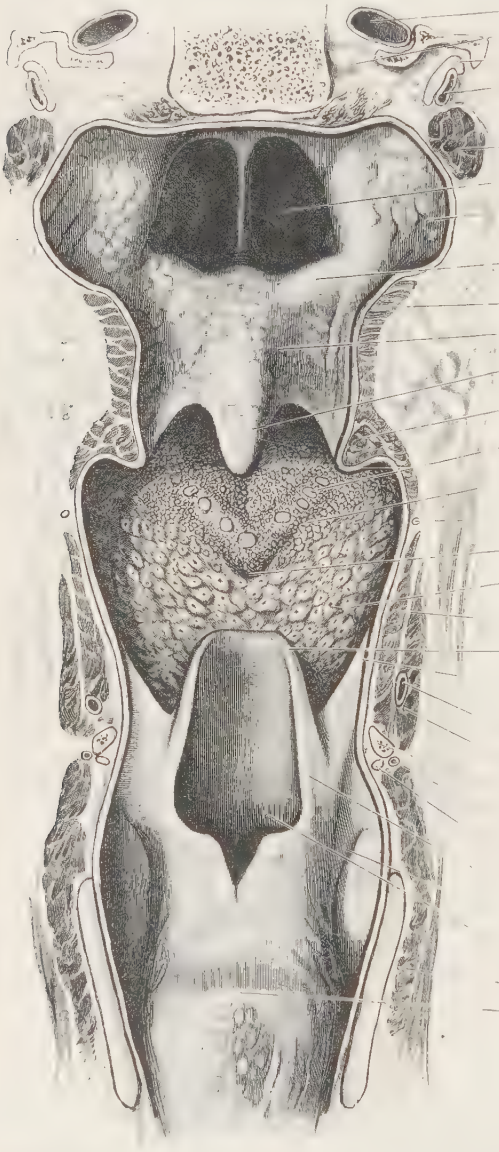

FIG. 729. THE ANTERIOR WALL OF THE PHARYNX WITH ITS ORIFICES, SEEN FROM BEHIND.

The specimen from which the drawing was made was obtained from a formalin-hardened body, by removing the posterior wall of the pharynx while leaving the anterior wall undisturbed. The following points should be noted: the greatest width of the pharynx, above, at the lateral recesses; the posterior nares, with the inferior turbinated bones seen through them; the levator cushion; and the pharyngeal portion of the tongue.

The pharynx presents the following **relations**:—*In front*, as already described, are the nasal cavities, the mouth, base of tongue, and larynx, all of which are seen on its anterior wall (Fig. 729). *Behind*, it is separated by loose areolar tissue (known as the **retro-pharyngeal space**) from the prevertebral fascia and muscles, which intervene between it and the six upper cervical vertebræ. *At the sides* are placed the carotid sheaths with their contents, whilst the styloid process with its muscles, and the glosso-pharyngeal nerve, running downwards and forwards, form lateral

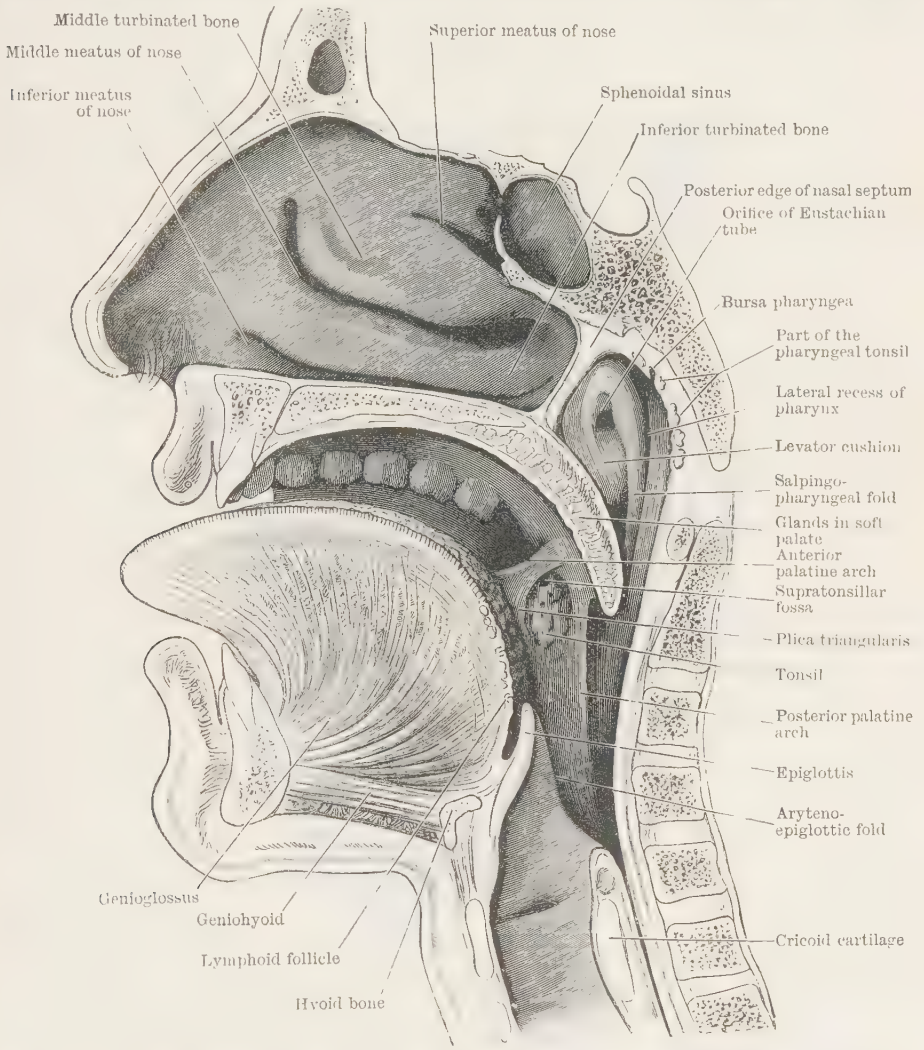

FIG. 730.—SAGITTAL SECTION THROUGH MOUTH, TONGUE, LARYNX, PHARYNX, AND NASAL CAVITY.

The section is slightly oblique, and the posterior edge of the nasal septum has been preserved. The specimen is viewed slightly from below, hence in part the low position of the inferior turbinated bone.

relations in its upper part. *Above*, the pharynx is united to the basi-occipital and the petrous portion of the temporal bones, as already described; and *below*, it joins the œsophagus.

The **cavity of the pharynx** is widest above in the naso-pharynx, immediately behind the Eustachian tubes (Fig. 729), where it extends out on each side, over the upper border of the superior constrictor, in the form of a pouch—the **lateral recess**. Its width is also considerable opposite the upper part of the thyroid cartilage, but it rapidly diminishes below the laryngeal orifice, and is narrowest at its termination in the œsophagus.

The cavity is interrupted above by the soft palate, a movable muscular sheet

which is attached in front to the hard palate, and laterally to the side walls of the pharynx. This sheet, sloping obliquely backwards and downwards, cuts into the cavity of the pharynx (Fig. 730), and, falling short of the posterior wall, incompletely divides it into two, namely, an upper part or **naso-pharynx** (pars nasalis), and a lower part or pharynx proper, which is further subdivided—perhaps unnecessarily—into the **oral pharynx** (pars oralis) lying behind the mouth and tongue, and the **laryngeal pharynx** (pars laryngea) behind the larynx.

The aperture left behind the soft palate and the posterior wall of the pharynx, through which the naso-pharynx communicates with the lower divisions

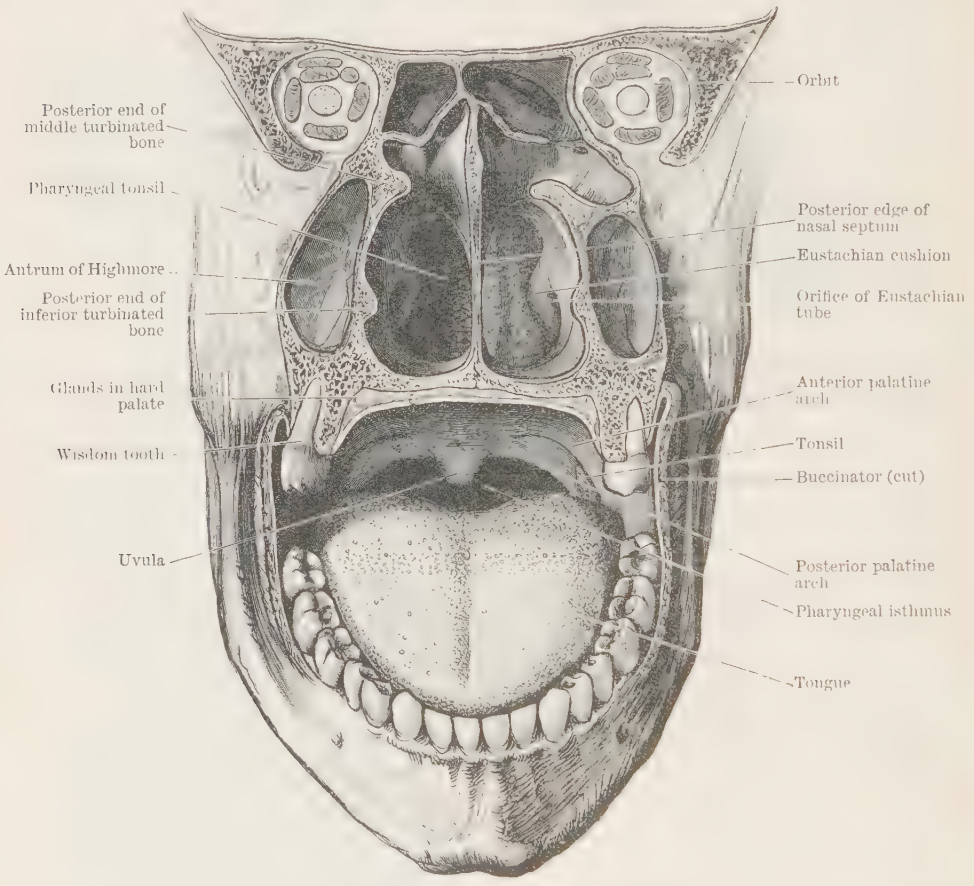

FIG. 731.—THE NASO-PHARYNX FROM THE FRONT.

A coronal section was made through the upper part of the head; this passed immediately in front of the posterior edge of the nasal septum, and extended into the mouth below. Through the posterior nares the naso-pharynx is seen. The prominence of the posterior margin of the Eustachian orifice, and the lymphoid nodules constituting the pharyngeal tonsil, should be noted. The palatine arches, the tonsils, and an unusually wide pharyngeal isthmus, are also seen.

of the cavity, may conveniently be called the **pharyngeal isthmus** (isthmus pharyngo-nasalis).

The pharynx presents *seven openings* through which it communicates with neighbouring cavities (Fig. 729). These are the two posterior nares (choanæ) on the anterior wall, and the two Eustachian tubes on the sides, of the naso-pharynx; the isthmus of the fauces leading into the mouth from the oral pharynx; the orifice of the larynx on the anterior wall of the laryngeal portion of the cavity; and finally, the opening of the œsophagus at its lower end.

**Naso-pharynx** (Figs. 730 and 731).—Although described as a part of the pharynx, this portion of the cavity should be regarded as an annex to the respiratory portion of the nasal cavities rather than as a subdivision of the pharynx proper, for, both

anatomically and functionally, it is all but completely marked off from the digestive tube. It differs from the rest of the pharynx in that its cavity remains, under all conditions, a distinct open chamber incapable of obliteration, owing to the fact that all its walls, with the single exception of the floor, are practically immovable.

The chamber of the naso-pharynx is irregular in shape, and is enclosed by *six walls*—namely, anterior, posterior, two lateral, and a floor—together with a roof or vault formed above by the approximation of the anterior and posterior walls.

The *anterior wall*, which slopes upwards and backwards, is entirely occupied by the two posterior nares, with the nasal septum between them (Fig. 729).

The *posterior wall* is inclined upwards and forwards, and forms the **vault of the pharynx** (fornix pharyngis) above by meeting the anterior wall at a rounded angle. On the upper part of the posterior wall, at and above the level of the Eustachian orifices, there is seen, particularly in early life, a considerable accumulation of lymphoid tissue, associated with a thickened and folded condition of the mucous membrane in the child. This is the **pharyngeal tonsil** (tonsilla pharyngea, Figs. 730 and 731). In old age it becomes very indistinct, or completely disappears; whilst in the child it is often increased in size, and occasionally, when greatly hypertrophied, blocks up the naso-pharynx almost completely.

In connexion with the lower part of the pharyngeal tonsil, there is found, constantly in the child and occasionally in the adult, a small median recess which runs upwards and backwards in the wall of the pharynx for some distance, and is known as the **bursa pharyngea** (Fig. 730).

Three leading views are held as to the nature of the bursa pharyngea, namely—1. That it is the remains of Rathke's pouch, from which the anterior lobe of the pituitary body is formed. 2. That it is a crypt connected with the formation of the pharyngeal tonsil. 3. That it is an independent outgrowth of the mucous membrane. The last view is perhaps most generally accepted.

The *floor* of the naso-pharynx is formed by the upper surface of the soft palate (Fig. 730), which in its anterior part is a direct continuation backwards of the floor of the nasal cavity, whilst posteriorly it slopes strongly downwards and backwards. Between the floor and the posterior wall is left the aperture referred to above as the pharyngeal isthmus, through which the naso-pharynx communicates with the rest of the pharyngeal cavity. By the action of the palatal muscles the floor can be raised or depressed, and these changes of position are accompanied by corresponding alterations in the size and shape of the cavity.

Each *lateral wall* of the naso-pharynx (Fig. 730) is occupied in the greater part of its extent by the opening of the Eustachian tube, behind which is seen a vertical slit-like depression leading into a recess, the **lateral recess** of the pharynx, or **fossa of Rosenmüller.**

The **pharyngeal orifice of the Eustachian tube** (ostium pharyngeum) is a considerable opening, usually of a somewhat triangular form, with a characteristic infundibular or funnel-like appearance (Fig. 730). It is bounded above and behind by a prominent rounded ridge, the **Eustachian cushion** (torus tuberius). This ridge is due to the projection of the cartilage, which surrounds the Eustachian passage above and behind, but is absent below and in front. The prominence of the posterior, as contrasted with the anterior margin of the orifice, and the direction of the tube itself, which runs strongly forwards as well as inwards (traced from the tympanum), greatly facilitate the introduction of a Eustachian catheter.

The exact position of the orifice is of importance in connexion with this latter operation. It is situated on the side-wall of the naso-pharynx, a short distance (about $\frac{1}{3}$ to $\frac{1}{2}$ inch) behind the posterior end of the inferior turbinated bone, and immediately above the level of the hard palate (Figs. 730 and 731).

A slight ridge of the mucous membrane descends from the lower end of the Eustachian cushion on the side-wall of the pharynx, and gradually becomes lost. This is known as the **salpingo-pharyngeal fold** (plica salpingo-pharyngea). Another less developed ridge, the **salpingo-palatine fold** (plica salpingo-palatina), passes from the anterior border of

the Eustachian orifice downwards and forwards to join the palate. In front of the latter lies an indistinct groove, the **naso-pharyngeal groove**, which indicates the separation of the nasal cavity from the naso-pharynx.

The levator palati muscle in descending runs parallel to the Eustachian tube, and along its lower border. As it enters the palate, it produces, particularly when in a state of contraction, an elevation just below the Eustachian orifice, known as the **levator cushion** (torus levatorius, Figs. 729 and 730), which in its outer portion abuts against the lower part of the orifice, and forms its base when that opening assumes its usual triangular shape.

Occasionally the Eustachian orifice is of an oval or slit-like form, with sloping edges, but the triangular shape described above is much more commonly found.

Immediately behind each Eustachian orifice is seen the **lateral recess of the pharynx** (recessus pharyngeus, fossa of Rosenmüller), a nearly vertical, slit-like depression of considerable depth (Figs. 729 and 730), which runs outwards in the form of a flattened pouch or diverticulum.

The lateral recesses project out over the upper margin of the superior constrictor, and beneath the petrous portion of the temporal bone, corresponding to the position of the sinus of Morgagni on each side. The recess is the remains of the inner or pharyngeal portion of the second visceral cleft, the lower part of which is represented in the supratonsillar fossa.

**Oral Pharynx** (pars oralis).—This is the portion of the pharyngeal cavity which lies behind the mouth, and intervenes between the soft palate above and the superior aperture of the larynx below. Its *anterior wall* is occupied by the isthmus of the fauces, leading into the mouth; and below this by the pharyngeal portion of the tongue, almost vertical in direction. Its *lateral wall* (Fig. 730) presents a triangular area (sinus tonsillaris), bounded in front by the anterior palatine arch, behind by the posterior palatine arch, and below by the sides of the tongue in its pharyngeal portion. This area is occupied in the greater part of its extent by the **tonsil**, above which is found a depression, the **supratonsillar fossa** (Fig. 730), which is of considerable interest clinically.

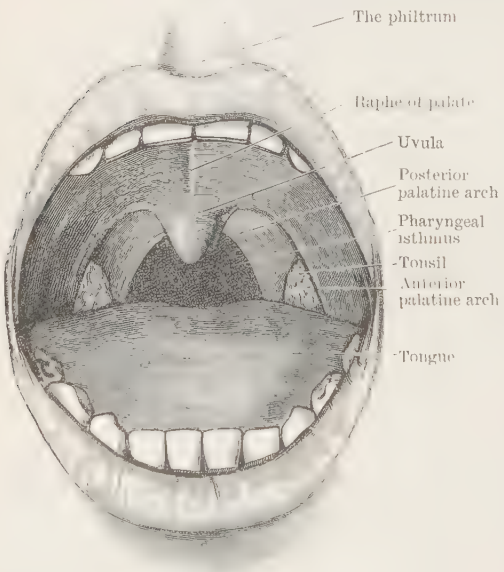

Fig. 732.—Open Mouth showing Palate and Tonsils.

It also shows the two palatine arches, and the pharyngeal isthmus through which the naso-pharynx above communicates with the oral portion of the pharynx below.

The **posterior palatine arch** (arcus pharyngo-palatinus, posterior pillar of the fauces) is a prominent fold of mucous membrane, containing the palato-pharyngeus muscle in its interior, which springs above from the posterior edge of the soft palate, and, passing downwards and slightly backwards, ends below on the side-wall of the pharynx (Fig. 730). The two posterior palatine arches form the lateral boundaries of the pharyngeal isthmus, which passage they can modify both in size and shape by the contraction of their contained muscles.

The anterior palatine arch is described on page 1000.

The **pharyngeal isthmus** (isthmus pharyngo-nasalis) is the very oblique and somewhat triangular orifice through which the oral pharynx communicates with the naso-pharynx (Fig. 732). It differs considerably in size and shape in different individuals, being in some so small that the naso-pharynx can be explored from the mouth only with very great difficulty; whilst in others it is of much larger dimensions (Fig. 731) and affords ample space for the rhinoscopic examination of the naso-pharynx and the back part of the nasal cavities.

In general it may be described as triangular in shape, the sides corresponding to the posterior palatine arches, and the base, which is behind, being formed by the posterior wall of the pharynx. The apex of the triangle is directed towards the soft palate, and is encroached upon, and overlapped from below by, the uvula, which assists in the closure of the orifice (Fig. 732).

By the contraction of the palato-pharyngei muscles, which are enclosed within the palatine arches, the sides of the isthmus can be approximated, like two curtains, and its size correspondingly diminished. When, at the same time, the uvula and soft palate are elevated, and the whole pharynx in this region is narrowed by the contraction of the superior constrictor, the aperture can be completely closed, and the oral separated from the nasal pharynx, as in the acts of swallowing and vomiting.

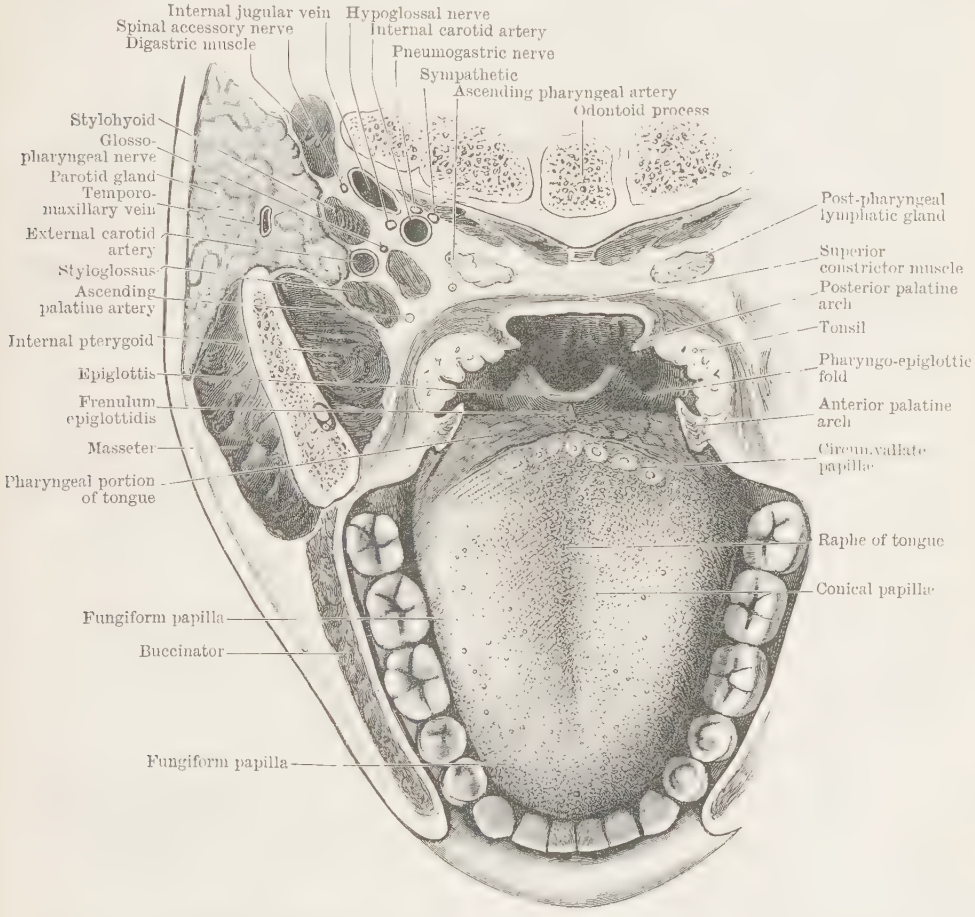

Fig. 733. –Horizontal Section through Mouth and Pharynx at the Level of the Tonsils.

The stylopharyngeus, which is shown immediately to the inner side of the external carotid artery, and the prevertebral muscles, are not indicated by reference lines.

The **tonsils** (tonsillæ palatinæ, amygdalæ) are two large, oval masses of lymphoid tissue which are embedded in the lateral walls of the oral pharynx, between the anterior and posterior palatine arches (Fig. 730). As already pointed out, there is in this region a triangular interval (the sinus tonsillaris), situated between the two palatine arches and the side of the tongue. The greater part of this interval is occupied by the tonsil. In its upper part, however, above the tonsil, there is usually found a variably-developed depression already referred to as the **supra-tonsillar fossa**.

The tonsil lies under cover of the ramus of the jaw, and corresponds in position to a point a little above and in front of its angle. Its *inner* or *pharyngeal surface* is prominent, and closely beset with numerous deep, pit-like depressions—the

crypts of the tonsil. These crypts are most numerous in the upper part of the mass, where, in particular, they form a series of irregular inter-communicating passages.

The *outer* or *attached surface* is enclosed in a distinct fibrous capsule connected with the pharyngeal aponeurosis, outside which lie the superior constrictor of the pharynx and the internal pterygoid muscles (Fig. 733).

The ascending palatine artery, running upwards and backwards between the stylo-glossus and stylo-pharyngeus, lies in close relation to the outer surface of the tonsil—separated only by its capsule and the superior constrictor—as does also the tonsillar artery, which is often represented by a branch of the last. More external still lies the internal pterygoid and the ramus of the jaw; whilst the internal carotid artery, with the large cranial nerve trunks, is placed $\frac{3}{4}$ to 1 inch behind and to its outer side (Fig. 733).

The size of the tonsils is extremely variable, but as a rule, in early life, they measure something under 1 inch (20 to 22 mm.) from above downwards, about $\frac{3}{4}$ inch (18 to 20 mm.) antero-posteriorly, and $\frac{1}{2}$ inch (12 to 15 mm.) from within out.

In the child and young adult there is usually seen a thin triangular fold of mucous membrane, **the plica triangularis** (His), which stretches from the anterior palatine arch backwards for a variable distance over the tonsil (Fig. 730). Its apex is directed upwards towards the soft palate, its base towards the tongue, and its free margin crosses the tonsil, to which it often adheres in later life. In this latter condition the plica encloses a more or less distinct space situated between itself and the tonsil, in which diseased processes are often set up.

Above the tonsil, as already mentioned, is found a variably-developed depression, the **supra-tonsillar fossa**, which occasionally is of considerable size, and then extends either upwards into the soft palate or forwards and downwards beneath the plica triangularis. This fossa is frequently the seat of suppurative changes, and is consequently of considerable clinical importance.

The supratonsillar fossa, like the lateral recess of the pharynx, is the remains of the pharyngeal portion of the second visceral cleft. The palate in its growth backwards crosses the cleft, which it divides into two parts—namely, the pharyngeal recess above, and the supratonsillar recess below the soft palate.

In the severe hæmorrhage which has been known to follow excision of an enlarged tonsil, and which has been erroneously attributed to the wounding of the internal carotid artery, the blood is derived chiefly from enlarged branches of the ascending palatine, tonsillar, or ascending pharyngeal vessels.

The **arteries** of the tonsil are derived from the ascending palatine and tonsillar branches of the facial, the ascending pharyngeal of the external carotid, and the dorsalis linguæ of the lingual. The **veins** pass to the tonsillar plexus, on the outer side of the tonsil, which is an offshoot of the pharyngeal venous plexus.

**Nerves.**—The tonsil receives a special branch from the glosso-pharyngeal; this unites with branches from the pharyngeal plexus in a small **plexus tonsillaris** which supplies the organ.

The **lymphatics** are extremely numerous, and pass down to join some of the submaxillary lymphatic glands near the angle of the jaw.

**Laryngeal Portion of the Pharynx** (pars laryngea).—This division of the pharyngeal cavity lies behind the larynx (Fig. 729). It is wide above, where it is continuous with the oral portion, and maintains a considerable width until within about an inch of its termination, when behind the cricoid cartilage it narrows rapidly and passes down to join the œsophagus. Except during the passage of food, the anterior and posterior walls of this latter part are in contact, and its cavity is reduced to a mere transverse slit (Fig. 730).

The *anterior wall* of the laryngeal portion of the pharynx is formed in its whole extent by the back of the larynx, of which the following parts are seen within the pharyngeal cavity (Fig. 729):—The epiglottis above; below this the superior aperture of the larynx, bounded at the sides by the aryteno-epiglottic folds; outside these folds is seen on each side a deep recess, the **sinus pyriformis** (recessus piriformis, Fig. 729). Lower down still, the back of the arytenoid and cricoid cartilage, covered by muscles and mucous membrane, are visible.

*Its posterior* and *lateral walls* are directly continuous with the corresponding walls of the oral pharynx, and present no features which require special notice.

A prominent fold of the mucous membrane, extending from the side of the epiglottis, runs up along the lateral wall, upon which it ends near the posterior palatine arch. This, the **pharyngo-epiglottic fold**, is often described as a lateral glosso-epiglottic fold (see p. 1002).

The **sinus pyriformis** is a deep depression, seen on each side between the aryteno-epiglottic fold and the ala of the thyroid cartilage. When viewed from above, as

in laryngoscopic examinations, it appears of a pyriform shape, the wider end being directed upwards and forwards. When viewed from behind, the recess is boat-shaped and elongated in the vertical direction. Its outer wall is formed by the thyroid cartilage and thyro-hyoid membrane, covered by mucous membrane; its inner wall by the aryteno-epiglottic fold, and slightly below by the upper part of the cricoid cartilage.

**Vessels and Nerves of the Pharynx.**—The **arteries** of the pharynx are derived from—1, the ascending pharyngeal; 2, the ascending palatine branch of facial; 3, the posterior palatine, from the internal maxillary, with a few twigs from the dorsalis linguæ, tonsillar (of facial), vidian, and pterygo-palatine of the internal maxillary. The **veins** go to the pharyngeal venous plexus, which is found between the constrictors and the bucco-pharyngeal aponeurosis. The plexus communicates with the pterygoid plexus above and with the internal jugular or facial vein below.

The **lymphatics** of the pharynx pass chiefly to the upper set of deep cervical glands. Those from the upper part of the posterior wall join a few post-pharyngeal glands which are found on each side between the pharynx and the rectus anticus major muscle. These latter glands, which are large in the child, small in the adult, but apparently always present (Fig. 733), are of considerable clinical interest, as they often form the starting-point of post-pharyngeal abscess.

The **nerves** of the pharynx, both motor and sensory, are derived chiefly from the pharyngeal plexus, which is formed by branches of the vagus, glosso-pharyngeal, and sympathetic. The soft palate and the neighbourhood of the tonsil are supplied by the posterior and external palatine branches of Meckel's ganglion. The tonsil receives a branch from the glosso-pharyngeal direct. The vault of the pharynx, and the region around the Eustachian orifice, as well as the orifice itself, are supplied by the pharyngeal branch of Meckel's ganglion. Finally, the superior laryngeal nerve supplies the mucous membrane of the back of the larynx, where it forms the anterior wall of the laryngeal portion of the pharynx.

**Structure of the Pharyngeal Wall.**—The pharyngeal wall is made up of the following layers:—(1) The thick mucous membrane, which is plentifully supplied with racemose mucous glands and lymphoid tissue, and is lined by stratified squamous epithelium, except in the naso-pharynx, where the epithelium is columnar and ciliated. (2) Outside the mucous membrane lies a layer of firm connective tissue, the pharyngeal aponeurosis, which is closely associated with the muscles, and receives the insertions of many of their fibres. This layer blends with the periosteum of the base of the skull superiorly, and is united to the Eustachian tube, the margins of the posterior nares, and the other fixed points to which the pharynx is connected anteriorly. It is thickest above, at the sinuses of Morgagni, where the muscular coat is wanting, and where it forms the chief constituent of the pharyngeal wall. Below, it gradually grows thinner as the lower end of the pharynx is approached. (3) External to the pharyngeal aponeurosis lies the muscular coat, formed of the three constrictors with the stylo- and palato-pharyngeus. The muscular coat is covered externally by (4) the bucco-pharyngeal fascia, a thin and, in places, ill-defined layer of fascia which surrounds the constrictors of the pharynx, and passes forward above to cover the outer surface of the buccinator. It is connected behind to the pre-vertebral fascia by loose connective tissue (the retro-pharyngeal space), and it is similarly connected by areolar tissue to the other structures with which the pharynx comes in contact.

The racemose glands of the mucous membrane, which are of the mucous type, are very numerous in the walls of the naso-pharynx and in the soft palate, where they form a thick continuous layer. They are also numerous about the aryteno-epiglottic folds and on the back of the arytenoid muscles in the laryngeal portion of the pharynx. Over the rest of this cavity, though numerous, they are not so thickly placed as in the regions just mentioned. The lymphoid tissue, either in a diffuse form or collected into lymphoid follicles, is found throughout the whole of the mucous membrane. As already pointed out, it is particularly abundant on the upper portion of the posterior wall of the naso-pharynx, where it forms the pharyngeal tonsil.

The pharyngeal aponeurosis, which is thick above and thin below, and the bucco-pharyngeal fascia, which is thin above and stouter below, are practically blended into one layer above, near the base of the skull, where the muscular coat is absent. Lower down they are separated by the constrictors, and become two distinct sheets. They are strengthened in the middle line posteriorly by a fibrous band descending from the pharyngeal tubercle.

### Development of the Pharynx and Tonsil.

For the development of the pharynx from the anterior portion of the foregut, and the formation and fate of the visceral arches and clefts which are found in its wall, the reader is referred to the chapter on General Embryology, p. 34.

The anterior palatine arch is derived from the second visceral arch, behind which, in the embryo, lies the pharyngeal portion of the second visceral cleft. This cleft is crossed by the palate in its growth backwards; the part above the palate is represented in the adult by the lateral recess of the pharynx and the part below it by the sinus tonsillaris. From the lower and greater part of the sinus tonsillaris the tonsil is developed; the upper part of the sinus persists, however, as the supratonsillar fossa. The tonsil at first is a smooth depression of the mucous membrane. About the fourth month of fœtal life downgrowths of the epithelium take place, which are afterwards converted into the tonsillar crypts. Subsequently lymphoid cells accumulate around the downgrowths and form the lymphoid tissue, which constitutes the mass of the organ.

The upper and anterior part of the naso-pharynx is derived from the stomatodeum, the remainder of the cavity from the foregut.

## THE ŒSOPHAGUS.

The **œsophagus** or **gullet** is the portion of the digestive canal which intervenes between the pharynx above and the stomach below. With the exception of the pylorus, it is the narrowest, and at the same time one of the most muscular parts of the whole alimentary tube.

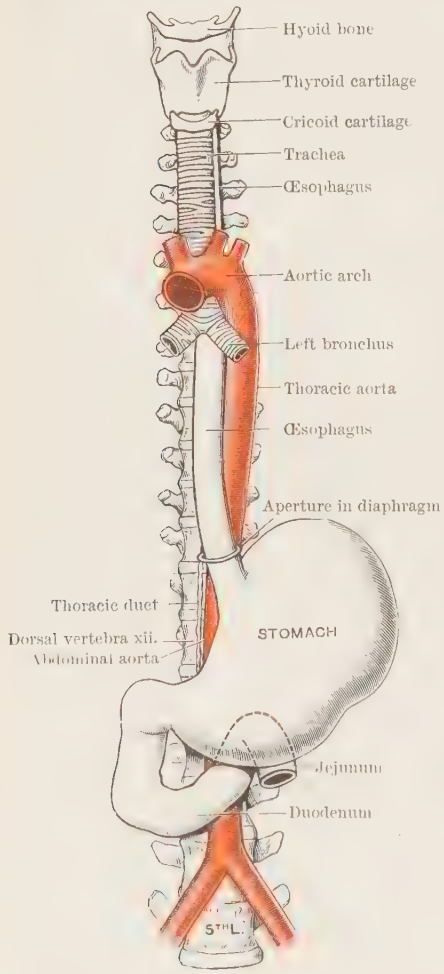

Fig. 734.—Diagram to show the Course of the Œsophagus.

It extends from the termination of the pharynx, at the lower border of the cricoid cartilage and opposite the sixth cervical vertebra, to the cardiac orifice of the stomach, opposite the eleventh dorsal vertebra. Between these two points it traverses the lower part of the neck, the whole length of the thorax, and, having pierced the diaphragm, it enters the abdomen, and immediately afterwards joins the stomach. In this course it does not adhere to the mesial plane of the body, but twice leaves it, and curves to the left. The first of these curvatures corresponds to the lower part of the neck and the upper part of the thorax, where the œsophagus projects beyond the left margin of the trachea to the extent of $\frac{1}{6}$ or $\frac{1}{4}$ inch (4 to 6 mm.). It returns to the middle line about the level of the aortic arch. Lower down, behind the pericardium, it again passes to the left, and at the same time forwards, in order to reach the œsophageal opening in the diaphragm (which is placed in front and to the left of the aortic opening), and it maintains this direction until the stomach is reached.

In addition to the curvatures just described, it is also curved in the antero-posterior direction, in correspondence with the form of the vertebral column upon which it, in great part, lies.

In *length* it usually measures about ten inches (25 cm.).

Its *breadth*, where the tube is widest, varies between half an inch (13 mm.) in the empty contracted condition and an inch or more (25 to 30 mm.) in the fully distended state.

When seen in sections of the frozen body (Fig. 735), the œsophagus usually

appears either as a flattened tube with a transverse slit-like cavity, or as an oval or rounded canal with a more or less stellate lumen. The former condition is more common in the neck, owing to the pressure of the trachea, and the latter in the thorax.

When exposed in the ordinary post-mortem examination soon after death, it has rather the appearance of a solid muscular rod or band than of a hollow tube.

The œsophagus presents two distinct *constrictions,* one situated at its beginning, the other at the point where it is crossed by the left bronchus. Both constrictions are of the same size, and will admit without injury an instrument with a maximum diameter of $\frac{4}{5}$ inch (20 mm.). At each of these points the tube is flattened from before backwards.

The œsophagus varies in length in different individuals, from 8 to 14 inches (20 to 35 mm.). The distance from the upper incisors to the beginning of the œsophagus averages about 6 inches (15 cm.).

During life the cervical portion is said, under ordinary circumstances, to be closed and flattened from before backwards by outside pressure, whilst the thoracic portion may be open owing to the negative pressure in the thorax. The passage into the stomach is also said to be open (Mickulicz), but this is doubtful.

The size at the two constrictions, when the tube is fully distended, is 23 mm. transversely, and 17 mm. antero-posteriorly. The other parts vary in diameter between 26 and 30 mm. (Jonnesco).

In its first curvature to the left the divergence is greatest opposite the third dorsal vertebra. The second inclination to this side begins about the seventh dorsal vertebra, and continues to the end of the œsophagus, being considerably increased as the diaphragm is approached.

**Relations of the Œsophagus.**—The relations (Fig. 735) differ so widely in the neck and thorax that they must be described separately for each of these regions.

**In the neck.**—*In front* lies the trachea—to the posterior membranous wall of which the œsophagus is loosely connected by areolar tissue—and in the groove at each side, between the two, the recurrent laryngeal nerve ascends to the larynx (Fig. 735, A). *Behind* lie the vertebral column and the longus colli muscles, from which the œsophagus is separated by the prevertebral layer of the cervical fascia. *At the sides* are placed the carotid sheaths with their contained vessels, and the lateral lobes of the thyroid body. Owing to the deviation of the tube to the left in the lower part of the neck, its relation to the carotid sheath and thyroid body is much more intimate on this than on the right side.

**In the thorax.**—The œsophagus passes successively through the superior and pos-

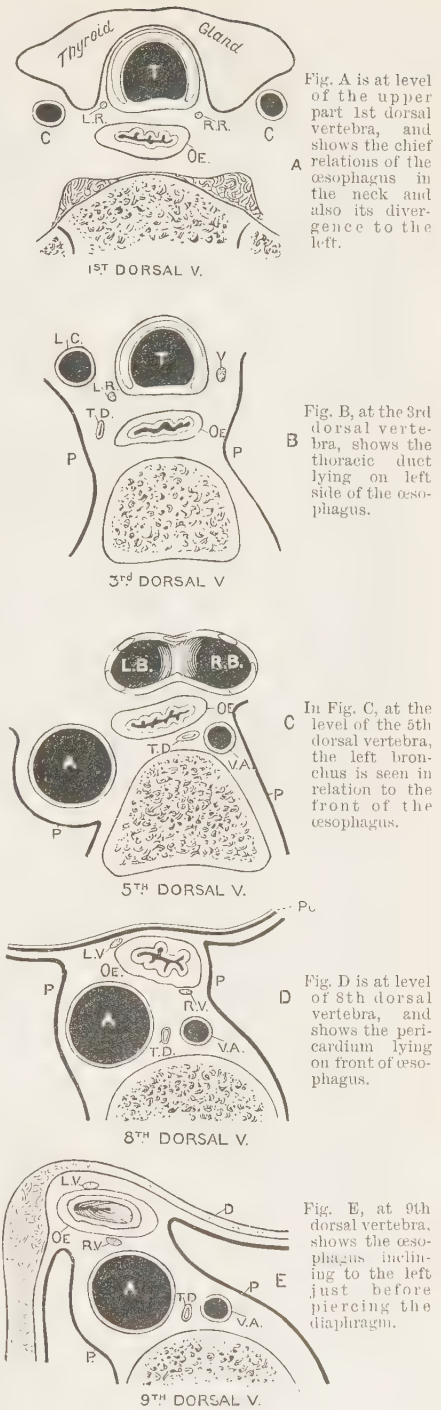

Fig. A is at level of the upper part 1st dorsal vertebra, and shows the chief relations of the œsophagus in the neck and also its divergence to the left.

Fig. B, at the 3rd dorsal vertebra, shows the thoracic duct lying on left side of the œsophagus.

In Fig. C, at the level of the 5th dorsal vertebra, the left bronchus is seen in relation to the front of the œsophagus.

Fig. D is at level of 8th dorsal vertebra, and shows the pericardium lying on front of œsophagus.

Fig. E, at 9th dorsal vertebra, shows the œsophagus inclining to the left just before piercing the diaphragm.

FIG. 735.—TRACINGS FROM FROZEN SECTIONS TO SHOW THE RELATIONS OF THE ŒSOPHAGUS at the levels of the 1st, 3rd, 5th, 8th, and 9th dorsal vertebræ respectively.

A, Aorta; C, Common carotid artery; D, Diaphragm; L.B, Left bronchus; L.C, Left subclavian artery; L.R, Left recurrent nerve; L.V, Left vagus; ŒE, Œsophagus; P, Pleura; Pc, Pericardium; R.B, Right bronchus; R.R, Right recurrent nerve; R.V, Right vagus; T, Trachea; T.D, Thoracic duct; V.A, Vena azygos major.

terior mediastina, in the former lying close to the vertebral column, but in the latter advancing somewhat into the thoracic cavity and coming into contact with the back of the pericardium. The trachea still lies *in front* as far as its bifurcation. Immediately below this the œsophagus is crossed by the left bronchus (Fig. 735, C), and in the rest of its thoracic course it lies in the closest relation to the back of the pericardium. *Behind*, it rests on the longus colli muscle and the vertebral column in the upper part of the thorax; but below the bifurcation of the trachea, as already explained, it advances into the cavity of the posterior mediastinum, and is soon separated from the spine by the vena azygos major, the thoracic duct, the upper six aortic intercostal arteries of the left side, and in its lower part by the aorta as well.

On its *left side* lie the thoracic duct, the pleura, and the left subclavian artery in the upper part of the thorax; the aorta in the middle region, and lower down the pleura again, for a little way, before the œsophagus pierces the diaphragm. On the *right side* the tube comes into relation with the arch of the azygos vein, whilst below this the pleura clothes it.

The two pneumogastric nerves, after forming the posterior pulmonary plexuses behind the roots of the lungs, descend to the œsophagus, where they form, by uniting with one another and with the branches of the sympathetic, the **plexus gulæ** or **œsophageal plexus**. Lower down the left nerve winds round to the front, whilst the right turns to the back, and in this relation they pass with the tube through the diaphragm to reach the stomach.

**Relation of the Aorta to the Œsophagus.**—The arch of the aorta, passing back to reach the vertebral column, lies in relation to the left side of the œsophagus; consequently the descending thoracic aorta lies at first to its left; lower down, however, as the aorta passes on to the front of the vertebral column, and the gullet inclines forwards and to the left, the œsophagus comes to lie at first in front, and then, as the diaphragm is approached, it lies not only in front, but also somewhat to the left of the artery (Figs. 734 and 735).

**Relation of the Thoracic Duct to the Œsophagus.**—The thoracic duct, lying to the right of the aorta below, is not directly related to the œsophagus (Fig. 735, E); but higher up (Fig. 735, D and E) it lies behind it. About the level of the aortic arch the duct passes to the left, and above this (Fig. 735, B and A) will be found resting against the left side of the œsophagus, which it accompanies into the neck.

**Relation of the Pleural Sacs to the Œsophagus.**—Above the level of the aortic arch and the arch of the vena azygos major, between which the tube descends, the pleuræ, though not lying in immediate contact with the œsophagus, are separated from it only by a little connective tissue, and on the left side also, behind the subclavian artery, by the thoracic duct (Fig. 735, B). Here, in thin bodies, the pleura is very close to the œsophagus, and the thoracic duct, lying on its left side, may occasionally be seen through the pleural membrane. Below the arch of the azygos vein the pleura clothes the right side of the œsophagus—and very often even a considerable portion of its posterior surface too, thus forming a deep recess behind it—almost as low down as the opening in the diaphragm. On the left side, below the level of the aortic arch, the pleura comes in contact with the gullet, only for a short distance, just above the diaphragm (Fig. 735, E).

**Divisions.**—Both a diaphragmatic (Jonnesco) and an abdominal part of the œsophagus are described. The **diaphragmatic portion**, said to be about half an inch in length (1 to 1·5 cm.), corresponds to the portion of the tube which lies in the œsophageal orifice (or canal) of the diaphragm. The plane of this orifice is very oblique or almost vertical, and its abdominal opening looks forwards and to the left, and but little downwards. Above and in front, where it is bounded either by the posterior edge of the central tendon or by a few decussating fibres of the muscular portion of the diaphragm, which meet behind the tendon, the œsophageal orifice has practically no length, and consequently the œsophagus here passes into the abdominal cavity immediately after leaving the thorax. At the sides and behind, on the other hand, the decussating bands from the two crura, which embrace the orifice, are so arranged that they turn a flat surface (not an edge) towards the opening, and thus, posteriorly and laterally, the orifice or canal is of some length; and on these aspects there is a portion of the tube in contact with the diaphragm for a distance of 1 to 1½ cm. But this contact takes place not around a horizontal line, but in a very oblique plane corresponding to that of the orifice. On the whole, it is perhaps more satisfactory not to describe a separate diaphragmatic portion, but to say that the œsophagus pierces the diaphragm very obliquely, and that at the sides and behind it is in contact with the walls of the orifice for a distance of half an inch or more.

The œsophagus, in passing through the orifice, is connected to its boundaries by a considerable amount of strong connective tissue, but it is extremely difficult, or impossible, to demonstrate any direct naked-eye connexion between the œsophageal muscular fibres and those of the diaphragm.

The anterior or right boundary of the œsophageal orifice, formed of fibres derived from both crura of the diaphragm, is strongly developed and prominent, and usually lies in the œsophageal groove, on the back of the left lobe of the liver, which groove is rarely due to the pressure of the œsophagus alone.

The **abdominal portion** of the œsophagus is very short, for immediately after piercing the

diaphragm the tube expands into the stomach. However, when the empty stomach is drawn forcibly downwards, a portion of the front and left side of the tube, about half an inch in length (1 to 1·5 cm.), is seen, to which the above term is applied. This part is covered with peritoneum, derived from the great sac in front and on the left, whilst its right and posterior surfaces are uncovered. It is generally described as lying against the œsophageal groove and the left lateral ligament of the liver in front, but it never actually comes in contact with the latter of these structures, which is attached to the upper surface of the left lobe of the liver by one edge, and to the diaphragm, over an inch in front of the œsophagus, by the other. As regards the former, the œsophageal groove of the liver is generally occupied by the prominent right margin of the œsophageal orifice of the diaphragm and occasionally by the œsophagus as well. Possibly this margin is so strongly developed and so prominent in order that it may bear the pressure of the liver off the gullet, which otherwise might be interfered with in its dilatation during the passage of food.

When the stomach is fully distended the abdominal part of the œsophagus almost disappears, being absorbed into the stomach in its distension.

**Variations.**—The chief anomalies found in the œsophagus are: (1) Annular or tubular constrictions; (2) diverticula, of which the most interesting—known as "pressure pouches"—are usually situated on the posterior wall close to its junction with the pharynx, and these sometimes require surgical interference; (3) doubling in part of its course; and (4) communications between the trachea and œsophagus.

**Structure of the Œsophagus** (Fig. 738).—The œsophageal wall is composed of three proper coats—(1) muscular, (2) submucous, and (3) mucous. In addition, it is surrounded by an outer covering of areolar tissue (tunica adventitia), by which it is loosely connected to the various structures related to it in its course. This loose covering permits of its free movement and of its increase in size, or of its diminution, during the act of swallowing.

The **muscular coat** (tunica muscularis) is composed of two layers—an outer of longitudinal, and an inner of circular fibres. The *longitudinal layer* is highly developed, and, unlike the condition usually found in the digestive tube, it is as stout as, or in places stouter than, the circular layer. Its fibres form along the greater length of the tube an even covering outside the circular layer, and below they are continued into the longitudinal fibres of the stomach. Above, near the upper end of the œsophagus, the longitudinal fibres of each side, separating at the back, pass round towards the anterior aspect and form two longitudinal bands (Fig. 736), which run up on the front of the tube, and are attached by a tendinous band to the upper part of the back of the cricoid cartilage (Fig. 737).

The *circular muscular fibres*, though not forming such a thick layer as the longitudinal fibres, are nevertheless well developed. Below they are continued into both the circular and oblique fibres of the stomach. Above they pass into the lower fibres of the inferior constrictor of the pharynx.

The muscular fibres are entirely of the striated variety at the upper end of the œsophagus. Soon unstriped fibres begin to appear, increasing in number as we descend. In the lower half or two-thirds, only unstriped muscle is found.

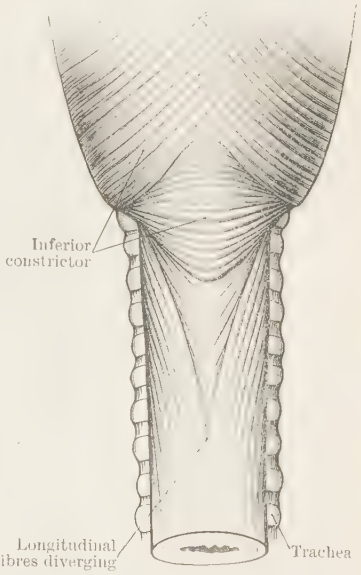

Fig. 736. — Dissection to show the arrangement of the muscular fibres on the back of the œsophagus and pharynx. Traced upwards, the longitudinal muscular fibres of the œsophagus are seen to separate behind; passing round to the sides, they form two longitudinal bands which meet in front above, and are united to the cricoid cartilage, as shown in the next figure.

The longitudinal fibres for about the upper fifth of the tube are entirely striped; in the second fifth striped and unstriped are mixed; whilst in the lower three-fifths unstriped fibres alone are present. The circular fibres are entirely striated for the first inch; after this unstriped fibres appear; and in the lower two-thirds, only unstriped muscle fibres are found (D. J. Coffey).

The longitudinal fibres are often joined by slips of unstriped muscle, or elastic fibres, which spring from various sources, including the left pleura (constant, Cunningham), the bronchi, back of trachea, pericardium, aorta, etc. These slips assist in fixing the œsophagus to the surrounding structures in its passage through the thorax, and have been aptly compared to the tendrils of a climbing plant (Treitz).

The **submucous coat**, composed of areolar tissue, is of very considerable thickness, in

order to allow of the expansion of the tube during swallowing. It connects the mucous membrane loosely to the muscular coat, and admits of the former being thrown into folds when empty. In this coat are contained the numerous racemose mucous glands which open into the cavity of the œsophagus (Fig. 738).

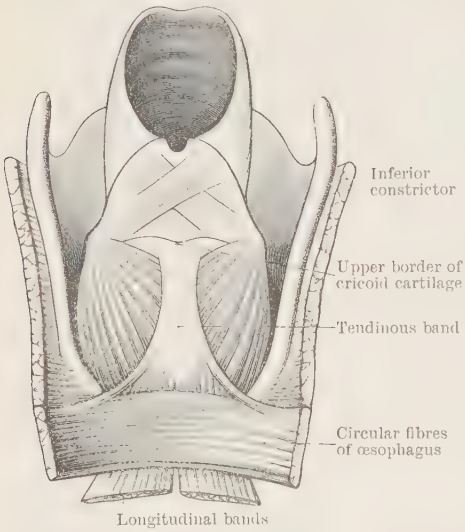

FIG. 737.—THE LOWER PART OF THE PHARYNX AND THE UPPER PART OF THE ŒSOPHAGUS have been slit up from behind, and the mucous membrane removed to show the muscular fibres. The two longitudinal bands are seen coming round to the front to be attached by a common tendon to the upper border of the cricoid cartilage. See explanation of last figure.

The **mucous membrane** is of a greyish pink colour, much paler than that of the pharynx, and of a firm and resistant texture. It is covered by a thick stratified, squamous epithelium, on the surface of which the openings of numerous glands are found. Below, its junction with the gastric mucous membrane is indicated by a distinct, irregularly dentated or crenated line, which runs transversely round the tube. In carefully preserved specimens the smooth mucous membrane of the œsophagus above this line contrasts strongly with the mammillated gastric mucous membrane below.

Owing to the inelasticity of this coat, and the fact that it is but loosely connected to the muscular coat by the submucosa, it is thrown into a series of longitudinal folds when the œsophagus is empty and contracted; hence the stellate lumen often seen in sections of the gullet.

**Glands.**—Numerous racemose mucous glands, large enough to be distinctly seen with the naked eye, are found in the submucosa. They are pretty evenly distributed over the whole tube, and do not appear to be more numerous towards either end (Coffey). In addition to these, other glands, resembling closely those of the cardiac end of the stomach, are found in the mucous membrane of certain portions of the œsophagus. They are entirely confined to the mucosa, and do not extend beyond the muscularis mucosæ. These glands are specially numerous at both the upper and lower ends of the tube (Coffey, Schäfer).

FIG. 738.—STRUCTURE OF THE ŒSOPHAGUS, transverse section (after Horsley).

**Vessels and Nerves.**—Its **arteries** consist of numerous small branches derived, in the neck, from the inferior thyroid, in the thorax, from the bronchial arteries and thoracic aorta, and in the abdomen, from the coronary artery of the stomach, and also from the left phrenic.

The **veins** form a plexus on the exterior of the œsophagus, from which branches pass, in the lower part of the tube, to the coronary vein of the stomach, and, higher up, to the azygos, and thyroid veins. There is thus established on the lower part of the œsophagus a free communication between the portal and systemic veins.

The **lymphatics** pass to the inferior set of deep cervical glands in the neck, and to the posterior mediastinal glands, many of which, of large size, are seen around the tube, in the thorax.

The **nerves** are derived from the recurrent laryngeal, and from the cervical sympathetic in the neck, from the pneumogastrics and sympathetic in the thorax.

## DEVELOPMENT OF THE ŒSOPHAGUS.

The œsophagus is developed from the foregut lying between the pharynx and the dilatation which represents the future stomach. At first, owing to the flexure of the head

on the trunk in the early embryo, it is relatively short, but, as the neck is developed, it gradually becomes elongated and more or less cylindrical.

The superficial epithelial cells are ciliated and somewhat cylindrical between the fourth and eighth months of fœtal life (Neumann); subsequently the adult condition is established.

## THE ABDOMINAL CAVITY.

As the remaining parts of the digestive system lie within the abdomen it will be necessary to describe that cavity as a whole, and to refer briefly to its lining membrane—the peritoneum—before passing on to the consideration of the viscera which are contained within it.

The **abdomen** is that portion of the cavity of the trunk which lies below the diaphragm. It is the largest of all the cavities of the body, and contains the greater part of the digestive, urinary, and generative systems of organs, in addition to numerous vessels, nerves, and other structures.

**Shape.**—In general, the abdominal cavity is of a somewhat oval form, with the long axis directed vertically, and the wide end upwards. It is strongly flattened from before backwards, and is encroached upon in the middle line posteriorly by the projection forwards of the vertebral column, on each side of which it presents the appearance of a deep wide groove.

**Boundaries.**—The cavity is limited *above* by the concave vault of the diaphragm, which is dome-shaped and divided into a right and a left cupola by an intervening depression. Into the right cupola fits the greater part of the liver; in the left lie the stomach and spleen. On the upper surface of each cupola is placed the base of the corresponding lung, whilst between them, on the depression, rests the under surface of the heart.

During expiration, the right cupola ascends almost to the level of the right nipple; it is highest at a point about one inch internal to the nipple line, and here it reaches the upper border of the fifth rib, or even the middle of the fourth intercostal space. On the left side it is one-half to one inch (12-25 mm.) lower, and in the middle line it crosses the inferior extremity of the gladiolus about the level of the sixth rib cartilage.

*Below*, the cavity is limited by the pelvic floor, formed by the levatores ani, and coccygei muscles, covered on their upper surface by the pelvic fascia. The *anterior wall* is formed by the aponeuroses of the three flat abdominal muscles, together with the two recti, which latter constitute powerful braces for the wall, on each side of the middle line. The *lateral walls* are formed by the muscular portions of the obliqui and transversales muscles, and below by the iliac bones with the iliacus muscles.

Finally, the cavity is limited *behind* by the lumbar portion of the vertebral column with the psoas muscle on each side, and the quadratus lumborum still further out. The iliac bones also enter into the formation of the lower portion of the posterior wall.

The upper portion of the cavity lies under cover of the ribs, which afford considerable protection to this part of the abdomen, particularly at the sides and behind, in which latter position the cavity is further protected by the vertebral column. Anteriorly, on the other hand, the ribs are wanting below the sternum, and here, the abdominal wall is formed only of aponeuroses and muscles. But even at the sides and back there is a considerable zone, usually one to two inches wide (Cunningham), between the lower ribs above and the crest of the ilium below, which has no bony support except that afforded by the vertebral column.

Whilst the circumference of the diaphragm is attached to the lower part of the thoracic framework in front and at the sides, and to the lumbar vertebræ behind, the central portion of the dome, on the other hand, namely, the central tendon, is placed high up, under cover of the ribs, and in a more or less horizontal plane. As a result, the peripheral muscular part slopes almost vertically upwards from the circumference of the thoracic framework to the central tendon, and lies for a considerable distance in contact with the deep surface of the ribs; thus the diaphragm comes to form, not only the roof of the cavity, but it also enters into

the formation of the lateral, posterior, and, to a less extent, of the anterior walls; and almost as much of the cavity of the abdomen as of the thorax lies under shelter of the ribs.

Owing to the fact that the boundaries of the abdomen are formed chiefly of muscles, it follows that its walls are capable of contraction to a very considerable extent, and the size of the cavity can consequently be altered in all directions. Its chief changes in form are due to the descent or elevation of the diaphragm, the contraction or relaxation of the anterior and lateral walls, and the raising or lowering of the pelvic floor.

Within the muscles forming its walls, the abdomen is lined by an envelope of

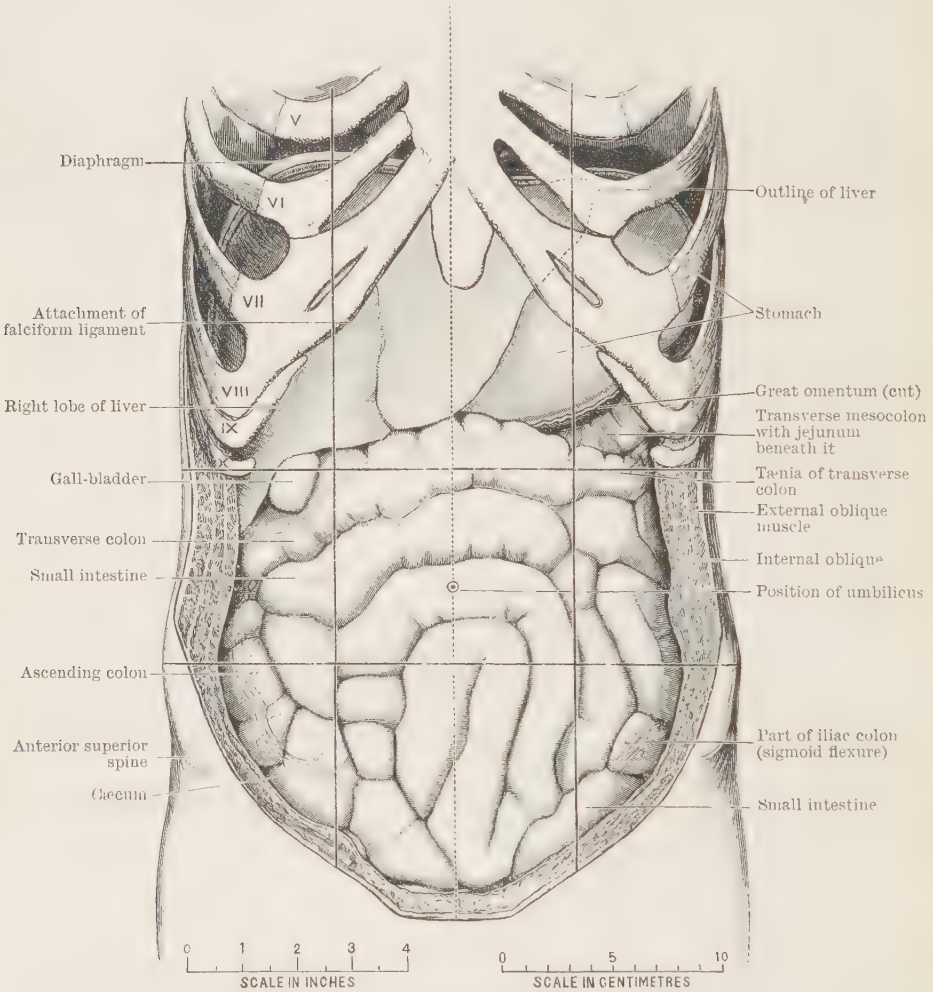

FIG. 739.—THE ABDOMINAL VISCERA IN SITU, as seen when the abdomen is laid open and the great omentum removed (drawn to scale from a photograph of a male body aged 56, hardened by formalin injections).

The ribs on the right side are indicated by Roman numerals; it will be observed that the eighth costal cartilage articulated with the sternum on both sides. The subcostal, intertubercular, and right and left Poupart lines are drawn in black, and the mesial plane is indicated by a dotted line. The intercostal muscles and part of the diaphragm have been removed, to show the liver and stomach extending up beneath the ribs. The stomach is moderately distended, and the intestines are particularly regular in their arrangement.

fascia, which separate the muscles from the extraperitoneal connective tissue and peritoneum. This aponeurotic layer is distinguished in different localities as:—(1) the *transversalis fascia* on the anterior and lateral walls, lining the deep surface of the transversalis muscle and continuous above with the fascia clothing the under surface of the diaphragm; (2) the *iliac fascia* on the posterior wall, covering the psoas and iliacus muscles; (3) the anterior layer of the *lumbar*

*aponeurosis*, also on the posterior wall covering the front of the quadratus lumborum; and (4) the *pelvic fascia*, lining the pelvis.

**Apertures.**—Certain apertures are found in the walls of the abdomen, some of which lead to a weakening of the parietes. These are: the three openings in the diaphragm for the passage of the inferior vena cava, the œsophagus, and the aorta respectively; the apertures in the pelvic floor, through which the rectum, the urethra, and the vagina in the female, reach the surface; the inguinal canal, through which the spermatic cord (or round ligament) passes, in leaving the abdominal cavity; and lastly, the crural canal, a small passage which runs down from the abdomen along the inner side of the femoral vessels. The two latter constitute on each side weak points in the abdominal wall, through which a piece of intestine occasionally makes its way, giving rise to inguinal or femoral hernia respectively.

**Extraperitoneal** or **Subperitoneal Connective Tissue** (tela subserosa).—Between the fascia which covers the deep surfaces of the abdominal muscles, and the peritoneum which lines the cavity, there is found a considerable quantity of connective tissue, generally more or less loaded with fat, which is known as the extraperitoneal or subperitoneal connective tissue. This is part of an extensive fascial system which lines the whole of the body cavity, outside its various serous sacs, and is continued on the several vessels, nerves, and other structures which pass from these cavities into the limbs and neck.

In the abdomen it is divisible into a parietal and a visceral portion, both composed of loose connective tissue. The former lines the cavity, whilst the latter passes forwards between the mesenteries and other peritoneal folds to the viscera. These two portions of the extraperitoneal tissue are perfectly continuous with one another, and contain in their whole extent a vascular plexus, through which a communication is established between the vessels of the abdominal wall, on the one hand, and those of the contained viscera on the other.

The *parietal portion* is thin and comparatively free from fat over the roof and anterior wall of the abdomen, and here the peritoneum is more firmly attached than where the tissue is fatty and large in amount. In the pelvis, on the other hand, the tissue is loose and fatty, and, as such, it is continued up for some inches on the anterior abdominal wall above the pubes, to permit of the ascent of the bladder during its distension, and the attendant stripping of the peritoneum off this portion of the anterior abdominal wall. Here also the urachus and the obliterated hypogastric arteries will be found passing up in its substance. On the posterior wall the tissue is large in amount and fatty, particularly where it surrounds the great vessels and kidneys.

From this latter portion especially the *visceral expansions* are derived in the form of prolongations around the various branches of the aorta. These expansions are connected with the areolar coats of the blood-vessels and are conducted by them into the mesenteries and other folds of the peritoneum, and thus reach the viscera.

The chief uses of this tissue are: (1) to unite the layers of the abdominal wall together; (2) to connect the viscera to these walls and to one another in such a loose manner that their distension or relaxation may not be interfered with, which would not be the case if the connecting medium were firm or rigid; (3) in addition, it is a storehouse of fat, forms sheaths for the vessels and nerves, and establishes, through its vascular plexus, communication between the parietal vessels and those distributed to the abdominal viscera.

## Subdivision of the Abdominal Cavity.

The abdomen is divided *naturally* by the pelvic brim into two parts, the **abdomen proper**, and the cavity of the **pelvis**. The former of these is further subdivided, *artificially*, into nine regions.

The **pelvic brim** (Figs. 166 and 167, p. 221), which separates the two natural divisions of the cavity, is formed behind by the base of the sacrum, at the sides by the iliopectineal lines of the innominate bones, and in front by the pubic crests and

the symphysis pubis. In the erect position it usually makes an angle of about 55 to 60 degrees with the horizontal. The two portions of the abdominal cavity which the brim separates meet at an angle, the abdomen proper running almost

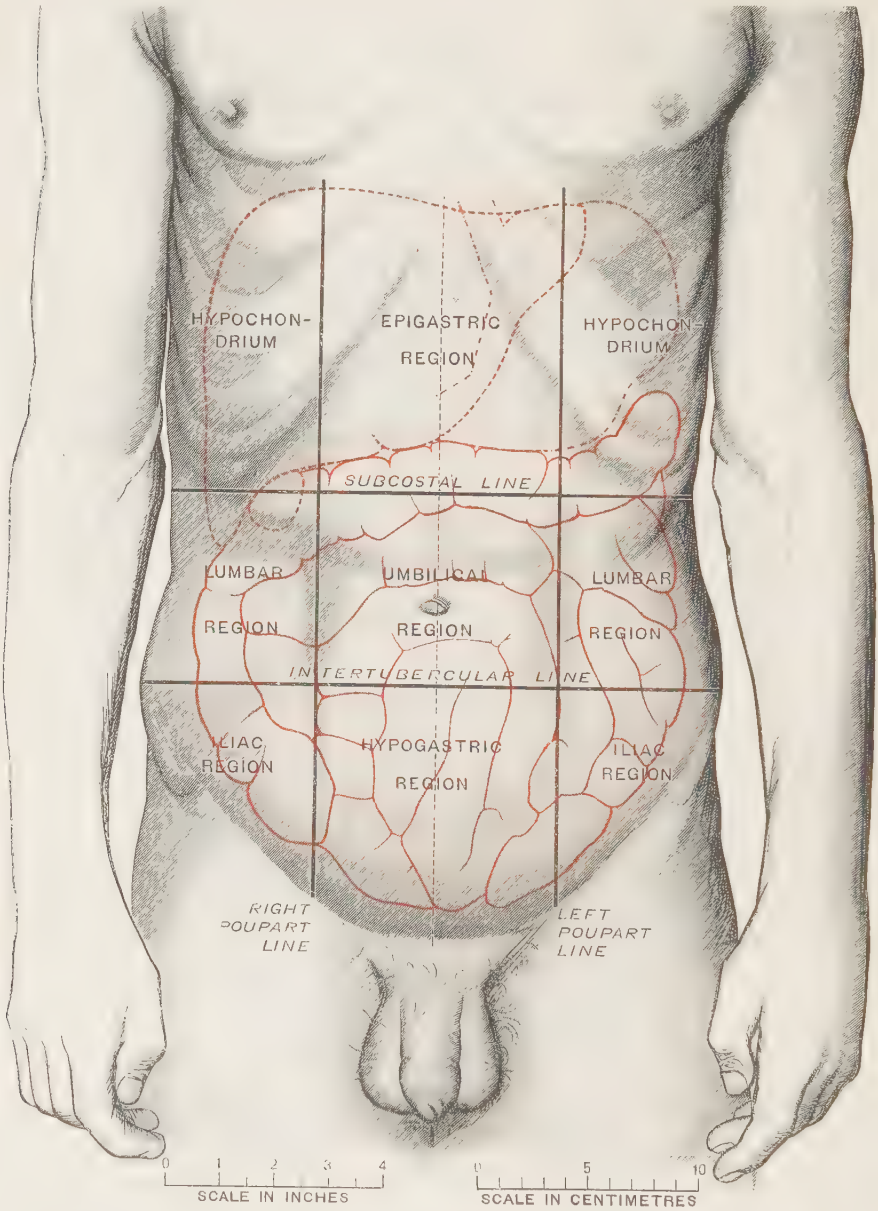

FIG. 740.—THE FRONT OF THE BODY, showing the subdivisions of the abdominal cavity and the position of the chief viscera. (From a photograph of the body represented in the preceding figure.) The viscera in Fig. 739 have been traced in red on this figure. The photographs for these two figures and for Fig. 744 were taken from the same body, under precisely similar conditions; consequently the relations of the deeper parts to the surface are correctly obtained by superimposing the pictures as in this illustration. The liver occupies a slightly lower position than usual.

vertically upwards from it, whilst the pelvic cavity slopes backwards and slightly downwards.

The **pelvic cavity** is bounded in front and at the sides by the portions of the innominate bones below the level of the iliopectineal line. These bony walls are partly clothed, in front and laterally, by the obturator internus muscles, and internal to these by the parietal portion of the pelvic fascia, as low down as the white line. The posterior

wall is formed by the front of the sacrum, covered on each side by the pyriformis muscle. This wall (as represented by the pyriformis muscles) meets the lateral wall at the anterior border of the great sciatic foramen; through this foramen the pyriformis passes out, thus closing up what would otherwise be a large aperture in the parietes of the cavity. The floor is composed of the two pairs of muscles which form the pelvic diaphragm, namely, the levatores ani and coccygei—covered by the visceral layer of the pelvic fascia. These muscles pass on each side, from the lateral wall of the pelvis, downwards and inwards towards the middle line, and present a concave upper surface towards the pelvic cavity.

**Subdivision of the Abdomen Proper.**—Owing to the large size of the cavity, and in order to localise more correctly the position of the various organs contained within it, the abdomen proper is artificially subdivided by two horizontal and two vertical lines (Fig. 740) drawn on its anterior wall. From these lines imaginary planes are supposed to be continued backwards, which divide up the cavity into nine regions.

Of the two *horizontal lines*, one is drawn around the trunk at the level of the lower border of the tenth costal cartilage; this is known as the **subcostal line**, and the imaginary plane corresponding to it, as the **subcostal plane.** The second horizontal line is drawn at the level of the highest point of each iliac crest, visible from the front; this point corresponds to the tubercle seen on the outer lip of the crest, about two inches behind the anterior superior spine, and can be easily located; the line and plane are consequently known as the **intertubercular line** and **plane** respectively.

The vertical lines are drawn, one on each side, perpendicularly upwards from a point on Poupart's ligament midway between the anterior superior spine and the symphysis pubis. These lines and the corresponding planes are known as the **Poupart lines** and **planes** respectively.

By the two horizontal lines the abdomen is divided into *three zones*, an upper or **costal**, a middle or **umbilical**, and a lower or **hypogastric zone.** By the two perpendicular lines each of these is subdivided into three parts, a central and two lateral. Thus, in the upper zone, we get a **hypochondriac region** or **hypochondrium** on each side, and an **epigastric region** or **epigastrium** in the centre. Similarly, the umbilical zone is divided into **right** and **left lumbar regions**, with an **umbilical region** between. And the hypogastric zone has a **hypogastric region** or **hypogastrium** in the centre, with **right** and **left iliac regions** at the sides.

In addition, the portion of the abdominal wall above the pubis is known as the *suprapubic region*, and that immediately above Poupart's ligaments, as the *inguinal region.*

The three central divisions, namely, the epigastric, umbilical, and hypogastric regions, can conveniently be further subdivided by the mesial plane, passing through the middle of the body, into right and left halves.

The upper horizontal, or subcostal, plane passes behind, through the upper part of the third lumbar vertebra, or the disc between the second and third lumbar vertebræ. The intertubercular plane cuts through the middle or upper part of the fifth lumbar vertebra.
